Adapted from Nazaria S, Rogum A, Zviman MM, et al: Clinical utility and safety of a protocol for noncardiac and cardiac magnetic resonance imaging of patients with permanent pacemakers and implantable cardioverter-defibrillators at 1.5 tesla. *Circulation* 2006;114:1277-1284.

Other electrolyte and metabolic abnormalities also have important effects on pacemaker function, although they are not as common. Hypokalemia can cause increased myocardial stimulation threshold¹⁵³ with resultant pacemaker exit block and can be treated with calcium, isoproterenol, or potassium repletion. Hyperglycemia, metabolic acidosis, metabolic alkalosis, and hypothyroidism can increase the capture threshold^{54,57}; these problems are best treated by aggressive correction of the underlying metabolic disturbance.

Systolic Heart Failure

The presence of a permanent pacemaker has been reported to be an independent predictor of poor outcome in patients with heart failure,^{154,155} and right ventricular apical pacing has been shown in some reports in specific patient populations to increase the incidence of death and hospitalization for heart failure.^{155a} Patients having exacerbations of heart failure symptoms may be manifesting evidence of pacemaker malfunction^{156,157} or suboptimal programming values, and these possibilities must be carefully evaluated.

SECTION II

Implantable Cardioverter-Defibrillator Emergencies

Since the first implant in 1980,¹⁸⁵ the implantable cardioverter-defibrillator (ICD) has become the first line therapy for patients at risk for sudden cardiac death. An ICD consists of pulse generator, pacing/sensing electrodes, and defibrillation coils. It is capable of bradycardia pacing similar to permanent pacemakers; hence the ICDs are susceptible to the same complications and emergencies as discussed in the pacemaker section. In addition, an ICD senses and detects ventricular tachycardia (VT) and ventricular fibrillation (VF) and delivers therapy in the form of overdrive antitachycardia pacing, low-energy cardioversion, and high-energy defibrillation (Fig. 26-17). In this section we discuss unique emergencies related to detection and therapy of VT/VF.

Figure 26-17. Continuous intracardiac electrogram recordings from interrogation of a biventricular implantable cardioverter-defibrillator in a 78-year-old man who received a shock through the device. The atrial electrogram (A) is on the *top* followed by marker channels and ventricular electrogram (V) on the *bottom*. The strip shows sudden onset of a fast rhythm in the ventricular channel (*star*) that is appropriately detected as ventricular fibrillation (F on marker channel) and treated with high-energy defibrillation.

Various randomized clinical trials have shown the effectiveness of ICD therapy for improving mortality in survivors of cardiac arrest (secondary prevention) and patients at risk for sudden death (primary prevention).¹⁸⁶⁻¹⁸⁸ Table 26-11 summarizes the indications for ICD implantation in adults according to the Task Force guidelines.²

Inappropriate ICD Shock

Inappropriate shock refers to delivery of an ICD shock for a rhythm different from VT or VF. This is the most common adverse effect observed among ICD patients; the incidence varies from 13% to 22% in various series.¹⁸⁹⁻¹⁹⁴ Inappropriate shocks can be caused by misdiagnosis of supraventricular tachycardia (SVT) as VT or inappropriate sensing due to lead malfunction or environmental interference (Table 26-12). It is important to understand the detection and therapy programming in the tachycardia zone in the ICD. Sensing is the process by which an ICD determines the timing of electrogram signals caused by cardiac depolarization. Detection is the algorithm by which an ICD processes a series of electrogram signals to classify the

cardiac signal and determine if treatment should be delivered. The sensing in the ICD is similar to the sensing in a pacemaker; the tachycardia zone is programmed based on detected rate on the ventricular channel. The device can be programmed to have more than one VT zone (slow VT, fast VT) and one VF zone. Therapy consists of antitachycardia pacing and low-energy cardioversion that is programmed in the VT zone and high-energy defibrillation that is programmed in the VF zone.

The most common cause of inappropriate shocks is misdiagnosis of SVT (e.g., atrial fibrillation [AF], sinus tachycardia) as VT or VF, as the ventricular rate during these episodes exceeds the programmed rate for VT (Fig. 26-18). Preoperatively documented AF, a maximal heart rate during exercise close to the detection interval, and a low detection rate have been found to be independent risk factors for inappropriate therapy.¹⁹² Various algorithms have been developed to differentiate SVT from ventricular arrhythmias and hence avoid inappropriate shocks.¹⁹⁵⁻¹⁹⁸ Sinus tachycardia is differentiated from VT based on onset criterion (sudden onset in VT while sinus tachycardia is gradual); this criterion might not differentiate slow VT with a cycle length similar to sinus tachycardia. Atrial fibrillation is differentiated from VT by stability criteria (VT is more regular); however, at faster rates AF can be regular and VT can show some irregularity. Dual-chamber devices have simultaneous recordings from the atrial and ventricular channels that can diagnose VT based on AV dissociation. The morphology criterion relies on the fact that the ventricular electrogram during VT will have a different morphology from the sinus and SVT morphologies. It is important to note that these SVT discriminators do not work in the VF zone and hence selection of appropriate rate cut-offs for the VT and VF zones is also very important to avoid inappropriate shocks. The performance of SVT discriminating algorithms used by different manufacturers is comparable.¹⁹⁹

Device-related causes of inappropriate shocks include inappropriate sensing due to lead malfunction or dislodgement, double counting of QRS complex, oversensing of diaphragmatic myopotentials, and T wave oversensing (Fig. 26-19). Rarely, older ICDs can deliver shocks for repetitive self-terminating episodes of VT (committed shock). These shocks can be prevented by increasing the number of beats required for detection of VT or VF or upgrading their devices to those that have noncommitted shock (redetection of VT or VF after the device has been charged). Electromagnetic interference (EMI) refers to noise on the ventricular

Table 26-11. Guidelines for Implantation of Implantable Cardioverter-Defibrillators in Adults: Class I and II Indications

Class I

- A. Cardiac arrest due to ventricular tachycardia (VT) or ventricular fibrillation (VF) not due to a reversible cause.
- B. Spontaneous sustained VT in association with structural heart disease.
- C. Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced during electrophysiologic study (EPS) when drug therapy is ineffective, not tolerated, or not preferred.
- D. Nonsustained VT in patients with CAD, prior MI, left ventricular dysfunction, and inducible VF or sustained VT during EPS that is not suppressed by a class I antiarrhythmic drug
- E. Spontaneous sustained VT in patients without structural heart disease that is not amenable to other treatments.

Class II

- A. Patients with left ventricular ejection fraction less than 30% at least 1 month post-MI and 3 months post-CABG
- B. Severe symptoms attributable to sustained ventricular arrhythmias while awaiting cardiac transplantation
- C. Familial or inherited conditions with a high risk for life-threatening ventricular arrhythmias such as long Q-T syndrome and hypertrophic cardiomyopathy
- D. Syncope of unexplained etiology or family history of sudden death in association with Brugada syndrome
- E. Syncope in patients with advanced heart disease in which thorough invasive and noninvasive investigation has failed to define a cause.

Abbreviations: CAD, coronary artery disease; CABG, coronary artery bypass grafting; MI, myocardial infarction.

Adapted from Gregoratos G, Abrams J, Epstein AE, et al: ACC/AHA/NASPE 2002 guidelines for implantation of cardiac pacemakers and antiarrhythmia devices: summary article: report of the American College of Cardiology/American Heart Association task force on practice guidelines (ACC/AHA/NASPE committee to update the 1998 pacemaker guidelines). *Circulation* 2002;106:2145-2161.

Table 26-12. Causes of Inappropriate ICD Shocks

1. Supraventricular arrhythmias

- Sinus tachycardia
- Atrial flutter and atrial fibrillation
- Paroxysmal supraventricular tachycardia
- Frequent premature atrial or premature ventricular complexes

2. Device-related causes

- Oversensing of T waves and/or P waves
- Double counting of R waves
- Loose setscrew
- Scanning of pacer stimulus artifact
- Oversensing due to lead fracture or insulation failure
- Electromagnetic interference (environmental noise)
- Oversensing of diaphragmatic myopotentials

Patients who receive an isolated shock with no symptoms to suggest a change in health status should be reassured and scheduled for elective evaluation of the ICD. Patients who feel unwell after an ICD shock or who receive more than one shock in a short period of time require emergent evaluation. Interrogation of the ICD with the programmer from the specific device company will immediately give an alert if therapy in the VT/VF zone has been delivered, battery status is close to end of life, and if there is lead malfunction (change in impedance). Analysis of the programmed parameters, episode summary, and the stored intracardiac electrogram during the episode will give clues to the etiology of the inappropriate shock. Multiple shocks can lead to increased anxiety and depression and can negatively impact the quality of life

Electrical Storm

331

Figure 26-19. Continuous electrogram recordings from interrogation of a single-chamber implantable cardioverter-defibrillator implanted in a 61-year-old man for sustained ventricular tachycardia. The patient complained of receiving multiple shocks while running. The ventricular electrogram shows oversensing of the T waves (stars) that leads to inappropriate detection of the rhythm as ventricular fibrillation. The patient received multiple shocks; this was corrected by changing the sensing algorithm in the implantable cardioverter-defibrillator so that it would not detect the T wave. Defibrillation testing was repeated at the changed algorithm to ensure appropriate detection of ventricular fibrillation.

Figure 26-20. Continuous electrogram recordings from routine interrogation of a biventricular implantable cardioverter-defibrillator implanted in a 72-year-old man for advanced heart failure. The atrial electrogram (A) is shown on the top followed by the marker channels and the ventricular electrogram (V) on the bottom. The strip shows sudden onset of rapid and irregular rhythm (stars) recorded in the atrial and ventricular channels that is suggestive of electromagnetic interference. It meets the rate criteria for ventricular fibrillation as denoted by the F markers on the ventricular channel (it was nonsustained, and no therapy was delivered). The patient had undergone a minor procedure using electrocautery that was the cause of the electromagnetic interference.

with an ICD. A patient having multiple shocks should be immediately seen in the emergency room and connected to telemetry to ascertain the appropriateness of the shocks. In a patient with multiple appropriate shocks, intravenous amiodarone is the first line of therapy²⁰⁴ while evaluating for reversible causes such as electrolyte abnormality and ischemia. Amiodarone-induced hyperthyroidism and proarrhythmic effects of antiarrhythmic drugs are other causes of electrical storm. Intravenous

β -blockers to suppress adrenergic drive,²⁰⁵ intubation and sedation with propofol,²⁰⁶ and intra-aortic balloon pump and ventricular assist devices for hemodynamic support have been used to suppress the ventricular arrhythmias. The ICD can be interrogated to ascertain programmed parameters to attempt pace termination of VT. Emergent catheter ablation of VT or VF has been successfully used as a treatment of last resort in selected patients.^{207,208}

Drug Effects on ICD Function

Antiarrhythmic drugs are often initiated in patients with ICDs to decrease the burden of ventricular and supraventricular arrhythmias. Based on data from various ICD trials, more than 50% of the patients with ICDs can be assumed to be taking these drugs.^{209,210} The advantage of adding antiarrhythmic drugs to ICD patients includes: (1) reduction in frequency of ICD discharges by decreasing the episodes of VT/VF; (2) reduction of VT rate that allows antitachycardia pacing to be effective and maintains consciousness during ICD therapy; (3) reduction in burden of SVT to prevent inappropriate shocks; (4) reduction in defibrillation threshold (DFT); and (5) improvement in quality of life. The potential deleterious effects of antiarrhythmic drugs on ICD patients include: (1) increased ICD discharge due to proarrhythmias; (2) slowing of the VT rate below the ICD detection rate, thus preventing therapy and leading to syncope; (3) altering the QRS morphology that interferes with sensing; (4) increased DFT; (5) increased pacing threshold at higher pacing rates (use dependence); and (6) heart failure exacerbation.^{66a,211,212}

An increase in pacing threshold is seen with class IC drugs (especially flecainide); however, in a prospective study of 14 ICD patients, there was no significant increase in pacing threshold with propafenone at clinically used doses.²¹³ Class IC drugs can lead to widening of the QRS electrogram morphology that may cause misclassification of SVT as VT by the device, while class IA and class III drugs can cause QT prolongation that might lead to double counting (R wave and T wave) and inappropriate shocks.^{66a}

The most potentially dangerous effect of drugs on ICD function is an increase in DFT that can lead to ineffective ICD therapy. In general, the drugs that block fast inward sodium current and shorten the action potential duration (e.g., lidocaine) can cause an increase in DFT, whereas potassium channel blocking drugs that prolong the action potential duration (e.g., sotalol) tend to decrease DFTs and are favorable choices in patients with high DFTs. Class IA drugs (procainamide, quinidine, and disopyramide) do not seem to have a significant effect on DFT, whereas class IB drugs (lidocaine and mexiletine) have consistently shown elevation in DFT.²¹⁴ The effects of class IC on DFTs are less clear, with flecainide showing an increase in DFT in animal studies while moricizine and propafenone did not show any effect on DFT.²¹¹ Among the class III drugs, N-acetyl procainamide (an active metabolite of procainamide), clofilium, sotalol, and dofetilide have been shown to reduce DFTs.²¹⁴⁻²¹⁶ Intravenous amiodarone was not found to have any effect on DFT, whereas oral amiodarone was associated with an increase in DFT in animal and human studies.²¹¹ Recent advances in defibrillator technology (use of biphasic waveforms and “active” can) have improved defibrillation efficacy and mitigated some of the adverse pharmacologic effects; however, amiodarone can cause a clinically significant increase in DFT (even in modern devices). DFT in patients after starting amiodarone should be re-evaluated.

Sotalol has been shown to significantly decrease the burden of ventricular arrhythmias and ICD shocks in randomized prospective trials.^{217,218} Azimilide, a novel class III drug, has also been shown to reduce ICD therapies (shocks and antitachycardia pacing) in large randomized placebo-controlled studies^{219,220}; however, it has not yet been approved in the United States by the Food and Drug Administration. Recently, the Optimal

Pharmacological Therapy in Cardioverter Defibrillator Patients (OPTIC) trial randomized ICD patients to receive β -blocker alone, amiodarone plus β -blocker, or sotalol. At 1-year follow-up, amiodarone plus β -blocker was the most effective regimen in reducing ICD shocks.²²¹ Recently, there has been interest in assessing the role of statins and novel antianginal agents such as ranolazine in reducing ventricular arrhythmias.

ICD-Pacemaker Interactions

Although new generation ICDs are equipped with pacemaker capability, patients with older ICDs might have separate pacemakers and ICDs. The potential adverse interaction between ICD and pacemaker can be classified as: (1) ICD effect on pacemaker function; and (2) pacemaker effect on ICD function.²¹²

ICD shock can lead to transient postshock loss of capture and sensing in the pacemaker because of exposure of the myocardium to high current density. This is related to the distance between the pacing and shocking electrodes and the amount of energy delivered. Another potential effect on pacemaker function after ICD shock is reprogramming of the pacemaker mode and/or polarity. These can be avoided by keeping the greatest possible separation between the pacing and shocking electrodes and using bipolar pacing systems in these patients. ICD shocks can potentially damage the pacemaker circuitry; this has not been observed in modern pacemakers. Nevertheless, comprehensive pacemaker interrogation should be performed after ICD shock. Another potential adverse effect is pacemaker reprogramming during ICD interrogation; this can be prevented by keeping adequate spatial separation between the pacemaker and ICD generators.

In patients with ICDs and separate pacemakers, the pacing stimulation artifact (PSA) can cause undersensing or oversensing in the ICD lead (especially in unipolar pacemakers) and hence prevent ICD therapy or cause an inappropriate ICD shock. It is recommended that pacing at the chronic pacing amplitude (maximal amplitude in new pacemakers) in sinus rhythm should cause a PSA amplitude less than 1 mV on the ICD rate sense lead to ensure appropriate ICD sensing during VF. Appropriate ICD sensing should also be documented during VF with simultaneous synchronous pacing from the pacemaker at this amplitude. In addition, the electrical artifact resulting from mechanical contact between the pacemaker and the ICD lead can be oversensed by the ICD and cause inappropriate shocks. Rate responsive pacemaker rates can achieve rates that cross over into the VT detection zone of the ICD, leading to inappropriate shocks. This can be corrected by appropriate ICD programming of the VT/VF zones.

Ineffective ICD Therapy

An ICD is programmed to provide therapy during life-threatening ventricular arrhythmias. Delayed or absent ICD therapy during VT/VF can be lethal for some patients. Ineffective ICD therapy can be due to: (1) inactivated device (some ICDs have a programmable magnet mode that can be triggered by EMI to turn off therapy); (2) undersensing of VT/VF due to change in the myocardial substrate, antiarrhythmic drug-induced decreased sensing, lead malfunction or displacement, generator malfunction, and pacemaker-ICD interaction; (3) lack of detection of VT/VF due to a high rate cut-off for detection, and slower

VT because of antiarrhythmic drugs; (4) ineffective therapy due to battery depletion with prolonged charge time; high DFT, and ICD component failure.

It is imperative that ICD patients undergo routine evaluation (every three months and after each exposure to EMI) to assess the battery status, charge time, lead integrity and function, and analysis of arrhythmia log to evaluate for appropriate and inappropriate therapy. The new generation ICDs have wireless telemetry and remote monitoring that are capable of monitoring the device more frequently at home and notifying the physician of device or lead malfunction.²²² Death due to unpredictable ICD generator failure has been reported recently,^{223,224} which has led to more aggressive reporting of device alerts, recalls, and advisories. The DFT needs to be evaluated appropriately at the time of implant to achieve an adequate safety margin (at least 10 J difference between DFT and maximum energy delivered through the ICD). This might require implantation of a separate SVC coil and subcutaneous array in selected patients. Antiarrhythmic drugs can adversely affect DFTs and also slow the VT rate, leading to underdetection of VT. This emphasizes the need for re-evaluation of DFT, especially after starting antiarrhythmic drugs that have adverse effects on ICD function. Drugs like sotalol and dofetilide that lower DFTs are suitable for patients with high DFTs.

Postshock electromechanical dissociation is the most common mechanism of sudden death in ICD patients after appropriate ICD therapy for VT/VF and it needs further investigation.²²⁵

Acute Presentations of Valvular Heart Disease

Wendy J. Austin, Jayaseelan Ambrose, Barry H. Greenberg

CHAPTER 27

Acute Aortic Insufficiency
Acute Mitral Regurgitation
Acute Prosthetic Valve Dysfunction
Tricuspid Regurgitation

Aortic Stenosis
Mitral Stenosis
Conclusion

ACUTE DETERIORATION in valvular function represents a tremendous challenge to the practicing clinician. The presentation of valvular emergencies is usually dramatic, and a thorough knowledge of predisposing etiologies, hemodynamic abnormalities, and therapeutic modalities are essential to making appropriate management decisions. Despite an increasing population of patients with prosthetic valves, a resurgence of rheumatic fever, and the continued rise in intravenous drug use-associated infective endocarditis, the overall incidence of valvular emergencies in intensive care settings is low. However, the consequences of a missed diagnosis or a delay in therapy can be devastating. Therefore, an important guideline is to always entertain the possibility of a valvular emergency in a patient having hemodynamic instability or acute congestive heart failure.

This review focuses primarily on acute dysfunction of the aortic and mitral valves leading to severe regurgitation. The unique valvular complications associated with prosthetic valves and acute tricuspid regurgitation will also be discussed. Finally, factors predisposing to acute decompensation of previously stable, chronic, aortic, and mitral stenosis will be addressed.

Acute Aortic Insufficiency

Etiology

Aortic insufficiency occurs as a result of either dilation of the aortic root and annulus or disruption of the valve leaflets. The most common etiologies of acute aortic insufficiency are infective endocarditis and aortic dissection.¹ Infective endocarditis is more likely to occur on a congenitally abnormal or rheumatically involved valve. Infective endocarditis results in acute aortic insufficiency through a process of endothelial damage, development of nonbacterial thrombotic vegetation, adherence of circulating organisms to the vegetation, proliferation of infection within the vegetation, and valve destruction.² Acute, type A, aortic dissection is complicated by some degree of aortic insufficiency in approximately 50% of cases.^{3,4} Abnormal wall stress in the presence of aortic media disease, such as that seen with chronic hypertension or Marfan disease, results in an intimal tear and subsequent dissection.⁵ Other etiologies of acute aortic insufficiency are listed in Table 27-1.

Pathophysiology

The presentation of acute, severe, aortic insufficiency differs significantly from that of chronic aortic insufficiency. The cardiovascular adaptation to acute and chronic left ventricle (LV) overload determines the dramatic difference in hemodynamic and clinical profiles. The basic function of the heart is to maintain cardiac output commensurate with body demands while operating on the flat portion of the LV diastolic pressure-volume relationship, so that filling pressures remain low. Cardiac output is the product of heart rate and forward stroke volume. Forward stroke volume is the total stroke volume minus the regurgitant volume. Under normal circumstances, the latter is negligible, so that total and forward stroke volumes are synonymous.

In acute, severe, aortic insufficiency, the large regurgitant volume imposed on the unprepared ventricle markedly reduces forward stroke volume and shifts the LV diastolic pressure-volume relationship to the steep ascending portion of the curve. Because the LV has limited distensibility, the acute increase in LV end-diastolic volume due to regurgitant flow results in an abrupt rise in LV end-diastolic pressure (LVEDP) (Fig. 27-1) and, subsequently, pulmonary venous pressure. In addition, reflex sympathetic activation, in response to a reduction in cardiac output and systemic blood pressure, produces tachycardia and increases systemic vascular resistance (SVR). This rise in SVR further worsens regurgitant flow and impedes LV ejection so that a rise in aortic systolic pressure is inhibited. As opposed to chronic aortic regurgitation, aortic diastolic pressure does not fall significantly for two reasons: (1) the rapid increase in LVEDP reduces the driving gradient between aorta and LV and (2) peripheral runoff is limited by an increase in SVR.^{6,7} In some cases, the LV and aortic diastolic pressures are equalized.

In contrast, the gradual progression of chronic aortic insufficiency allows the ventricle to dilate and undergo eccentric hypertrophy, which shifts the LV pressure-volume curve rightward (see Fig. 27-1), and maintains a normal LVEDP. This compensatory mechanism also increases total stroke volume to preserve forward stroke volume despite the presence of a large regurgitant volume. As a result, there is no reflex tachycardia or rise in SVR. Aortic systolic pressure rises as a result of the increased stroke volume, and diastolic pressure falls in response to the regurgitant volume, decreased SVR, and rapid peripheral

Granulomatous diseases
Tertiary syphilis
Giant cell arteritis
Takayasu arteritis

Figure 27-1. Diastolic pressure-volume relationships in the left ventricle. *Acute regurgitation* is sudden volume loading of the left ventricle without the benefit of adaptive ventricular remodeling. It results in the left ventricle functioning on the steep portion of the normal curve (dotted line). *Chronic regurgitation* is volume loading in the presence of a remodeled ventricle. It shifts the curve to the left and allows normalization of left ventricular (LV) filling pressure at significantly increased LV volumes. *Hypertrophy* (e.g., aortic stenosis) shifts the curve to the right and results in a noncompliant ventricle that is highly dependent on atrial booster pump function for LV filling. (From Hall RJ, Julian DG: *Diseases of the Cardiac Valves*. New York, Churchill Livingstone, 1989, p 291.)

runoff. These factors are responsible for the classic finding of a wide pulse pressure in chronic aortic insufficiency.

Clinical Presentation

The clinical features of acute aortic insufficiency are profoundly different from those of chronic disease. These differences result primarily from the presence of markedly elevated LVEDP and absence of a wide pulse pressure in patients with acute severe

Table 27-2. Classic Peripheral Manifestations of Chronic Aortic Insufficiency*

• Musset sign
Head bobbing with each systole
• Corrigan pulse
Water-hammer pulse felt with abrupt distention and quick collapse
• Traube sign
"Pistol shot" sounds—booming systolic and diastolic sounds heard over the femoral artery
• Müller sign
Systolic pulsations of the uvula
• Duroziez sign
Systolic murmur heard over the femoral artery when it is compressed proximally and diastolic murmur when it is compressed distally
• Quincke sign
Visible capillary pulsations in the nail bed (seen by shining light source), fingertips, or lip (detected with glass slide pressed against the lip)
• Hill sign
Popliteal cuff systolic pressure exceeding brachial cuff pressure by more than 60 mm Hg

*Not typically seen with acute aortic insufficiency.

aortic insufficiency as described above. Because the pulse pressure is usually normal in the acute setting, the classic findings of severe aortic insufficiency in the periphery are absent (Table 27-2). In addition, the striking elevation in LVEDP accounts for the often dramatic presentation of congestive heart failure and cardiogenic shock.⁸

Patients typically have severe dyspnea, weakness, or hypotension. They are often tachycardic, and the LV impulse may be normal. Early mitral valve closure, a hallmark of severe acute aortic insufficiency, results from a rapid elevation of LVEDP, which exceeds left atrial (LA) pressure early in diastole. This reversal of pressures between the LV and LA in late diastole results in a soft or inaudible first heart sound (S1). Occasionally, mitral valve closure may be heard during diastole and accompanied by diastolic mitral regurgitation.^{9,10} The Austin-Flint murmur, which is thought to represent turbulent flow from the LA to the LV because of partial mitral valve closure from the aortic insufficiency jet is either absent or brief and ceases when LV pressure exceeds LA pressure in diastole.^{11,12} An accentuated pulmonic closure sound suggests pulmonary hypertension, and a third heart sound (S3) is frequently heard. A fourth heart sound (S4), however, is usually not present because the mitral valve is either closed before atrial systole occurs or LVEDP is already so high that there is little flow to the ventricle during this period. The acute aortic insufficiency murmur is usually short, early, and of medium pitch, which is in contrast to the long, high-pitched murmur of chronic aortic insufficiency. In tachycardic patients, this murmur can easily be overlooked. Edema and weight gain are not often seen in severe acute aortic insufficiency because

there is inadequate time for substantial secondary salt and water retention. The extremities may be cool and mottled, owing to both poor cardiac output and elevated SVR.

Diagnosis

The diagnosis of acute aortic insufficiency should be considered in any individual having pulmonary edema or circulatory collapse. A history of known valvular disease, evidence of infective endocarditis, long-standing hypertension, Marfan syndrome, or chest trauma should make one particularly suspicious. Initial diagnostic testing in patients suspected of having acute aortic insufficiency includes an electrocardiogram (ECG), chest radiograph, blood cultures (if infective endocarditis is suspected or if the patient has a prosthetic valve), and a transthoracic echocardiogram (TTE).

An ECG is important in the evaluation of any patient with pulmonary edema, primarily to rule out myocardial infarction. In the absence of pre-existing heart disease, the chest radiograph generally reveals a normal cardiac silhouette with evidence of pulmonary edema (Fig. 27-2). Noninvasive imaging by TTE provides crucial information regarding the presence, severity, and etiology of aortic insufficiency. With severe aortic regurgitation, in addition to visualizing the regurgitant jet with color Doppler, quantitative measurements, such as jet or vena contracta (narrowest portion of regurgitant jet just distal to valve orifice) width, can be obtained. A jet width greater than 65% of LV outflow tract and vena contracta greater than 0.6 cm are consistent with severe aortic regurgitation.^{12A} Continuous wave Doppler is used to calculate the pressure half-time, which reflects the equilibration between aortic and LV diastolic pressure. With acute, severe aortic regurgitation, the rapid equilibration of pressures results in a short pressure half-time of less

Figure 27-2. Chest radiograph from a patient with acute aortic insufficiency secondary to pneumococcal endocarditis. Note the classic findings of acute pulmonary edema with a normal cardiac silhouette.

Figure 27-3. Long-axis transesophageal echocardiogram shows the presence of a large aortic valve vegetation. Ao, aorta; LA, left atrium; LV, left ventricle; Veg, vegetation.

than 200 msec.¹³ Other echocardiographic findings supportive of severe aortic regurgitation include premature closure of the mitral valve, detected best by M-mode echocardiography and holodiastolic flow reversal in the descending aorta. Transesophageal echocardiography (TEE) may be required in individuals in whom transthoracic echo windows are limited (Fig. 27-3). In addition, TEE has increased sensitivity for evaluating the underlying etiology of aortic regurgitation, such as endocarditis (vegetations or aortic root abscess) or aortic dissection (dissection flap).^{14,15}

Aortic dissection must be considered in the differential diagnosis of any patient having acute aortic regurgitation. This diagnosis is confirmed either by computed tomography (CT), TEE, or magnetic resonance imaging (MRI). These imaging modalities have largely replaced aortography, the previous gold standard. A recent meta-analysis compared the effectiveness of TEE, CT, and MRI for the diagnosis of aortic dissection. After pooling 16 studies with 1139 patients, TEE, helical CT, and MRI were found to have sensitivities of 98%, 100%, and 98%, respectively, and specificities of 95%, 98%, and 98%, respectively.¹⁶ CT is the most widely used modality given its speed and ease of accessibility to most emergency rooms (Fig. 27-4). CT also may provide identification of the intimal flap and involvement of major branch arteries. TEE has an advantage in that it is a bedside procedure and allows direct visualization of the aortic regurgitant jet. However, it is unable to detect dissections localized to the distal ascending aorta or proximal aortic arch. MRI has the best positive likelihood ratio for the detection of aortic dissections, but is time consuming, often not readily available in an emergent setting, and not feasible for a critically ill patient.

Treatment

In general, most patients with acute severe aortic insufficiency are desperately ill and have evidence of both systemic hypoperfusion and pulmonary edema. Acute aortic regurgitation usually requires urgent surgery. However, medical therapy has an important role in optimizing hemodynamics perioperatively. In the presence of severe hemodynamic compromise, admission to the cardiac intensive care unit is clearly indicated. The principles of management are to recognize the degree of hemodynamic

Figure 27-4. CT angiogram reveals a type A aortic dissection with the presence of an intimal flap in the ascending and descending aorta. AscAo, ascending aorta; AV, aortic valve; DscAo, descending aorta; LA, left atrium; LV, left ventricle.

impairment, reduce pulmonary venous pressure, maximize cardiac output, and initiate therapy for any underlying disorder.¹⁷ Invasive hemodynamic monitoring, by placement of a Swan-Ganz pulmonary artery catheter, allows the clinician to assess the response to therapy and gauge the tempo of the illness.

Medical therapy for acute congestive heart failure can usually be achieved with a combination of loop diuretics and intravenous vasodilators. The objectives are to achieve maximum cardiac output with minimum intracardiac filling pressures. The hemodynamic response to medical therapy in large part determines the urgency of surgical intervention.

Intravenous vasodilator therapy significantly reduces pulmonary artery pressures. Nitroprusside is the vasodilator of choice, starting at 0.25 $\mu\text{g/kg/min}$ given intravenously and gradually titrating upward by increments of 0.25 to 0.5 $\mu\text{g/kg/min}$ with the goal of achieving optimal hemodynamics or until systemic hypotension supervenes.¹⁸ The speed of uptitration is dictated by the degree of hemodynamic compromise. In severely ill patients the nitroprusside dose can be increased every 5 minutes, whereas in stable patients, a more gradual approach can be used. During maintenance therapy, one needs to be alert for signs and symptoms of both cyanide and thiocyanate toxicity. These compounds are breakdown products of nitroprusside, which accumulate with prolonged use, especially in the presence of renal insufficiency.

Diuretics should be initiated in sufficient doses to induce a brisk sustained urine output, using pulmonary capillary wedge pressure as a guide to therapy. Titrating the intravenous doses of furosemide (start 40 to 80 mg every 6 to 12 hours; maximum 600 mg/day), bumetanide (start 0.5 to 2 mg every 12 to 24 hours; maximum 10 mg/day), and torsemide (10 to 20 mg daily; maximum 200 mg/day) with or without oral metolazone (2.5 to 20 mg/day) 30 minutes before administering the loop diuretic is extremely effective in most cases of acute heart failure.

In general, inotropic agents do not have a significant role in management because most cases of acute aortic insufficiency occur in the setting of normal or even accentuated LV function.

However, if pre-existing myocardial dysfunction exists, agents such as dobutamine at a dose of 5 to 15 $\mu\text{g/kg/min}$ may assist in maintaining cardiac output.¹⁹ Intra-aortic balloon pumps (IABP) are contraindicated with aortic regurgitation. Additional medical therapy includes appropriate antibiotics in suspected infective endocarditis.²⁰ In the case of aortic dissection, intravenous β -blockers are thought to be useful in reducing the velocity of LV ejection, thereby minimizing aortic wall stress. However, when aortic dissection is complicated by acute aortic regurgitation, β -blockers should be used cautiously, if at all, as the compensatory tachycardia would be blunted, further reducing cardiac output.

If, despite medical therapy, hemodynamic instability persists, emergent surgical valve repair or replacement represents the only definitive option for cure. Indications for surgery in the presence of infective endocarditis are outlined in Table 27-3. Even in the presence of active infective endocarditis, valve surgery should not be delayed to achieve bacteriologic cure. In the International Registry of Acute Aortic Dissection, patients with type A dissection had an in-hospital mortality of 26% with surgery and 58% with medical management.²¹ Of those undergoing surgery for type A aortic dissection, 16% had involvement of the aortic valve requiring valve repair or replacement in conjunction with aortic root/arch surgery.

Acute Mitral Regurgitation

Etiology

The presentation of acute severe mitral regurgitation is not unlike acute aortic insufficiency. Both valve lesions result in sudden, severe LV volume overload. To better understand the underlying pathophysiologic states leading to acute mitral regurgitation, it is important to first recognize the functional components of

Table 27-3. Indications for Surgery in Infective Endocarditis

Native Valve Endocarditis

Congestive heart failure refractory to routine management (Class I)
Elevated LV end-diastolic pressure or LA pressures (Class I)
Fungal or highly-resistant organisms (Class I)
Complications: heart block, annular or aortic abscess, destructive penetration lesions (Class I)
Recurrent emboli and persistent vegetations despite appropriate antimicrobial therapy (Class IIa)
Mobile vegetations is in excess of 10 mm (Class IIb)

Prosthetic Valve Endocarditis

Congestive heart failure (Class I)
Valve dehiscence (Class I)
Increasing valve obstruction or worsening regurgitation (Class I)
Complications, as above (Class I)
Persistent bacteremia or recurrent emboli (Class IIa)
Relapsing infection (Class IIa)

From Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 practice guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2006;48:1.

the mitral valve apparatus. These components include the LA, mitral annulus, mitral valve leaflets, chordae tendineae, papillary muscles, and the LV wall. All these structures must work in concert to produce effective mitral valve leaflet apposition during systole.

Infective endocarditis may cause acute mitral regurgitation by mechanisms including leaflet perforation, alteration of mitral valve annulus secondary to abscess formation, or chordae tendineae rupture. Other etiologies of chordal rupture are myxomatous degeneration secondary to mitral valve prolapse or Marfan's disease spontaneous rupture, trauma, rheumatic disease, or spontaneous.^{22,23} Coronary artery disease is another major cause of acute mitral regurgitation and may affect valvular function in a number of ways: (1) papillary muscle rupture after myocardial infarction²⁴; (2) ischemic papillary muscle dysfunction²⁵; (3) papillary muscle fibrosis²⁵; (4) dyssynergy of the LV segment adjacent to a normally functioning papillary muscle²⁶; and (5) diffuse LV enlargement with mitral annular dilation. The posteromedial papillary muscle has only one vascular supply arising from either the right coronary or left circumflex artery and is, therefore, more susceptible to ischemic dysfunction or myocardial infarction. With the increasing use of percutaneous balloon valvotomy for rheumatic mitral stenosis, iatrogenic mitral regurgitation requiring valve replacement is more frequent as compared with closed surgical valvotomy.²⁷⁻²⁹ Finally, degeneration of a bioprosthetic valve, impaired closure of a mechanical valve, or paravalvular regurgitation from suture disruption may lead to acute, prosthetic valve, mitral regurgitation.

Pathophysiology

The severity of mitral regurgitation depends on the volume of regurgitant flow, LA compliance, and pre-existing LV function. The volume of regurgitant flow is a function of the size of the incompetent valve orifice and the pressure gradient between the LV and LA.³⁰ In the presence of a relatively noncompliant LA, the abrupt increase in pressure is transmitted to the pulmonary circuit with resultant pulmonary edema.³¹ With continuing acute regurgitation, the LV begins to fail secondary to elevated wall stress due to the mismatch between elevated LV end-diastolic volume/pressure and wall mass. In the presence of mitral regurgitation, there are two outlets to flow from the LV: (1) the relatively high-impedance systemic circulation and (2) the low-impedance LA. In this setting, forward stroke volume is highly dependent on SVR. As SVR increases, a greater proportion of the total LV stroke volume is directed to the LA and the regurgitant fraction increases [(total stroke volume – forward stroke volume)/total stroke volume].³² Thus the reduction in cardiac output increases SVR through neurohormonal activation, which worsens the severity of mitral regurgitation. As regurgitant flow increases further and cardiac output continues to decline, intense peripheral vasoconstriction ensues, leading to a vicious cycle of worsening mitral regurgitation and further impairment in forward stroke volume.

Clinical Presentation

The clinical features of acute mitral regurgitation reflect both the pathophysiology and pathoanatomy of the mitral valve apparatus as described above. A wide spectrum of clinical illness may be seen, ranging from complete papillary muscle rupture with cardiovascular collapse to mild dyspnea after rupture of a secondary or tertiary chordae.

The general appearance of the patient may provide important diagnostic clues regarding the underlying etiology of mitral regurgitation. A specific phenotype, such as Marfan or Ehlers-Danlos syndrome, may suggest a diagnosis of chordal rupture. Alternatively, peripheral manifestations of vascular (emboli, Janeway lesions) or immunologic (Osler nodes, Roth spots) findings consistent with the diagnosis of infective endocarditis may be seen. Finally, the presence of anginal-type chest pain leads one to suspect myocardial ischemia or infarction with resulting papillary muscle disease as the underlying etiology of acute mitral regurgitation.

Most patients with acute mitral regurgitation are tachycardic, which represents a compensatory mechanism to maintain cardiac output in the presence of declining forward stroke volume. The jugular venous pulse may be elevated with 50% of patients having a prominent “a” wave.³³ Precordial examination often reveals a hyperdynamic, nondisplaced apical impulse with a prominent presystolic expansion suggesting LV overload with increased atrial systole. A left parasternal lift is also common and is an indication of severe mitral regurgitation, often in association with elevated right ventricular systolic pressures. A systolic apical thrill may be felt in up to 75% of patients with ruptured chordae tendineae.³³ The presence of a thrill is less common in papillary muscle dysfunction or rupture.³⁴

Cardiac auscultation reveals a normal S1 because in most cases of acute mitral regurgitation the mitral valve leaflets are normal. This is in contradiction to chronic mitral regurgitation in which S1 is soft secondary to intrinsically abnormal mitral valve leaflets. Accentuated pulmonary valve closure suggests pulmonary hypertension³³ and because the LV empties rapidly, the aortic component may close early, giving rise to a widened split.³⁵ The presence of an S4 is common. An S3 gallop is almost universally heard and is related to LV volume overload. The murmur of acute mitral regurgitation differs according to the underlying pathophysiology. In papillary muscle dysfunction, a crescendo-decrescendo murmur may be heard during mid-to-late systole, while papillary muscle rupture results in a pansystolic murmur. Acute chordal rupture results in an ejection murmur that begins in the apex and radiates to the base of the heart.³⁶ Chronic mitral regurgitation, on the other hand, gives rise to a soft blowing holosystolic murmur heard throughout systole that begins at the apex and radiates to the axilla and back. Early termination of the murmur in acute mitral regurgitation results from rapid equalization of LA and LV pressures and suggests a greater degree of regurgitation.³⁷ The severity of the murmur may not reflect the degree of volume overload.³⁸ A summary of the differences in clinical presentation between acute and chronic mitral regurgitation is listed in [Table 27-4](#).

Diagnosis

As in the case of acute aortic insufficiency, immediate assessment of intracardiac filling pressures becomes critical, especially in the patient who is hemodynamically unstable. Initial noninvasive diagnostic maneuvers include a chest radiograph, which typically reveals a normal cardiac silhouette with pulmonary venous congestion or edema.³⁹ However, with pre-existing valvular or myocardial disease, there may be radiographic evidence of cardiac enlargement. Occasionally, an unusual pattern of right upper lobe pulmonary edema⁴⁰ may result that can be confused with pneumonia. However, prompt resolution with diuretic and vasodilator therapy rapidly clarifies the diagnosis

(Fig. 27-5). TEE has demonstrated that this radiologic finding may be related to the regurgitant jet being directed toward the right superior pulmonary vein.⁴¹

The ECG often reveals sinus tachycardia; however, atrial fibrillation with a rapid ventricular response is another

common presenting rhythm. A large negative deflection of the P wave in lead V₁ suggests LA volume overload. Nonspecific ST segment and T wave abnormalities are quite common; however, if acute mitral regurgitation occurs as a result of ischemia or infarction, the ECG becomes invaluable for both diagnosis and treatment.

Because the underlying pathoanatomy of the mitral valve influences prognosis and determines the type of therapeutic intervention, echocardiographic assessment of the mitral valve apparatus becomes essential. In the presence of good echocardiographic windows, transthoracic imaging can be performed quickly and safely at the bedside to determine the underlying etiology and severity of mitral regurgitation. In addition, overall LV function and wall motion abnormalities indicative of ischemia or infarction can be assessed. Finally, structural cardiac disorders that mimic mitral regurgitation, such as ventricular septal rupture, can be ruled out.⁴²

Depending on the etiology of acute mitral regurgitation, a variety of echocardiographic abnormalities may be seen. There may be an obvious flail leaflet, chordal rupture, or vegetation. Papillary muscle rupture is often directly visualized as a mass attached to the involved leaflet with discontinuity of the base of the muscle.⁴³ Despite the accuracy of transthoracic imaging, technical difficulties may impair visualization and limit interpretation. In these circumstances, TEE is a useful alternative modality for assessing acute mitral regurgitation (Fig. 27-6). Compared with TTE, TEE has superior resolution and a significant advantage in terms of visualizing the mitral valve apparatus, especially in the presence of a prosthetic mitral valve. Doppler imaging provides both qualitative and quantitative assessment of the mitral regurgitation severity. A color Doppler jet width at the vena contracta of more than 6 mm by multiplane TEE identifies angiographically severe mitral regurgitation with a sensitivity and specificity of 95% and 98%, respectively.⁴⁴ If systolic retrograde flow into the pulmonary veins is detected, mitral regurgitation is at least moderate. Finally, echocardiography clearly distinguishes acute mitral regurgitation from ventricular septal rupture, which has a very similar clinical presentation (Table 27-5).

If diagnostic studies, including ECG and echocardiography indicate ischemia or infarction as the underlying etiology of acute mitral regurgitation, then urgent cardiac catheterization must be considered depending on the hemodynamic stability

Feature	Acute	Chronic
Congestive heart failure	Rapid and sudden	Insidious
Rhythm	Sinus tachycardia	Atrial fibrillation
Point of maximal impulse	Hyperdynamic and nondisplaced	Hyperdynamic and shifted inferolaterally
Right ventricular lift	Present	Absent
Precordial thrill	Usually present	Absent
Jugular venous pressure	Prominent "a" wave	Normal tracing
Heart sounds		
S1	Normal	Soft
S2	Accentuated P2 with wide split	Normal P2 with wide split
S3	Present	Present
S4	Present	Absent
Mitral regurgitation murmur	Loud, decreasing in late systole	Blowing holosystolic
Radiation of mitral regurgitation murmur	Toward base	Toward axilla
Mitral diastolic flow murmur	Present	Absent

Figure 27-6. Transesophageal echocardiogram in the horizontal plane at the level of the mid-esophagus shows prolapse and loss of coaptation of the anterior mitral valve leaflet suggesting the diagnosis of mitral valve prolapse (MVP) with chordal rupture. AOV, aortic valve; LA, left atrium; LV, left ventricle; RV, right ventricle; SEP, interventricular septum.

Table 27-5. Differentiation of Papillary Muscle Rupture and Ventricular Septal Rupture

Feature	Papillary Muscle Rupture	Ventricular Septal Rupture
Age (mean, years)	65	63
Days post myocardial infarction	3-5	3-5
Anterior myocardial infarction	25%	66%
Murmur	Variable systolic	Pansystolic at lower sternal border
Palpable thrill	Rare	Yes
"v" wave in pulmonary capillary wedge tracing	++	++
Oxygen step-up from right atrium to pulmonary artery	±*	++
Echocardiographic findings	Flail or prolapsing leaflet	Visualize defect
Doppler	Regurgitant jet in LA	Detect shunt
Mortality		
Medical	90%	90%
Surgical	40%-90%	50%

*Oxygen step-up may occasionally be seen in papillary muscle rupture as a result of the regurgitant "v" from left atrium contaminating the mixed venous sample from the pulmonary artery.

++ , invariably present; + , occasionally present; ± , rarely present.

of the patient. Coronary angiography defines coronary anatomy and may delineate a culprit lesion amenable to catheter-based or surgical intervention.

Treatment

The management of acute severe mitral regurgitation is similar to that of acute aortic insufficiency. The principles of treatment focus on reducing LVEDP, decreasing aortic impedance to LV ejection so that blood flow can be directed in a forward rather than retrograde direction, and initiating specific therapy for the precipitating etiology. As with acute aortic insufficiency, right heart catheterization is an integral component in the management of acute mitral regurgitation. The clinical severity of the regurgitation and the tempo of the illness as dictated by serial hemodynamic measurements, determine the rapidity with which one proceeds with emergent valve surgery. In the case of papillary muscle rupture, which is the cause of death in 1% to 5% of fatal myocardial infarctions, urgent surgical intervention is mandatory.⁴⁵ However, barring this catastrophic event, the majority of patients having acute, severe mitral regurgitation can often be stabilized initially with medical therapy.

Vasodilator therapy is the key component of medical management, and the preferred agent is intravenous nitroprusside (for dosage, see therapy for aortic insufficiency).⁴⁶ Its rapid onset and offset of action allow careful titration to optimize the hemodynamic response. Nitroprusside improves forward stroke volume directly by decreasing aortic impedance and also indirectly by decreasing LV volume, which reduces the area of the incompetent mitral valve orifice, thereby minimizing regurgitant flow.⁴⁷ Reduction of mean LA pressure and the regurgitant "v" wave reduce pulmonary congestion. Optimal therapy is defined as the maximal increase in cardiac output and reduction in pulmonary artery wedge pressure that can be obtained without provoking symptoms of systemic hypotension. An additional degree of afterload reduction may be provided by placing an IABP.⁴⁸ Improvement in diastolic coronary flow that occurs in response to an IABP may also have some salutary effects on LV function, especially in the presence of myocardial ischemia. If there is significant hypotension, dopamine (start at 1 to 3 µg/kg/min to a maximum of 10 to 20 µg/kg/min) may be a useful agent to maintain systemic blood pressure. However, at doses greater than 5 µg/kg/min, α-adrenergic-induced peripheral vasoconstriction may actually worsen the degree of regurgitation by increasing afterload. If LV contractility is impaired and cardiac output is significantly reduced, the addition of dobutamine (start at 1 to 2 µg/kg/min to a maximum 10 to 15 µg/kg/min) can be beneficial. Finally, diuretics (as outlined under therapy for aortic insufficiency) are useful to reduce pulmonary congestion.

Infective endocarditis complicated by chordal rupture or leaflet perforation should be treated with appropriate antibiotics in addition to medical therapy as noted above to optimize the hemodynamics of acute mitral regurgitation. The decision to proceed with emergent valve surgery is based on the hemodynamic response to medical management of the acute congestive heart failure and other factors (see Table 27-3). Recurrent systemic emboli, despite appropriate antimicrobial therapy, and infection with resistant organisms or fungi are additional indications for valve replacement. Finally, more complex infections, such as those complicated by valve ring abscess or fistula formation, also require surgical intervention.

Ischemic Mitral Regurgitation

Significant ischemic mitral regurgitation occurs in 3% of patients with acute myocardial infarction⁴⁹ and 8% of those having cardiogenic shock.⁵⁰ Patients with ischemic mitral regurgitation have a worse prognosis than those with other etiologies of mitral regurgitation. In addition, despite the significantly improved survival after acute myocardial infarction with thrombolytic therapy or percutaneous intervention, 1-year mortality for patients with concomitant severe ischemic mitral regurgitation is 52% compared with 11% in a cohort without mitral regurgitation.⁴⁹

Papillary muscle rupture in the setting of myocardial infarction represents the most dramatic presentation of ischemic mitral regurgitation and is a surgical emergency. Although this occurs in only 1% to 3% of patients with acute myocardial infarction, it accounts for up to 5% of infarct-related deaths.⁴⁵ Despite aggressive medical management, previous studies have documented the dismal prognosis of these patients with an up to 95% mortality in the first 48 hours without surgical intervention.^{51,52} In a series of 22 patients from the Mayo Clinic, there was significant improvement of functional class with an overall survival of 47% at 7 years with mitral valve replacement. This survival advantage occurred despite an overall decrease in LV function. Of note was the observation that the addition of coronary artery bypass surgery appeared to confer significant benefit in long-term outcome.⁴⁵ From the Shock Trial Registry, an observational study of 1190 patients with acute myocardial infarction complicated by cardiogenic shock, 98 patients were determined to have acute mitral regurgitation as the underlying etiology of shock. Acute mitral regurgitation occurred more frequently in patients with inferior or posterior myocardial infarction. In-hospital mortality for this subset of patients was 55%; and was reduced to 39% if undergoing surgical repair.⁵⁰

Ischemic mitral regurgitation may also be secondary to papillary muscle dysfunction without rupture. The mechanism actually involves ischemic apical and posterior papillary muscle displacement and wall motion abnormalities, which result in tethering of mitral valve leaflets and systolic tenting with incomplete closure. This condition can occur intermittently or continuously. Intermittent papillary muscle dysfunction classically presents as recurrent episodes of dyspnea associated with pulmonary edema. Several small case series suggest that percutaneous coronary intervention can improve acute regurgitation without requiring valve surgery.⁵³⁻⁵⁵ However, a report from the Thrombolysis in Myocardial Infarction (TIMI) phase I trial did not show a statistically significant relationship between coronary artery patency and the resolution or prevention of acute severe mitral regurgitation.⁵⁶ To further complicate this issue, a nonrandomized study from Duke University also failed to show significant reversal of valvular incompetence with either thrombolytics or angioplasty.⁴⁹ Finally, coronary artery bypass grafting as the sole treatment for ischemic mitral regurgitation resulted in a resolution (9%) and reduction to mild severity (51%) of mitral regurgitation.⁵⁷ Based on current data, correction of severe, ischemic mitral regurgitation often requires valve surgery in addition to revascularization. The combination of complete coronary revascularization with either mitral valve repair or replacement with preservation of the chordal apparatus is the current standard of care for acute ischemic mitral regurgitation refractory to medical management and nonsurgical reperfusion strategies.⁵⁸

Table 27-6. Acute Complications of Prosthetic Valves

Structural Valve Dysfunction

Bioprosthesis

Valvedegeneration—usually associated with leaflet calcification and tear

Mechanical prosthesis

Ballor disk variance—change in ball or disk size and function due to infiltration of by lipid

Strutfracture (particularly with the older Bjork-Shiley valves)

Nonstructural Valve Dysfunction

Perivalvular leak

Thrombosis or pannus formation

Embolization

Hemolysis

Prosthetic valve endocarditis

Early($\leq$ 60 days postsurgery)—occurs before endothelialization of valve, usually caused by *Staphylococcus epidermidis* or *S. aureus*; occasionally gram-negative organisms or fungi may be implicated

Late($\geq$ 60 days post surgery)—occurs after endothelialization of valve; caused by typical endocarditis organisms (i.e., viridans streptococci, enterococci, etc.)

Acute Prosthetic Valve Dysfunction

Prosthetic heart valves have been in use for over half a century. They are primarily implanted for hemodynamically significant valvular stenosis or regurgitation. A tremendous amount of experience with these devices has been gained over the past several decades. What has become apparent is that prosthetic valves, despite their obvious benefit, constitute another type of valvular heart disease. It is therefore important to remember that prosthetic valve implantation represents a palliative intervention.

Prosthetic valves are either mechanical or bioprosthetic. Mechanical bioprosthetic valves are further classified based on their structure as caged-ball (Starr-Edwards), single-tilting disk (Bjork-Shiley), or bileaflet-tilting-disk (St. Jude Medical) valves. Bioprosthetic valves are either heterografts (Carpentier-Edwards), which are formed from porcine or bovine tissue, or homografts, which are human aortic valves. Although bioprosthetic valves have better hemodynamic characteristics and do not require long-term anticoagulation, they are less durable and deteriorate over time. Mechanical valves, on the other hand, have tremendous durability but require life-long anticoagulation and are inherently stenotic.⁵⁹

Etiology and Clinical Presentation

Acute prosthetic valve complications, which affect both mechanical and bioprosthetic valves, may be classified as either structural or nonstructural (Table 27-6). Although bioprosthetic valves sustain a high structural failure rate within 15 years, mechanical valves may last more than 30 years. However, mechanical prosthetic valves are more thrombogenic

with caged-ball valves having the highest thrombogenicity and bileaflet-tilting disk valves the lowest.

The usual clinical presentation of acute prosthetic valve dysfunction is that of rapidly progressive heart failure with evidence of either prosthetic valvular regurgitation or stenosis. Other manifestations include thromboembolism (cerebral or peripheral),⁶⁰ which suggests prosthetic valve thrombosis (PVT)⁶¹ or prosthetic valve endocarditis (PVE).⁶² Normally functioning prosthetic valves are associated with various opening and closing clicks and systolic and occasionally diastolic flow murmurs.⁶³ A new or changing murmur may therefore signal a pathophysiologic alteration in prosthetic valve function. In addition, the absence or damping of normal valve clicks also suggests abnormalities in valve function.

Diagnosis

As part of the initial evaluation, determining the class, type, and model of the implanted valve and the date of implantation is extremely important. The chest radiograph can be invaluable in assessing for the presence of heart failure and may provide confirmatory radiologic evidence as to the type of valvular prosthesis.⁶⁴ The ECG may show signs of LV overload, but these findings are not specific in detecting prosthetic dysfunction because these ECG changes may antedate valve replacement. However, in the setting of aortic PVE, the development of new atrioventricular conduction delay is specific for the presence of a valve ring abscess.⁶⁵ Anemia and an elevated serum lactic dehydrogenase level greater than 600 IU, suggesting hemolysis are virtually never found in a normal functioning prosthesis and should always raise the suspicion of a paravalvular leak.⁶⁵

Echocardiography is an essential tool in the evaluation of prosthetic valve dysfunction.⁶⁶ It serves the dual purpose of identifying the etiology of the valve abnormality and assessing LV function. Continuous-wave Doppler imaging is effective in assessing valvular stenosis by virtue of the modified Bernoulli equation:

$$\text{Pressure gradient} = 4 \times \text{maximum transvalvular velocity}^2$$

In general, there has been an acceptable correlation between echo-derived and catheterization-based valvular gradients. Although transvalvular pressure differences are proportional to the degree of stenosis, variables such as heart rate, contractility, and cardiac output, and the size and type of prosthesis, can significantly alter the measured gradient.⁶⁷ Because there is a potential for underestimating the degree of prosthetic aortic stenosis, especially in the presence of low cardiac output, it has been suggested that it may be more appropriate to calculate prosthetic valve area using the continuity equation^{68,69}:

$$\text{Area}_1 \times \text{Time Velocity Integral}_1 = \text{Area}_2 \times \text{Time Velocity Integral}_2$$

It should also be remembered that there is a wide variation in valvular gradients depending on the class, type, and model of the valve. This highlights the importance of obtaining a baseline echocardiogram after valve replacement, which then serves as a control for comparison of pressure gradients with future follow-up studies. Caution must be exercised when using non-invasive hemodynamic data to make clinical decisions regarding prosthetic valve dysfunction. It is therefore essential to interpret echocardiographic data in light of the presenting clinical illness.

Color Doppler flow mapping has several important applications in prosthetic valve disease: (1) directing continuous-wave Doppler cursor parallel to the stenotic flow jet, allowing more accurate estimation of transprosthetic velocities and gradients⁷⁰; (2) semiquantitative evaluation of prosthetic valve regurgitation, which has been shown to correlate well with angiographically derived measurements^{71,72}; and (3) differentiating valvular from paravalvular leaks.⁷⁰

When transthoracic imaging is limited secondary to reverberatory artifacts caused by metallic components of a mechanical valve or technically difficult echocardiographic windows, TEE is a useful adjunctive tool.⁷³⁻⁷⁹ Because imaging is performed without intervening cardiac structures, excellent delineation of valvular anatomy and function may be obtained. This is particularly true in the case of the mitral valve because the esophageal "window" is not obstructed by the metallic valve components. In addition, several studies have suggested that TEE may, in fact, be more sensitive and specific than transthoracic echocardiography in the evaluation of partial valve thrombosis,^{80,81,82} PVE with aortic ring abscess,⁸³ paravalvular leaks,⁷⁸ Starr-Edwards prosthesis function,⁷⁷ and bioprosthetic valve degeneration.⁷⁹ TEE may also be appropriate when transthoracic echocardiographic findings are not consistent with the observed clinical syndrome. However, it should be emphasized that the combined approach of using transthoracic with transesophageal echocardiography facilitates a more complete evaluation of LV function.

In the case of acute prosthetic valve dysfunction with heart failure, a bedside right heart catheterization is an essential monitoring tool that allows continuous hemodynamic assessment and appropriate therapeutic interventions. Because echocardiography has in large part replaced traditional catheterization measurements for valvular insufficiency and stenosis, cardiac catheterization is withheld unless the available echocardiographic data are inconclusive or there is a suspicion of significant coronary artery disease. In some cases, simple fluoroscopy may be used to identify prosthetic valve dysfunction and assess the effects of thrombolytic therapy.⁸⁴⁻⁸⁶ When frank dehiscence is present, a rocking motion of the valve ring may be seen. In the case of mechanical valves, the excursion and movement of the ball, leaflet, or disc may be limited, suggesting PVT.

Treatment

Congestive Heart Failure

Therapy for acute prosthetic valve dysfunction depends on the type and severity of hemodynamic abnormality, the valve involved, and the underlying etiology. If the valve becomes obstructed acutely, the clinical presentation is likely to be dramatic with syncope and death in the absence of immediate surgical intervention. On the other hand, stenotic lesions that develop more gradually present as progressive heart failure and a low cardiac output state. Medical management consists of reducing LA pressure and maximizing ventricular performance with inotropic agents. Acute regurgitant lesions are managed according to the guidelines outlined under the treatment for aortic, mitral, and tricuspid regurgitation. Usually this will involve a combination of vasodilators, diuretics, and inotropic support. Definite therapy usually involves reoperation and replacement of the dysfunctional valve. The mortality for reoperation will depend primarily on the preoperative functional class, the underlying etiology of the valve dysfunction (endocarditis and

valve thrombosis carrying the highest risk), and the need for emergency surgery.

Prosthetic Valve Endocarditis (PVE)

Specific management of PVE consists of obtaining blood cultures and initiating empiric antibiotic therapy. Because there is a fairly well-defined difference between the pathophysiology and type of organisms responsible for early and late PVE, the initial choice of antibiotics will depend on the time of presentation relative to the date of surgical valve replacement; that is, “early” PVE (<60 days) and “late” PVE (>60 days). Staphylococcal, particularly *Staphylococcus epidermidis*, infections predominate in early PVE, whereas in late PVE there are equal percentages of streptococcal and staphylococcal infections.⁸⁷ In addition to progressive heart failure, PVE may also have embolic phenomena, para-valvular leak, or hemolytic anemia. Therefore, in patients with prosthetic valves who have these complications it is appropriate to obtain blood cultures and initiate empiric antibiotic therapy. Invariably, the vast majority of patients with PVE will require valve replacement. Table 27-3 lists indications for surgery for prosthetic valve endocarditis. The reoperative mortality for PVE ranges from 20% to 80%, but these figures have shown improvement since 1965.⁸⁸ Recently, a prospective cohort of 556 patients with definite prosthetic valve endocarditis as determined by the modified Duke criteria reported advanced age, health-care associated infection *Staphylococcus aureus* and complications (CHF, cerebrovascular accident, abscess, persistent bacteremia) as predictors of in-hospital mortality.⁸⁹ Although overall in-hospital mortality is no different, subsets of patients with staphylococcal endocarditis (27% vs 73% mortality) or complications of endocarditis (18% vs 48% mortality) benefit from early surgical treatment as compared with conservative medical management.⁹⁰ This trend toward enhanced survival may be related to improvements in both surgical technique and myocardial preservation.

Prosthetic Valve Thrombosis (PVT)

Valvular obstruction may occasionally be secondary to bacterial vegetations but more commonly is the result of pannus ingrowth or thrombus. The incidence of PVT with currently available mechanical devices varies from 0.03% to 4.3% per year.⁸⁵ Although a major risk factor for PVT is inadequate anticoagulation, approximately 40% of patients have adequate prothrombin times at the time of presentation.⁶³ This may be explained by the fact that PVT is a complex process that consists of a significant component of fibrous tissue ingrowth with associated secondary thrombosis. However, the percentage of valves involved with fibrous pannus varies significantly and depending on the study may range from 20% to 80%.⁹¹⁻⁹³ PVT may present acutely with heart failure or as a slowly progressive disorder with protean symptomatology.^{91,94} A high level of suspicion must be maintained in any patient with a valvular prosthesis who has nonspecific cardiac symptoms. As described above, TTE provides assessment of hemodynamic severity, whereas TEE or fluoroscopy is often used to delineate valve motion and clot burden. In general, the mortality for reoperation is high but tends to be variable, ranging from 4.5% to 35%, depending on the functional class. It does, however, appear that PVT has an independent effect on operative mortality.⁶⁷

Medical options to potentially restore prosthetic valvular function include thrombolytic therapy and anticoagulation with heparin. Thrombolytic therapy for hemodynamically

stable right-sided prosthetic valve thrombosis is relatively safe. If emboli occur in this setting, they tend to be small and confined to the pulmonary vasculature.^{95,96} However, in the case of prosthetic mitral and aortic thrombosis, there have been concerns regarding thrombolysis because of the increased risk of cerebral or systemic embolization arising from dissolution of the obstructive clot. Several studies have demonstrated that in patients selected for thrombolytic therapy there is a 70% to 88% hemodynamic success rate with an approximately 20% risk of complications, including hemorrhage and emboli.^{85,91,97-99} Thrombolytic therapy remains a viable option in those individuals whose operative mortality would be unacceptably high with surgical intervention or who have right-sided PVT. Streptokinase, urokinase, and recombinant tissue plasminogen activator have been used in various studies for PVT, but it should be noted that none of these agents have been approved by the Food and Drug Administration for use in this setting. Incomplete resolution of the obstruction or complete failure of therapy with thrombolytics may be related to the presence of pannus formation. In cases in which medical therapy fails, surgical intervention is required to restore complete forward flow.

In summary, PVT is a clinically and pathologically complex process that despite its relatively low incidence represents a serious complication in individuals with prosthetic heart valves. The 2006 American College of Cardiology/American Heart Association guideline for valvular disease endorses a class IIA recommendation for emergent surgery of left-sided or fibrinolytic therapy of right-sided PVT that is complicated by either New York Heart Association (NYHA) class III-IV CHF or a large thrombotic burden. Class IIB indications for fibrinolytic therapy include: left-sided PVT with both NYHA class I-II CHF (class III-IV CHF if high surgical risk) and small clot burden; and obstructed left-sided PVT with CHF and large clot burden but high surgical risk. Finally, unfractionated heparin for small thrombus and class I CHF is also a Class IIB indication.⁸⁷

Tricuspid Regurgitation

In general, the hemodynamic impact of acute tricuspid regurgitation is less significant than that of acute left-sided valvular lesions. However, in the setting of acute massive RV overload, hypotension and shock may ensue. More commonly, persistent, severe, chronic tricuspid regurgitation results in salt and water retention leading to peripheral edema, ascites, and congestive hepatomegaly. Massive RV volume overload secondary to acute tricuspid regurgitation may also lead to a significant reduction in LV ejection fraction due to paradoxical early systolic septal motion that results from ventricular interdependence.¹⁰⁰ Despite the hemodynamic instability at initial presentation, many of these patients can be effectively managed with a combination of diuretics and inotropic agents, provided that pulmonary arterial pressure remains normal and RV function is preserved. Once stabilized the long-term prognosis of these patients tends to be favorable. In general, the clinical presentation, response to medical therapy, and underlying pathology determine the need for surgical intervention.

Etiology

It should be emphasized that isolated, acute tricuspid regurgitation is a relatively uncommon medical emergency. The chronic form of tricuspid regurgitation predominates and usually

results from annular dilation secondary to left-sided valvular pathology, severe LV dysfunction, or pulmonary hypertension. In the current era, infective endocarditis remains the most common cause of acute tricuspid regurgitation and is almost exclusively a disease of intravenous drug users.¹⁰¹ Despite antibiotic sterilization of the valve lesion, these individuals frequently develop ruptured chords or leaflet perforation. Occasionally, a large, healed vegetation may impair leaflet apposition leading to tricuspid regurgitation. Rarer causes of acute tricuspid regurgitation include nonpenetrating chest trauma^{102,103} and RV infarction.^{104,105} With the growing number of cardiac transplant recipients, an iatrogenic form of tricuspid regurgitation has been recognized with increasing frequency.¹⁰⁶⁻¹⁰⁹ These patients undergo repeated endomyocardial biopsies for evaluation of cardiac allograft rejection; and occasionally during these procedures the biptome may inadvertently damage the tricuspid valve chordae or leaflet, resulting in acute tricuspid regurgitation.

Clinical Presentation

The physical findings in acute tricuspid regurgitation are dependent, in part, on the severity of the RV volume overload. In the case of papillary muscle rupture or RV infarction, there may be hypotension and cardiovascular collapse. Most patients, however, maintain blood pressure within the normal range and typically demonstrate findings consistent with right-sided heart failure. There is usually a prominent “v” wave visible in the jugular venous pulse and a holosystolic murmur along the left sternal border. The tricuspid regurgitation murmur increases in intensity with inspiration and, by this variation with respiration, can be differentiated from mitral regurgitation. An S3 gallop originating from the RV can be heard; and abdominal examination reveals pulsatile hepatomegaly. In general, peripheral stigmata of infective endocarditis are absent when the tricuspid valve is affected and, if present, suggest paradoxical emboli or additional, left-sided valvular lesions. In the case of intravenous drug users, track marks and evidence of “skin popping” may be seen.

Diagnosis

The diagnostic modality of choice is two-dimensional and Doppler echocardiography.¹¹⁰ The echocardiogram provides structural information about the tricuspid valve, including detection of vegetations (Fig. 27-7). In addition, the severity of tricuspid regurgitation and RV dysfunction can be assessed. Most importantly, pulmonary artery pressures can be estimated using the modified Bernoulli equation:

$$PAS = RAP + 4 \times V^2$$

where PAS = pulmonary artery systolic pressure, RAP = right atrial pressure measured by physical examination [5 cm + JVP (cm above clavicle)], and V is the peak velocity of the tricuspid regurgitation jet measured by continuous-wave Doppler.¹¹¹ In general, transthoracic echocardiography is satisfactory for assessing tricuspid valve structure and RV function. Transesophageal echocardiography may not offer any significant diagnostic advantage. In a prospective study by San Román and colleagues, transthoracic echocardiography was equivalent to transesophageal echocardiography in the diagnosis of tricuspid valve infective endocarditis; however, the relationship of the vegetation to the leaflet was better characterized by transesophageal echocardiography.¹¹²

Figure 27-7. Transthoracic echocardiogram of an apical four-chamber view shows a large vegetation present on the tricuspid valve, preventing coaptation of valve leaflets with subsequent severe, tricuspid regurgitation.

The ECG in cases of trauma may show right bundle branch block. If the tricuspid regurgitation has been of long standing, there may be ECG criteria for RV hypertrophy. RV infarction with acute tricuspid regurgitation rarely occurs in isolation and typically presents in conjunction with inferior myocardial infarction, which can be diagnosed by the characteristic ST segment elevation in leads II, III, and aVF. The presence of ST segment elevation in the right-sided lead V₄R confirms the diagnosis of an RV infarct and suggests that the patient may be at high risk for complications.¹¹³

The chest radiograph may show signs of cardiomegaly that represent RV and right atrial (RA) enlargement. The presence of cavitary septic pulmonary emboli may also be seen with tricuspid valve endocarditis. In addition, blood cultures form an essential component of the diagnostic work-up for patients with suspected infective endocarditis. In patients with infective endocarditis from intravenous drug use, staphylococcal organisms are the predominate isolate.

Right heart catheterization can be extremely helpful in confirming the diagnosis of pure tricuspid regurgitation and ruling out significant LV abnormalities. The presence of a large “v” wave in the RA tracing with concomitant elevation in mean RA pressure usually signifies the presence of significant tricuspid regurgitation. In addition, if the pulmonary artery and capillary wedge pressures are normal, the tricuspid regurgitation is likely to be related to primary dysfunction of the valvular apparatus and not secondary to left-sided heart function or pulmonary hypertension.

Treatment

The management strategy for acute tricuspid regurgitation should be focused primarily on medical therapy. In general, most patients can be effectively treated with a diuretic alone or in combination with an inotropic agent, such as dobutamine. In rare instances of acute massive tricuspid regurgitation, the patient who is refractory to medical therapy may require immediate surgical intervention. When possible, tricuspid valve repair, often with ring annuloplasty is preferred over valve replacement. However, when valve replacement is required,

a bioprosthetic valve is often used.¹¹⁴ The choice of a bioprosthesis is based on the extremely high incidence of valve thrombosis when mechanical valves are implanted in the tricuspid position. In the case of tricuspid regurgitation related to infective endocarditis, the decision to implant a prosthetic valve becomes even more complex. Because many of these patients are young, noncompliant, and often return to intravenous drug use, their risks for adverse events—whether self-induced or iatrogenic—are significant. The operative mortality for reoperation particularly for recurrent prosthetic valve endocarditis can be extremely high. Furthermore, if a bioprosthesis is used, the risk of valve failure is higher because of the younger age of the intravenous drug using population. The choice of a mechanical valve for durability is also fraught with complications, from both the inherently higher thrombotic risk despite anticoagulation and the general trend of medication noncompliance among these patients. Although treatment cannot be generalized for the intravenous drug use population, these recurring problems have fostered the development of several unique surgical approaches. These options include complete valve excision with no prosthetic replacement,¹¹⁵ valve repair after sterilization of the infection,¹¹⁶ and “vegetomy,”¹¹⁷ which refers to isolated resection of the bacterial vegetation with preservation of the valvulochordal apparatus. Many of these patients, even with complete valve excision, continue to do well, with minimal symptoms of right-sided heart failure. This is particularly true when the pulmonary vascular resistance is normal and RV function is preserved. Naturally, any management plan for infective endocarditis must include appropriate antibiotic coverage for an adequate period of time.

The treatment goal for tricuspid regurgitation secondary to an inferior myocardial infarction with RV involvement is revascularization. The type of revascularization procedure will depend on the nature of the coronary anatomy, the extent of atherosclerotic disease, the myocardial territory at risk, and the status of LV function.

Aortic Stenosis

Etiology

Aortic stenosis presents as a slowly progressive disorder characterized by narrowing of the aortic valvular orifice resulting in dyspnea, angina, or syncope.¹¹⁸ The etiology varies, but the lesion is usually the result of a degenerative, calcific process of the aortic leaflets. This disease process commonly presents in the sixth or seventh decade; however, if the valve is congenitally bicuspid, then the manifestations may occur earlier. Aortic stenosis may also be the result of commissural fusion secondary to chronic rheumatic heart disease.

Clinical Presentation

Physical examination reveals a small volume, slowly rising, sustained pulse, and an apical impulse that may be displaced downward and to the left with a marked presystolic impulse or “a” wave. The harsh ejection systolic murmur of aortic stenosis is best heard at the base and is transmitted to the carotids but may also be heard at the apex. In general, late peaking murmurs of longer duration signify more severe stenosis.^{119,120} However, it is important to remember that with decreasing cardiac output, there is a fall in the gradient with an associated diminution in the intensity of the murmur.

Diagnosis

The ECG usually reveals LV hypertrophy with strain, and there may be evidence of atrioventricular conduction delay in patients with calcific aortic stenosis involving the conduction system.¹²¹ The chest radiograph demonstrates LV enlargement, and some degree of aortic calcification is noted in most adults with significant aortic stenosis. Poststenotic dilation of the proximal ascending aorta may also be noted along the right heart border in the posteroanterior chest film.

Echocardiography has replaced cardiac catheterization for the initial assessment of valvular aortic stenosis. This noninvasive modality can accurately predict the severity of the valvular stenosis and estimate the valve area using the continuity equation.¹²² In addition, the anatomy of the valve leaflets can be assessed along with LV function.

When there is an inability to obtain adequate echocardiographic windows, it is likely that cardiac catheterization will be required to invasively assess the severity of valve stenosis. In addition, when the suspicion of coronary disease exists, angiography is imperative before valve replacement to determine the need for concomitant coronary artery bypass surgery.

Acute Complications

Several conditions may predispose to an acute deterioration in patients with aortic stenosis. To discern the inciting events leading to acute decompensation in valvular aortic stenosis, it is important to understand the underlying pathophysiologic state. Progressive valvular aortic stenosis leads to increasing LV systolic pressure and wall stress. In an effort to normalize this afterload mismatch, the LV hypertrophies. Initially, this normalizes wall stress, but it also results in a shift of the LV pressure-volume curve upward and to the left (see Fig. 27-1). This necessitates higher filling pressures for a given ventricular volume leading to elevated pulmonary venous pressures with consequent dyspnea on effort. Because of this abnormal LV pressure-volume relationship, any diminution in preload will seriously impair stroke volume. Therefore conditions that lead to acute volume shifts (e.g., dehydration or acute blood loss) will result in a significant impairment of cardiac output. The altered LV pressure-volume relationship reduces passive LV filling, making LV preload critically dependent on atrial contraction.¹²³ Any impairment in the contribution of diastolic filling by atrial systole, such as atrial fibrillation or atrioventricular dyssynchrony, can lead to acute decompensation. In addition to atrial arrhythmias and conduction abnormalities, increasing heart rate may also impair LV filling simply by decreasing the diastolic filling period. It is also important to realize that a markedly reduced heart rate will also impair forward cardiac output because the stroke volume is limited by the severe valvular stenosis. This is particularly true in the setting of impaired LV function. Any condition that further impairs LV relaxation will also have a significant impact on diastolic filling (e.g., acute coronary ischemia). Relative ischemia may also occur in the setting of normal coronary arteries or nonobstructive coronary artery disease when myocardial oxygen demands have exceeded coronary reserve.¹²⁴

Treatment

The treatment of severe aortic stenosis is valve replacement that corrects the underlying pathophysiology of afterload mismatch. Improvement in LV function and long-term survival will

follow valve replacement in the vast majority of patients.¹²⁵ In the event of rapid clinical deterioration, the inciting event must be identified and treated promptly. In the case of volume depletion (e.g., dehydration, blood loss), volume replacement must be judicious to avoid pulmonary edema. In some cases, this may require a pulmonary artery catheter to monitor pulmonary capillary wedge pressure. Systemic hypoperfusion unresponsive to increased preload should be treated with inotropic agents, which have the dual effect of increasing stroke volume and systemic vascular resistance to maintain tissue perfusion. A combination of dobutamine and dopamine may be particularly useful in this regard. If pulmonary congestion occurs, loop diuretics can be used cautiously to decrease pulmonary capillary pressure.

Atrial fibrillation should be treated with urgent synchronized cardioversion, particularly if systemic hypotension or pulmonary congestion has supervened. Atrioventricular conduction abnormalities should be managed with temporary pacing followed by a permanent pacemaker if the conduction disturbance persists. Once the patient is stabilized, urgent valve replacement should be undertaken. If there is a question of coronary artery disease, cardiac catheterization should be performed, focusing specifically on coronary anatomy. Occasionally when the patient is gravely ill from LV failure, it may be necessary to proceed directly to valve replacement without preoperative coronary angiography.

Mitral Stenosis

Etiology

Mitral stenosis generally results as a sequela to group A streptococcal infections. Goldstein and colleagues¹²⁶ were the first to demonstrate that group A streptococci have antigens that cross react with the structural glycoprotein of heart valves, thus directly linking this organism with rheumatic valvular disease. The classic pathologic features include fusion of the commissures, thickening of the valve leaflets, and shortening of the chordae tendinae.¹²⁷ These abnormalities of valve structure result in progressive narrowing of the valve orifice, leading to restriction of LV inflow. The predicted pathophysiologic effects are that of progressive LA enlargement accompanied by elevation in LA pressure. This results in pulmonary venous hypertension with the clinical accompaniment of progressive dyspnea. Secondary pulmonary arteriolar constriction may also occur, which worsens pulmonary hypertension. Rheumatic heart disease overwhelmingly represents the most common cause of mitral stenosis¹²⁸; however, other rare etiologies include congenital mitral stenosis¹²⁹ and Lutembacher syndrome (atrial septal defect associated with mitral stenosis).¹³⁰

Clinical Presentation

Typically symptomatic mitral stenosis presents in the fourth or fifth decade; however, in socioeconomically disadvantaged areas it may occur much earlier.¹³¹⁻¹³³ Patients have progressive dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea. Hemoptysis may also occur secondary to rupture of bronchopulmonary venous connections. With long-standing mitral stenosis, patients frequently develop atrial fibrillation,¹³⁴ and this, in turn, may lead to thrombus formation in the LA. The development of clot in the LA poses considerable risks to

Table 27-7. Physical Findings in Mitral Stenosis

• Low volume pulse
• Jugular venous pulse with prominent “a” wave
• Point of maximal impulse is not displaced and is “tapping” in quality (reflecting a loud S1)
• Palpable localized apical diastolic thrill
• Midsystolic rumbling apical murmur with presystolic accentuation (if the patient is in sinus rhythm)
• Loud S1 with accentuated P2 (if pulmonary hypertension is present)
• Opening snap at the lower left sternal border (signals mitral valve opening and the presence of pliable leaflets)
• Graham Steell murmur of pulmonary regurgitation (a feature of pulmonary hypertension)

the patient, including systemic thromboembolic events and acute valvular obstruction. In most cases, the physical findings are quite striking and reflect both the restriction to LV filling and the accompanying signs of pulmonary hypertension (see Table 27-7).

Diagnosis

In more severe cases of mitral stenosis, the ECG may show characteristic changes suggestive of LA enlargement. With progressive pulmonary hypertension, the frontal axis shifts rightward and is accompanied by ECG evidence of RV hypertrophy.^{135,136} The chest radiograph may reveal the presence of LA enlargement and dilation of the main pulmonary artery. These findings, plus a normal aortic arch, give the characteristic radiographic appearance of a straight left heart border. Cardiac catheterization with simultaneous pulmonary capillary wedge (a surrogate for LA pressure) and LV pressure measurements demonstrates a gradient from LA to LV. The valve area may be calculated using the Gorlin equation, based on the diastolic pressure difference between LA and LV, cardiac output, and the diastolic flow period. In the evaluation of uncomplicated mitral stenosis, echocardiography has replaced the use of cardiac catheterization. Echocardiography not only accurately estimates the degree of valvular stenosis but also gives additional information about the anatomy of the valve.¹³⁷ However, coronary angiography is still a prerequisite before surgical therapy in individuals with known or suspected coronary artery disease.

Treatment

Over the past several years, the treatment of mitral stenosis has evolved in a dramatic fashion. The original surgical treatment for mitral stenosis was described by Cutler and Levine at the Peter Bent Brigham Hospital in 1923.¹³⁸ The procedure was initially fraught with a high mortality. However, by 1948, with Harken's report in the *New England Journal of Medicine*, it became apparent that closed mitral valvuloplasty was an acceptable form of treatment for symptomatic mitral stenosis.¹³⁹ Since then, surgical techniques have evolved to include open surgical commissurotomy with cardiopulmonary bypass and, more recently, percutaneous balloon mitral valvuloplasty. Several

recent randomized clinical trials have demonstrated percutaneous balloon mitral valvuloplasty to be equivalent to surgical therapy.^{140,141}

Several different conditions may be superimposed on the substrate of mitral stenosis, resulting in acute emergencies. Atrial fibrillation occurs commonly in mitral stenosis and classically with deterioration in functional class, and marked dyspnea and fatigue. These symptoms result from an elevation in LA pressure and a fall in cardiac output. The increased ventricular rate associated with atrial fibrillation causes a significant rise in LA pressure, much more so than the loss of atrial booster pump function.¹⁴² In addition, the shortened diastolic filling time and loss of atrial systole compromises stroke volume leading to impaired cardiac output. This pathophysiology also occurs with other tachyarrhythmias complicating mitral stenosis.^{142,143} Hemodynamic deterioration may also present in mitral stenosis during pregnancy. Other important and often life-threatening complications include obstruction of the mitral orifice with thrombus or infected vegetation¹⁴⁴⁻¹⁴⁵ and massive hemoptysis¹⁴⁶⁻¹⁴⁸ from rupture of dilated bronchial veins. The literature with reference to treatment of these dire complications remains limited; however, anecdotal studies suggest that urgent treatment of the valvular obstruction surgically or percutaneously can be life saving. An interesting report from South Africa describes a young patient with severe mitral stenosis and hemodynamic collapse secondary to overwhelming sepsis with high obligate flow rates.¹⁴⁹ Emergent percutaneous balloon mitral valvuloplasty was performed with marked improvement in hemodynamics and clinical status. This patient subsequently succumbed to other complications unrelated to mitral stenosis, but this case study does demonstrate the feasibility of percutaneous balloon mitral valvuloplasty in an acutely ill patient with compromised cardiac output secondary to sepsis. A similar strategy has been employed during pregnancy complicated by mitral stenosis.¹⁵⁰

Conclusion

Acute heart failure secondary to valvular dysfunction remains an extremely difficult clinical dilemma from the standpoint of both diagnosis and treatment. In this review, we have focused primarily on acute aortic insufficiency and acute mitral regurgitation with some additional information about prosthetic valve dysfunction and acute tricuspid regurgitation. A brief description of acute hemodynamic decompensation in aortic stenosis and mitral stenosis has also been discussed. Our intention has been to emphasize the importance of prompt recognition of these clinical syndromes by understanding their underlying pathophysiology. Emphasis has been placed on expeditious treatment with appropriate diagnostic testing. In most cases of acute heart failure secondary to valvular disease, the use of a bedside pulmonary artery catheter is invaluable, allowing the clinician to assess both the degree of hemodynamic embarrassment and to guide therapy. In conclusion, for the treating physician to effectively manage these patients he or she must not only understand the pathophysiology of the disease but also be cognizant of the limitations of medical therapy. It is essential to understand that, in general, surgical intervention represents the most definitive intervention and, therefore, early cardiothoracic surgical consultation is a critical step in the management algorithm of these desperately ill individuals.

Hypertensive Emergencies

Eduardo Pimenta, David A. Calhoun, Suzanne Oparil

CHAPTER 28

Definition

Prognosis

Definition

HYPERTENSIVE EMERGENCIES are characterized by severe elevations in blood pressure (BP) ($>180/120$ mm Hg) complicated by evidence of impending or progressive target-organ dysfunction.¹ The major types of hypertensive emergencies are summarized in Table 28-1. In reality, however, it is not the absolute level of BP that is hazardous, but the rate of rise of BP. Patients with chronic hypertension can tolerate much higher BP than previously normotensive persons. Diastolic BP (DBP) of 140 mm Hg or higher may be well tolerated in a patient with chronic hypertension without symptoms, whereas a DBP of 110 mm Hg may be devastating in a previously normotensive woman with preeclampsia or a child with acute glomerulonephritis. The diagnosis of hypertensive emergency, whatever the BP level, requires immediate reduction of BP, generally with an intravenous antihypertensive agent in an intensive care unit for continuous monitoring of BP. In contrast, a severe elevation in BP without evidence of progressive end-organ damage, considered an urgent hypertensive crisis, can usually be managed with oral medication in an outpatient setting. In this case, gradual reduction in BP over a period of 24 to 48 hours is usually sufficient.

Included among hypertensive emergencies is the syndrome of malignant or accelerated hypertension. As first described by Volhard and Fahr in 1914, malignant hypertension was characterized by severe hypertension, retinopathy with papilledema, renal insufficiency, fibrinoid necrosis of renal arterioles, and a rapidly progressive and fatal clinical course.² Later, the definition was generalized to include severe hypertension accompanied by papilledema (grade IV Keith-Wagener retinopathy). In contrast, accelerated hypertension was considered severe elevation of BP in the presence of retinal hemorrhages and exudates but without papilledema (grade III Keith-Wagener retinopathy). Subsequent

studies showed that severe hypertension complicated by retinal hemorrhages and exudates with or without papilledema had similar clinical features and prognosis, so that the terms *malignant* and *accelerated hypertension* are used interchangeably.³ Presently, these terms are not used, and, instead, *hypertensive emergency* is used to refer to the syndrome of elevated BP complicated by acute end-organ damage, including grade III or IV retinopathy.

Incidence and Prevalence

In spite of improvements in the diagnosis and treatment of hypertension, the control rate remains low. In the National Health and Nutrition Examination Survey III (NHANES III) only 37% of patients with hypertension had controlled BP levels.⁴ However, widespread outpatient antihypertensive treatment has reduced the incidence of hypertensive emergencies, and nonadherence to prescribed medication now accounts for most cases.⁵ Hypertensive emergencies occur in approximately 1% of hypertensive patients.⁶ In a Brazilian retrospective study of 76,723 patients admitted to the emergency department, 273 (0.35%) were considered hypertensive urgencies and only 179 (0.23%) had a diagnosis of hypertensive emergency.⁷ Similarly, 118 of 17,952 (0.65%) patients admitted to an emergency department in Spain were diagnosed as having a hypertensive crisis (defined as BP $\geq 210/120$ mm Hg), but only 28 (0.15%) were diagnosed as a hypertensive emergency.⁸ In an Italian series, 108 hypertensive emergencies comprised 0.76% of visits to the internal medicine section of an emergency department during 1 year.⁹ The estimated prevalence of hypertensive crisis in the general hypertension population is 1% in the United States.¹⁰ Two major university hospitals in the United States have reported similar findings: in New York, 0.6% of 9851 medical service admissions were for hypertensive emergency, whereas in Miami, 1.1% of 2898 medical emergency department visits resulted in hospital admissions for hypertensive emergency.^{11,12} This contrasts with a 7% incidence of accelerated hypertension with papilledema in patients with untreated essential hypertension in the era before the development of effective antihypertensive therapy.^{13,14} The reduction in incidence of hypertensive emergencies has generally been attributed to the success of antihypertensive therapy in preventing progression from the early stages of hypertension to more advanced disease with target-organ damage. Poor access to health care and noncompliance to medications are generally associated with hypertensive crisis and should be assessed in patients having hypertensive emergencies before hospital discharge.

Table 28-1. Types of Hypertensive Emergencies

- Hypertensive encephalopathy

- Unstable angina pectoris
- Dissecting aortic aneurysm
- Eclampsia

Table 28-2. Conditions Related to Hypertensive Emergencies

Essential hypertension
Renal parenchymal disease
• Acute glomerulonephritis • Aasculitis • Hemolytic uremic syndrome • Thrombotic thrombocytopenic purpura
Renovascular disease
Pregnancy
Endocrine
• Pheochromocytoma • Cushing syndrome • Renin-secreting tumors • Mineralocorticoid hypertension
Drugs
• Cocaine, sympathomimetics, erythropoietin, cyclosporin, antihypertensive withdrawal • Interactions with monoamine-oxidase inhibitors (tyramine), amphetamines, lead intoxication
Autonomic hyperactivity
• Guillain-Barré syndrome, acute intermittent porphyria
Central nervous system disorders
• Head injury, cerebral infarction/hemorrhage, brain tumors

From Vaughan CJ, Delanty N: Hypertensive emergencies. *Lancet* 2000;356:411-417.

Etiology and Pathogenesis

The etiology of malignant or accelerated hypertension is unknown, but many conditions are related to hypertensive emergencies and urgencies (Table 28-2). The degree of BP elevation does not correlate closely with the severity of end-organ deterioration, and it is uncertain whether malignant or accelerated hypertension is a nonspecific consequence of very high BP or is triggered by a specific constellation of neurohumoral factors and cytokines.¹⁴⁻¹⁷

The primary abnormality in patients with hypertensive emergencies is the impaired autoregulatory capacity (i.e., the ability of blood vessels to dilate or constrict to maintain normal perfusion, particularly in the cerebral and renal beds). An initial abrupt rise in vascular resistance in response to excess production of catecholamines, angiotensin II, vasopressin, aldosterone, thromboxane and/or endothelin, or deficient production of endogenous vasodilators—such as nitric oxide and prostacyclin—seems to precipitate increased vasoreactivity and resultant hypertensive emergency (Fig. 28-1).¹⁷

Autoregulatory function is compromised, resulting in end-organ ischemia, which triggers the release of additional vasoactive substances, thus initiating a vicious cycle of further vasoconstriction, myointimal proliferation, and end-organ ischemia.¹⁸ Preclinical studies have provided evidence that activation of renin-angiotensin-aldosterone system (RAAS) plays an important role in the pathophysiology of severe hypertension,

leading to hypertensive crisis. Animals that are double transgenic for the human renin and angiotensinogen genes develop severe hypertension plus inflammatory vasculopathy similar to that seen in severe human hypertension.¹⁹ Angiotensin II has direct cytotoxic effects on the vessel wall through activation of expression of genes for proinflammatory cytokines and the transcription factor nuclear factor κ B (NF- κ B).^{20,21} The RAAS also induces expression of proinflammatory cytokines and vascular cell adhesion molecules, which may contribute to the vascular injury and target-organ damage.¹⁷ Arteriolar fibrinoid necrosis ensues, precipitating endothelial damage, platelet and fibrin deposition, and thromboxane release. Some studies have also reported a relation between genetic polymorphisms in components of the RAAS and hypertensive crisis. For example, the DD and ID genotypes of the angiotensin-converting enzyme (ACE) gene are more frequent in patients having malignant hypertension or hypertensive crisis.^{22,23}

Malignant or accelerated hypertension is more prevalent among patients with secondary hypertension, particularly hypertension secondary to renal artery stenosis or renal parenchymal disease, than among essential hypertensive patients. However, essential hypertension is the most common underlying cause of malignant or accelerated hypertension because of its greater prevalence. Based on postmortem analysis, Kincaid-Smith found that of 124 cases of malignant hypertension, 44% occurred in the setting of primary hypertension; 13% had chronic glomerulonephritis; 9% had polyarteritis nodosa; and 6% had unilateral renal artery stenosis.²⁴ In a study of 123 patients without evidence of primary renal parenchymal disease referred to a tertiary care center for evaluation of severe hypertension with grade III or IV retinopathy, Davis and associates found that 43% of the white patients and 7% of the black patients had renal artery stenosis documented by renal arteriography.²⁵ Of the 242 patients with malignant hypertension identified by Lip and associates, 97 (40%) had secondary hypertension, most commonly related to renal parenchymal disease. Twenty-five patients (10%) had pregnancy-induced hypertension.²⁶ Aldosterone excess has also been detected in patients with hypertensive crisis. Labinson and colleagues reported eight patients with a clinical diagnosis of primary aldosteronism whose course was complicated by hypertensive emergencies.²⁷ All of these responded well to laparoscopic adrenalectomy or medical treatment with aldosterone receptor blockers. Accordingly, any patient who has experienced malignant or accelerated hypertension should undergo evaluation for secondary hypertension.

Diagnosis

The common presenting symptoms and target organ complications of hypertensive emergencies are listed in Table 28-3.²⁶ The physician evaluating a patient for hypertensive emergency should focus on the history, physical examination, and laboratory evaluation to assess the severity of BP elevation and related end-organ damage.¹⁶ This includes a determination of the duration, severity, and level of control of preexisting hypertension, antihypertensive drug treatment, and the extent of preexisting end-organ damage. The presence of concomitant illnesses and all medications, including prescription drugs, over-the-counter preparations such as sympathomimetic agents, and illicit drugs such as cocaine, should be noted. The physician should assess specific symptoms suggesting end-organ damage such as chest pain (myocardial ischemia or aortic dissection), back pain (aortic

Figure 28-1. Putative vascular pathophysiology of hypertensive emergencies. **A**, The endothelium modulates vascular resistance through the autocrine/paracrine release of vasoactive molecules such as nitric oxide (NO) and prostacyclin (PGI₂). **B**, Acute changes in vascular resistance occur in response to excess production of catecholamines (CAT), angiotensin II (ATII), vasopressin (ADH), aldosterone, thromboxane (TxA₂), and endothelin 1 (ET1), or low production of endogenous vasodilators such as NO and PGI₂. Acute or severe increases in blood pressure can also promote expression of cellular adhesion molecules (CAMs) by the endothelium. **C**, During a hypertensive emergency, endothelial control of vascular tone may be overwhelmed, leading to end-organ hyperperfusion, arteriolar fibrinoid necrosis, and increased endothelial permeability with perivascular edema. Loss of endothelial fibrinolytic activity coupled with activation of coagulation and platelets promotes disseminated intravascular coagulation (DIC). RBC, red blood cell. (From Vaughan CJ, Delanty N: Hypertensive emergencies. *Lancet* 2000;356:411-417.)

Table 28-3. Most Common Presenting Symptoms and Complications of Hypertensive Emergencies

Symptoms/Complications	Frequency
• Visual disturbance	26%
• Headache	12%
• Headache and visual disturbance	10%
• Heart failure	8%
• Stroke and transient ischemic attack	7%
• Dyspnea	5%
• No symptoms	10%
• Heart failure	11%
• Stroke	10%
• Angina	4%
• Myocardial infarction	4%
• Chronic renal failure	32%
• None	61%

From Lip GYH, Beevers M, Beevers G: The failure of malignant hypertension to decline: a survey of 24 years' experience in a multiracial population in England. *J Hypertens* 1994;12:1297-1305.

dissection), dyspnea (pulmonary edema or congestive heart failure), and neurologic symptoms (hypertensive encephalopathy).

The signs of hypertensive emergency that should be assessed on physical examination are listed in Table 28-4. Supine and upright BP should be measured to assess volume status. The BP should also be measured in both arms because a significant difference increases the suspicion of aortic dissection. The ocular fundi should be examined for evidence of acute hypertensive retinopathy. The heart and lungs should be auscultated for signs of acute left ventricular dysfunction. The presence of an abdominal bruit suggests renal artery stenosis and palpation of the abdomen may reveal evidence of an aortic aneurysm. Discrepancies in peripheral pulses and the murmur of aortic regurgitation suggest aortic dissection. The neurologic examination may yield evidence of encephalopathy or stroke, including disorientation, localized weakness, and visual field deficits.

Basic diagnostic evaluation for patients with hypertensive crisis is listed in Table 28-5. Urinalysis and determination of serum electrolytes, urea nitrogen, and creatinine levels should be obtained to confirm or exclude acute renal insufficiency; a complete blood cell count with peripheral blood smear should be performed to look for evidence of microangiopathic anemia; and a serum glucose test should be done to identify concomitant diabetes.^{5,17} An electrocardiogram to help identify or rule out myocardial ischemia and chest radiograph to look for pulmonary edema secondary to left ventricular failure and for widening of the mediastinum secondary to thoracic aortic dissection are indicated.^{5,17} In some cases, measurement of plasma renin

activity and aldosterone drawn at the time of admission can be useful in making a retrospective diagnosis. If aortic dissection is suspected, computed tomography, magnetic resonance imaging, and transesophageal echocardiography may be needed.²⁸

Any evidence of acute or rapidly progressive end-organ deterioration in the history, physical examination, or laboratory evaluation distinguishes a hypertensive emergency from an urgent hypertensive crisis.⁶ As soon as the physician diagnoses or suspects target organ damage from the history, physical examination, or laboratory analysis, the patient should be placed on a cardiac monitor and have intravenous access established. BP reduction (usually with an intravenous drug) should begin during the arrangements for hospital admission.

Treatment

Patients with a hypertensive emergency should be admitted to an intensive-care unit and require immediate but controlled reduction in BP to protect end-organs from further damage. In general, the goal of therapy is to lower the mean arterial pressure

by approximately 25% or to reduce the DBP to 100 to 110 mm Hg over a period of several minutes to hours, depending on the clinical situation.^{1,6} Precipitous reductions in BP and rapid reductions to normotensive or hypotensive levels should be avoided because they may provoke end-organ ischemia or infarction. BP should be maintained at the initial target level for 2 to 6 hours. If the BP is tolerated and the patient is clinically stable, further gradual reductions can be implemented in the next 24 to 48 hours.¹ Ischemic stroke and aortic dissection are exceptions. There is no evidence from clinical trials to support immediate antihypertensive treatment in patients with ischemic stroke.²⁹ Oral or intravenous antihypertensive treatment should be instituted if DBP greater than 120 mm Hg or if the patient is eligible for thrombolysis.³⁰ Aortic dissection is a dramatic and fatal complication, and these patients should have their systolic BP (SBP) reduced to less than 100 mm Hg if tolerated.¹ Therapy for acute dissection aims to reduce stress on the aortic wall by lowering BP and heart rate. These goals are achieved with a combination of β -blockers (labetalol is most commonly used) and vasodilators. Nitroprusside can cause reflex tachycardia and thus β -blockers should be started first.¹⁷

The goal of therapy is to interrupt the cycle of impaired autoregulatory capacity and vasoreactivity by reducing peripheral vascular resistance.⁶ Sodium nitroprusside is the drug of choice for the treatment of most hypertensive emergencies because it allows for the controlled reduction of BP. In all situations in which an antihypertensive agent is being delivered intravenously, constant BP monitoring, preferably through an arterial line, is mandatory. Most patients who have a hypertensive crisis are volume-depleted, presumably secondary to a pressure-related diuresis. Accordingly, diuretics should be reserved for patients in whom there appears to be fluid overload, such as pulmonary edema.

Parenteral antihypertensive agents should be gradually withdrawn after BP has been controlled for 12 to 24 hours, with concomitant introduction of oral agents. Evaluation for secondary hypertension may be started during hospitalization while oral antihypertensives agents are titrated. Attempting to ensure adherence to antihypertensive therapy during long-term follow-up is an important step to prevent recurrent hypertensive crisis.⁵

Prognosis

The development of successful antihypertensive therapy has greatly improved the prognosis of patients with hypertensive emergencies.⁵ In 1939, Keith and colleagues found that mean survival of patients with hypertension and grade IV retinopathy was 10.5 months, with no survivors at 5 years.³¹ More recently, authors have reported that the survival of patients with malignant hypertension approaches that of patients with uncomplicated primary hypertension.^{32,33} Using life-table analysis, the estimated survival of patients with malignant hypertension was 18 years, versus 21 years in patients with uncomplicated hypertension.³² The leading cause of death (50%) in patients with accelerated hypertension was myocardial infarction. In Birmingham, UK, 74% of 315 patients with malignant hypertension were alive after 5-year follow-up and renal failure was the most common cause of death.³³ Acute target-organ damage secondary to hypertensive emergency (e.g., acute renal failure may return toward normal if BP is controlled in the long term).⁵

An exception to this rule is eye and central nervous system damage, which tends to be irreversible.

Specific Hypertensive Emergencies

Hypertensive Encephalopathy

Hypertensive encephalopathy is the most difficult neurologic emergency to diagnose and frequently it is a diagnosis of exclusion.¹⁷ With better diagnosis and treatment of primary hypertension, hypertensive encephalopathy is infrequent. However, prompt recognition and treatment is essential to prevent progression to hemorrhage. This becomes a particularly difficult issue when hypertensive encephalopathy occurs in previously normotensive persons, as with preeclampsia or “crack” cocaine

abuse. Hypertensive encephalopathy is also associated with secondary causes of severe hypertension, such as renal disease, immunosuppressive therapy,^{34,35} erythropoietin use,³⁶ and thrombotic thrombocytopenic purpura.³⁷

Ordinarily cerebral blood flow is autoregulated (i.e., cerebral resistance vessels constrict and dilate in response to changes in systemic pressure) to maintain a constant perfusion pressure (Fig. 28-2).^{17,38-41} In normotensive subjects, perfusion pressure is maintained over a wide range of mean arterial pressure (60 to 120 mm Hg). With chronic hypertension, the mean BP range over which cerebral perfusion is maintained is shifted upward (160 to 180 mm Hg), such that persons with long-standing hypertension can tolerate greater elevations in BP without compromising cerebral perfusion. When elevations in systemic BP exceed the brain's ability to locally autoregulate cerebral perfusion, overperfusion ensues, resulting in cerebral edema, small vessel damage, and microinfarctions. As indicated earlier, breakdown in autoregulation of cerebral perfusion occurs at much lower BP levels in previously normotensive subjects than in persons with chronic hypertension.

Hypertensive encephalopathy most commonly develops over a period of several days. The patient usually complains of headache, nausea, visual changes, or focal neurologic symptoms. Physical examination generally reveals disorientation, obtundation, focal neurologic signs, seizures, and retinopathy, including papilledema. Hypertensive encephalopathy is a diagnosis of exclusion after ruling out stroke, subarachnoid hemorrhage, seizure disorder, encephalitis, and drug overdose.¹⁷

The drug of choice for treatment of hypertensive encephalopathy is nitroprusside (Table 28-6). It should be titrated to reduce

Figure 28-2. Autoregulation of cerebral blood flow. (From Vaughan CJ, Delanty N: Hypertensive emergencies. *Lancet* 2000;356:411-417.)

Table 28-6. Types of Hypertensive Emergency and Treatment Recommendations

Type of Hypertensive Emergency	Recommended Treatment	Drugs to Avoid
Hypertensive encephalopathy	Nitroprusside, labetalol	β -blockers, methyldopa, clonidine, nicardipine, diazoxide, nitroglycerin
Stroke	Labetalol, nitropaste, nicardipine	β -blockers, methyldopa, clonidine, diazoxide, hydralazine, nitroglycerin
Intracerebral hemorrhage, subarachnoid hemorrhage	Nimodipine,* nitroprusside, nicardipine, labetalol	β -blockers, methyldopa, clonidine, diazoxide, hydralazine, nitroglycerin
Myocardial ischemia, myocardial infarction	Nitroglycerin, labetalol, nitroprusside, β -blockers†	Hydralazine, diazoxide, minoxidil
Acute pulmonary edema	Nitroprusside or nitroglycerin‡ and loop diuretic	Hydralazine, diazoxide, β -blockers, labetalol
Aortic dissection	Nitroprusside, β -blockers, labetalol	Hydralazine, diazoxide, nicardipine, minoxidil
Acute renal insufficiency	Fenoldopam, nitroprusside, labetalol, calcium channel β -blockers	β -blockers, ACE inhibitors, angiotensin receptor blockers
Preeclampsia, eclampsia	Hydralazine, labetalol	Diuretics, β -blockers, ACE inhibitors
Postoperative hypertension	Nitroprusside, nitroglycerin, calcium channel blockers, β -blockers	—
Hyperadrenergic states	Labetalol, phentolamine, calcium channel blockers,§ nitroprusside	β -blockers (in cocaine overdose)

*Nimodipine is used to reduce cerebral artery vasospasm, not to lower BP in subarachnoid hemorrhage.

†Should not be used if left ventricular function is compromised.

‡Drug of choice if left ventricular failure is due to or complicated by ischemia.

§Useful for treating associated coronary spasm.

mean arterial pressure by about 20% or to a DBP of 100 mm Hg within the first hour.¹⁷ Particular caution is needed in elderly patients and in those with preexisting hypertension in whom overaggressive reduction in BP may be accompanied by worsening of neurologic status and even stroke. Neurologic function should improve with BP reduction. If not, a diagnosis other than hypertensive encephalopathy should be entertained. Labetalol can be used as an alternative to nitroprusside. Agents that suppress central nervous system function, such as β -blockers and central nervous system active agents, and agents that increase cerebral blood flow, such as nicardipine and nitroglycerin, should be avoided.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage is caused by ruptured aneurysms in 85% of patients and the fatality rate is 50%.⁴² Headache is the most characteristic symptom of subarachnoid hemorrhage and focal neurologic deficits occur when the aneurysm compresses a cranial nerve or bleeds into the brain parenchyma or from local ischemia due to acute vasoconstriction. Acute BP reduction in this setting, regardless of the presenting BP, has not been shown to improve morbidity and mortality.⁴² Therefore, antihypertensive therapy should not be prescribed unless mean arterial pressure is 130 mm Hg.^{43,44}

Patients having subarachnoid hemorrhage should receive nimodipine, a calcium channel blocker.^{42,44,45} The evidence for nimodipine is based on a single large trial in which patients treated with nimodipine had a 40% reduction in poor outcomes defined as severe disability, vegetative state, and death.⁴⁶ Nimodipine should be dosed at 60 mg orally or per nasogastric tube every 4 hours for 21 days, starting within 96 hours of the subarachnoid hemorrhage.⁴⁵ The benefits of nimodipine are likely secondary to inhibiting cerebral artery vasospasm and not to BP reduction because there is no significant change in BP with the above doses.

Stroke

Approximately 80% of patients with stroke are hypertensive on presentation and 30% have a prior history of hypertension.⁴⁷ The elevated BP usually falls spontaneously without treatment after a few days, and 10 days after a stroke approximately, two thirds of patients are normotensive.^{48,49} BP regulation after a stroke can be precarious, particularly in the elderly, with even minimal intervention causing precipitous drops in BP. Optimum management of hypertension in acute ischemic stroke remains controversial.²⁹ Aggressive treatment of BP may lead to neurologic worsening by reducing perfusion pressure of the penumbra area and extension of the damage.⁵⁰⁻⁵³ A prospective study conducted in 115 patients admitted within 24 hours of stroke noted that each 10% decrease in SBP was associated with an increased odds ratio of 1.89 for developing an unfavorable outcome.⁵⁴ However, a trial has reported significantly reduced cumulative mortality and number of cardiovascular events in patients treated with candesartan from the first day after stroke.⁴⁹ Because BP tends to decrease spontaneously in the first few days after a stroke, antihypertensive therapy should be withheld unless some other target organ is being compromised.⁵⁵

Although the appropriate treatment of arterial hypertension in the setting of acute ischemic stroke remains controversial, the American Heart Association (AHA) recommends no antihypertensive treatment unless BP elevations are extremely high (SBP >220 mm Hg or DBP >120 mm Hg) or if the patient is

eligible for thrombolysis.^{55,50} If antihypertensive therapy is necessary, the BP should be gradually reduced by 15% to 25% during the first 24 hours.⁵³ Drug therapy is similar to that for hypertensive encephalopathy (see Table 28-6). Inducing hypertension in hypotensive patients is theoretically beneficial (i.e., increasing cerebral blood flow in the ischemic penumbra of the brain could potentially salvage ischemic tissue). However, a study in patients with intracranial arterial stenosis showed that increased BP is associated with increased risk of ischemic stroke and stroke in the territory of the stenotic vessel.⁵⁶ Further data from large clinical trials are not available and therefore pressor therapy is not currently recommended.⁵³ Two randomized studies on BP management during acute stroke are under way and may help with clinical decision making.^{57,58}

Intracerebral Hemorrhage

The clinical benefit of BP reduction after intracerebral hemorrhage remains controversial. It has been difficult to determine whether elevated BP in the setting of intracerebral hemorrhage is a cause of hemorrhagic extension or an effect of increasing intracranial volume and pressure. It has been customary to recommend BP reduction in patients with severe hypertension after an intracerebral hemorrhage in an effort to prevent further bleeding, but to do so may precipitate cerebral hypoperfusion. Controlled studies have not shown benefit from reducing BP after intracerebral hemorrhage. Therefore, AHA recommends intravenous antihypertensive therapy based on peripheral BP and if elevated intracranial pressure is suspected (Fig. 28-3).⁵⁹

Myocardial Ischemia or Infarction

The target BP is less than 130/80 mm Hg in patients with acute coronary syndromes.⁶⁰ All patients with unstable angina and hypertension should receive oxygen, aspirin, and nitroglycerin. Nitroglycerin is indicated to promote coronary dilation, improve coronary perfusion, and reduce symptoms, and should be used as needed to reduce BP. β -blockers reduce heart rate and myocardial oxygen consumption and are useful in combination with nitrates unless ventricular function is compromised. BP should be reduced gradually to less than 130/80 mm Hg until the symptoms subside. In patients with elevated DBP, the BP should be lowered slowly and caution is advised in inducing reductions in DBP to below 60 mm Hg.⁶⁰ If nitroglycerin is ineffective or contraindicated, labetalol can be used to reduce BP while improving myocardial oxygenation (see Table 28-6). Nitroprusside should be used only if the hypertension is refractory to other agents because of the possibility of the coronary steal phenomenon (i.e., in the setting of fixed coronary obstruction, blood flow can be redirected from ischemic areas, worsening myocardial ischemia). Agents that may reflexively increase myocardial oxygen demand, such as hydralazine, should be avoided.

Once the BP is reduced below 180/110 mm Hg, thrombolytic therapy can be considered if evidence of ongoing ST-elevation myocardial infarction persists⁶¹ and primary angioplasty is not readily available. Risk of bleeding is increased in patients who are very hypertensive acutely, particularly if they are ordinarily normotensive.

Renal Insufficiency

Acute renal insufficiency may be either a cause of severe hypertension, as in renal parenchymal disease, acute glomerulonephritis, vasculitis, or renal artery stenosis, or a consequence of

Figure 28-3. Guidelines suggested by the American Heart Association for treating hypertension in patients with intracerebral hemorrhage. BP, blood pressure; CPP, cerebral perfusion pressure; ICP, intracranial pressure; IV, intravenous; MAP, mean arterial pressure; SBP, systolic blood pressure.

severe BP elevation.⁶ Patients having severe hypertension and microscopic hematuria or acutely worsened renal function should be diagnosed as a hypertensive emergency. A urinalysis and measurement of serum creatinine should be performed in these patients and the latter compared with recent values to establish whether the deterioration in renal function is acute.⁵ In patients with kidney transplants, additional causes of severe elevations in BP include stenosis of the graft site, the use of cyclosporine, corticosteroids, or both, and excessive secretion of renin by the native kidney.⁶² A renal sonogram should be obtained in all patients with acute renal insufficiency to evaluate kidney size and to rule out obstructive uropathy because obstruction of the urinary tract at any level, including the bladder outlet, can raise BP. In patients with severe hypertension and renal insufficiency, the goal of medical therapy is to reduce BP without compromising renal blood flow. High-dose loop diuretic treatment may be necessary to maintain urine flow. Sodium nitroprusside is cost-effective in controlling BP in this setting, but the risk of cyanide and thiocyanate toxicity is increased. Fenoldopam is an attractive alternative in renally impaired patients.^{63,64} Calcium channel blockers are effective and well tolerated, particularly in renal transplant recipients.⁶⁵ β -blockers reduce blood flow and glomerular filtration rate and should be avoided. ACE inhibitors and angiotensin receptor blockers may be effective but can be hazardous, precipitating hypotension or worsening renal function.

Preeclampsia or Eclampsia

Hypertension in pregnant women is defined as SBP =140 mm Hg and/or DBP = 90 mm Hg after 20 weeks of gestation in a woman with previously normal BP.⁶⁶ Preeclampsia is a syndrome characterized by hypertension and proteinuria (urinary protein excretion of 300 mg/24 hr) and may be associated with visual disturbances, headache, and epigastric pain. Seizures indicate progression to eclampsia. It is more common in nulliparous women, multiple gestations, women with hypertension for

4 years, family history of preeclampsia, hypertension in previous pregnancy, and women with renal disease.

Preeclampsia is caused by impaired placentation of the trophoblast and incomplete vascular remodeling. This failure of vascular invasion compromises blood flow to the maternal-fetal interface and reduces placental perfusion, causing systemic hemodynamic changes through activation of soluble fms-like tyrosine kinase 1 (sFlt1) and soluble endoglin (sEng) (Fig. 28-4). The clinical manifestation of preeclampsia is due to systemic maternal endothelial cell dysfunction, resulting in reduced organ perfusion caused by vasospasm, activation of the coagulation cascade, and loss of vascular integrity.⁶⁷ sFlt1 is a potent antagonist of VEGF (vascular endothelial growth factor) and placental growth factor (PlGF), a related proangiogenic protein.⁶⁸ Glomerular endotheliosis, the classic renal lesion in preeclampsia, is a consequence of suppressed levels of VEGF. VEGF also induces nitric oxide and prostacyclin release by endothelial cells, favoring vasodilation. The functional significance of overexpression of sEng and sFlt1 has been demonstrated in a rodent model: pregnant rats expressing high levels of these proteins develop nephrotic-range proteinuria, severe hypertension, biochemical evidence of HELLP syndrome (elevated lactate dehydrogenases [LDH] and aspartate aminotransferase [AST], low platelets) and intrauterine growth restriction.⁶⁹ Histology reveals severe glomerular endotheliosis in the kidney, infarction in the placenta, areas of necrosis in the liver, and schistocytes in the peripheral blood.

Decreased levels of urinary PlGF during midgestation predict subsequent development of clinical preeclampsia and endoglin levels are most elevated in women who develop preterm preeclampsia and preeclamptic pregnancies with small-for-gestational-age infants.⁶⁸

Definitive treatment of preeclampsia and eclampsia is delivery of the placenta. However, the decision to deliver a patient with preeclampsia must balance both the maternal and fetal risks.⁷⁰ The patient with eclampsia requires prompt intervention.

Figure 28-4. Pathophysiology of preeclampsia. (Adapted from Noris M, Perico N, Remuzzi G: *Mechanisms of disease: pre-eclampsia*. *Nat Clin Pract Nephrol* 2005;1:98-114.)

Temporizing measures for preeclampsia include bed rest, hydration, and magnesium sulfate administration to reduce central nervous system irritability. If delivery is imminent, acute treatment of hypertension is required for DBP of 105 to 110 mm Hg or higher. The DBP goal is 95 to 105 mm Hg (Table 28-7).^{70,71} Hydralazine is considered the first-line agent. Labetalol is considered second line and nifedipine use is controversial. However, a meta-analysis of randomized trials reported greater maternal and fetal complication rates with hydralazine compared with labetalol or nifedipine.⁷² Thus the choice of antihypertensive agent is somewhat controversial. Nitroprusside can be used when other agents fail, but generally should be avoided because of potential risk of fatal cyanide poisoning. If delivery is likely to be delayed for more than 48 hours, an oral agent such as methyldopa or labetalol is required. Women who develop preeclampsia are at increased risk of long-term cardiovascular complications, such as coronary heart disease, stroke, and cardiovascular disease in general.⁷³

Postoperative Hypertension

Postoperative hypertension is common, particularly following vascular surgical procedures. It is reported in upward of 30% to 50% of patients following coronary artery bypass graft surgery.⁷⁴ Complications of postoperative hypertension include bleeding from suture sites, myocardial infarction, and stroke. Postoperative hypertension is characterized by increased sympathetic tone and a high systemic vascular resistance. BP in this setting is generally easily controlled with a number of easily titratable agents, including nitroprusside, labetalol, and nicardipine. Nitroglycerin is also effective and is preferable when coronary ischemia is suspected. Nicardipine and isradipine have been evaluated in clinical trials and have been reported to safely and effectively reduce BP after cardiac and noncardiac surgery.⁷⁵⁻⁷⁷

Table 28-7. Treatment of Hypertension in Preeclampsia

Hydralazine	5 mg IV bolus, then 10 mg every 20 to 30 min to a maximum of 25 mg, repeat in several hours as necessary
Labetalol (second line)	20 mg IV bolus, then 40 mg 10 min later, 80 mg every 10 min for two additional doses to a maximum of 220 mg
Nifedipine (controversial)	10 mg PO, repeat every 20 min to a maximum of 30 mg. Caution when using nifedipine with magnesium sulfate; can see precipitous BP drop. Short-acting nifedipine is not approved by FDA for managing hypertension.
Sodium nitroprusside (used rarely, when others fail)	Fetal cyanide poisoning may occur if used for more than 4 hr.

Hyperadrenergic States

Severe BP elevation can be caused by hyperadrenergic states, including cocaine overdose (which can be complicated by drug-induced seizures, stroke, myocardial infarction, or encephalopathy),⁷⁸ clonidine or β -blocker withdrawal, monoamine oxidase inhibitor crisis, and pheochromocytoma.⁶ Cocaine is a sympathomimetic agent that blocks the presynaptic reuptake of norepinephrine and dopamine, resulting in an excess of these neurotransmitters at postsynaptic receptor sites. This leads to sympathomimetic effects, including tachycardia, hypertension, mydriasis, and hyperthermia. Cocaine can also release norepinephrine stores in sympathetic nerve terminals and stimulate the release of catecholamines from the adrenals. Patients with cocaine-associated myocardial infarction should be treated with aspirin, nitrates, and benzodiazepines.⁷⁹ Hypertension and vasospasm related to cocaine toxicity can be treated with benzodiazepines alone or combined with calcium channel blockers or the α -adrenergic antagonists labetalol and phentolamine. Nitroprusside can be used for severe hypertension. β -adrenergic receptor antagonists should be avoided due to the potential of aggravating the hypertension as a result of unopposed α -adrenergic stimulation.^{79,80}

Other sympathomimetic drugs, such as amphetamines, phencyclidine hydrochloride (PCP), lysergic acid diethylamide (LSD), and diet pills may also precipitate hypertensive crisis. Adrenergic antagonists such as phentolamine and labetalol are also effective in this setting.⁸⁰ Nitroprusside can be used alternatively or in refractory cases.

Pheochromocytoma is a rare but dangerous catecholamine-producing neuroendocrine tumor originated from chromaffin cells of the adrenal medulla or extra-adrenal paraganglia. Catecholamine excess can cause severe hypertension, headache, inappropriate sweating, and palpitations in patients with pheochromocytoma. Hypertensive crisis can be precipitated by stress related to stimuli, such as surgery or trauma in these patients. Thus failure to diagnose pheochromocytoma can be fatal for

Table 28-8. Parenteral Drugs for Treatment of Hypertensive Emergency

Drug	Dosing (Intravenous)	Onset of Action	Duration of Action	Adverse Effects
Nitroprusside	0.25-10 µg/kg/min; increase by 5-10 µg/kg/min q5-10 min	Immediate	2-3 min	Hypotension, nausea, vomiting, cyanide and thiocyanate toxicity
Nitroglycerin	5-100 µg/min; increase q3-5 min	2-5 min	5-10 min	Hypotension, headache, nausea, vomiting
Labetalol	20-80 mg as IV bolus every 10 min; up to 2 mg/min continuous infusion	5-10 min	3-6 hr	Hypotension, heart block, bronchospasm, nausea, flushing, headache, scalp tingling
Nicardipine	5-15 mg/hr; increase by 1-2.5 mg/hr q15 min	5-10 min	1-4 hr	Increase in heart rate, headache, nausea, vomiting
Phentolamine	2-5 mg q5-10 min	1-2 min	3-10 min	Hypotension, tachycardia, angina, headache, nausea, vomiting
Esmolol	200-500 µg/kg loading dose over 1 min, then 50 µg/kg for 4 min, then increase dose by 50 µg/kg q5 min up to 200 µg/kg/min	1-2 min	10 min	Hypotension, nausea, heart block, heart failure, apnea, bronchospasm, dry mouth
Enalaprilat	0.625-1.255 mg q6h	15 min	6 hr	Hypotension, angioedema, rash
Hydralazine	10-20 mg as IV bolus or 10-40 mg IM, repeat every 4-6 hr	10-20 min	3-8 hr	Tachycardia, angina, worsening aortic dissection, fluid retention, headache, nausea, flushing, rash, dizziness
Fenoldopam	0.1-0.6 mg/kg/min	5-10 min	10-15 min	Headache, dizziness, reflex tachycardia, excessive hypotension, flushing

patients undergoing surgical procedures or in pregnant women. The diagnosis can be made by measurement of plasma and 24-hour urine metanephrines. Free plasma metanephrines is the best screening test due to its high sensitivity (99%) and should be performed when pheochromocytoma is suspected.^{81,82} Patients with pheochromocytoma who have very severe hypertension can be treated with intravenous administration of sodium nitroprusside, nitroglycerin, labetalol, or phentolamine to control BP in preparation for surgery.^{82,83} Surgical removal of the tumor is the definitive treatment.

Specific Therapeutic Considerations

Sodium Nitroprusside

Sodium nitroprusside is the most widely recommended and used antihypertensive agent for treatment of hypertensive crisis (Table 28-8). Its rapid onset of action and short half-life allow for minute-by-minute titration of BP, and it is efficacious and generally safe.⁸⁴ However, potentially life-threatening side effects can occur with nitroprusside use. A clear understanding of the mechanism of action of nitroprusside is essential to appreciating these risks.

Nitroprusside consists of a ferrous core, five cyanide groups, and a nitrosyl group (Fig. 28-5). Sulfhydryl groups in the cell walls of vascular smooth muscle donate electrons to the ferrous group in nitroprusside, destabilizing it and causing it to break up into cyanide and NO, the active component of nitroprusside. NO is a free radical that activates guanylate cyclase, causing levels of cyclic guanosine monophosphate to increase in smooth muscle cells. Cyclic guanosine monophosphate inhibits calcium influx, causing venous and arterial smooth muscle relaxation. Venous dilation results in increased venous capacitance, peripheral pooling of blood, and consequent preload reduction. Arterial

**Figure 28-5.** Structural formula of nitroprusside.

dilation results in decreased systemic vascular resistance and lowers arterial BP. NO dilates coronary arteries, resulting in increased myocardial perfusion. However, in the setting of fixed coronary obstruction, blood flow can be redirected from ischemic areas, a phenomenon known as “coronary steal.” When this occurs, nitroprusside therapy can worsen myocardial ischemia.

The most common adverse effect of nitroprusside is hypotension. Nitroprusside is potent and has a rapid onset of action that allows for rapid and precise modulation of BP but also, if used injudiciously, predisposes to potentially catastrophic hypotension. Continuous monitoring of BP, preferably with an arterial line, is obligatory during nitroprusside infusion. If hypotension does occur, the nitroprusside infusion should be discontinued immediately. BP will generally return to pretreatment levels in 1 to 10 minutes.

Cyanide Toxicity

Cyanide, when released from nitroprusside, first binds all available methemoglobin in the circulation.⁸⁵ After saturating methemoglobin, cyanide binds the sulfhydryl group of endogenous

Table 28–9. Signs and Symptoms of Cyanide Toxicity

Central Nervous System
• Headache • Anxiety • Disorientation • Lethargy • Seizures • Coma
Cardiovascular
• Hypertension (tachyphylaxis) • Electrocardiographic changes • Tachycardia/bradycardia • ST-T wave changes • Dysrhythmias • Atrioventricular block
Oxygenation/pH
• Tachypnea • Venous hyperoxemia ◦ Red venous blood ◦ Increased mixed venous O₂ content (SVO₂) ◦ Decreased O₂ consumption (VO₂) ◦ Narrow arteriovenous oxygen difference (AVO₂ difference) ◦ Brick-red skin (occasional cyanosis) • Metabolic acidosis ◦ Elevated blood lactate or elevated lactate/pyruvate ratio
Other
• Nausea, vomiting, abdominal pain • Increased salivation

thiosulfate in the liver to form thiocyanate, which is excreted by the kidney. A normal adult generally has sufficient thiosulfate stores to combine with 50 mg or one vial of nitroprusside. In the absence of renal dysfunction, the normal elimination half-life of thiocyanate is approximately 2.7 days.

Once all available methemoglobin is saturated and all stores of thiosulfate are depleted, free cyanide begins to accumulate in blood and tissues and binds the ferric moiety of cytochrome oxidase, inactivating it. Cytochrome oxidase is an essential enzyme in the oxidative phosphorylation process, forming adenosine triphosphate. With cytochrome oxidase inactivated, tissue anoxia, anaerobic metabolism, and lactic acid formation ensue. In addition, inactivation of oxidative phosphorylation, ordinarily an important buffer, leads to worsening metabolic acidosis.

Symptoms and signs of cyanide toxicity (Table 28-9) reflect central nervous system deterioration, cardiovascular instability, and alteration of oxygenation and pH. An early indication of impending toxicity is tachyphylaxis (i.e., requiring larger and larger doses of nitroprusside to maintain BP control). Acidosis often occurs late in the course of cyanide toxicity; its absence does not preclude cyanide accumulation and the development of toxicity. Cyanide levels should be followed to forewarn of subclinical toxicity, but waiting for results should not delay confirmation of the diagnosis (Table 28-10). If cyanide

Table 28–10. Cyanide Levels and Associated Symptoms

Level	Symptoms
<0.05 µg/mL	None
>0.15 µg/mL	Headache, palpitations, tachypnea
>0.25 µg/mL	Seizures, acidosis, coma
>0.3 µg/mL	Death

toxicity is suspected, the nitroprusside infusion should be stopped immediately. The patient should be placed on 100% oxygen even in the absence of signs of hypoxia and even if arterial partial pressure of oxygen is normal because tissue oxygenation may be inadequate.

Current dosing recommendations for nitroprusside are 0.25 to 10 µg/kg/min. The duration of infusion at the maximal rate should not exceed 10 minutes. Cyanide accumulation can occur if more than 1.5 mg/kg of nitroprusside is given over 3 to 4 hours, and potentially lethal toxicity can occur if 5 to 10 mg/kg/min of nitroprusside is given over 5 to 10 hours. However, individual differences do exist, and toxicity can occur very quickly, even when nitroprusside is dosed per recommendations. Malnutrition, stress, and volume depletion tend to deplete thiosulfate stores, accelerating the accumulation of cyanide.

In cases of nitroprusside toxicity, the Lilly Cyanide Antidote Kit (Eli Lilly, Indianapolis), which contains sodium nitrite, amyl nitrite, and thiosulfate, should be used. The sodium nitrite should be given first: one 10 mL vial of 3% sodium nitrite administered intravenously over 2 to 4 minutes. If intravenous access is not available, the amyl nitrite should be given orally. Both sodium nitrite and amyl nitrite induce methemoglobinemia, providing a source of iron to which the cyanide can bind. The thiosulfate (12.5 g vial given intravenously over 2 to 4 minutes) should be administered second. Thiosulfate acts as a sulfur donor, facilitating conversion of cyanide to thiocyanate. If symptoms of thiocyanate toxicity persist 2 hours after the initial dosing of thiosulfate, half of the original dose can be readministered.

Thiocyanate Toxicity

As discussed earlier, thiocyanate is formed from the binding of cyanide and thiosulfate. Thiocyanate is 100-fold less toxic than cyanide and is excreted by the kidney with an approximate elimination half-life of 2.7 days. Renal insufficiency prolongs elimination. Symptoms of thiocyanate toxicity are primarily neurologic. In persons with normal renal function, toxicity is unlikely before 9 days of nitroprusside infusion, whereas in persons with renal dysfunction, thiocyanate toxicity can occur as early as 3 days after initiation of infusion. Thiocyanate can be removed by dialysis, but this is rarely necessary.⁸⁶

Nitroglycerin

At low doses (5 µg/min), intravenous nitroglycerin predominantly dilates venous capacitance vessels, reducing venous return to the heart, whereas at higher doses both venous and arterial dilation occur. The overall hemodynamic effect of nitroglycerin is to decrease myocardial oxygen demand while increasing myocardial oxygen supply. Myocardial oxygen demand is decreased by decreasing preload and afterload, and myocardial oxygen supply is increased by improving myocardial perfusion

primarily through dilation of coronary arteries. BP is reduced as a consequence of arterial dilation.

Because of its favorable effects on myocardial oxygenation, intravenous nitroglycerin is the agent of choice for treatment of hypertensive crisis complicated by myocardial ischemia or infarction.⁸⁷ It can also be used as an alternative to nitroprusside to reduce afterload for treatment of pulmonary edema and postoperative hypertension.⁸⁸ Prolonged intravenous use of nitroglycerin can induce tolerance but is not associated with toxicity.⁸⁸ Nitroglycerin and nitroprusside are both effective in most patients with hypertensive emergency,⁸⁸ but nitroprusside appears to be more universally effective.⁸⁹ Therefore, in the setting of severe BP elevation, nitroprusside is the drug of choice for most hypertensive emergencies. Nitroglycerin tends to increase intracranial pressure, so it should not be used to treat hypertensive encephalopathy, stroke, or subarachnoid or intracerebral hemorrhage.

Labetalol

Labetalol is a nonselective β -antagonist with some α_1 -antagonist activity.⁹⁰ The ratio of β - to α -blockade is approximately 7:1. BP is reduced primarily through decreases in peripheral vascular resistance, whereas cardiac output is preserved and heart rate is maintained or slightly reduced owing to blockade of reflex tachycardia.

Labetalol is used preferentially in cases in which mixed adrenergic antagonism is desirable, including treatment of aortic dissection, and in situations of catecholamine excess, such as pheochromocytoma, rebound hypertension secondary to clonidine withdrawal, and crack cocaine overdose.⁹¹ Labetalol is also widely used as the primary alternative to nitroprusside for treatment of other types of hypertensive crisis. Because of its β -blocking properties, labetalol is contraindicated in patients with decompensated heart failure, reactive airway disease, and heart block.

Nicardipine

Nicardipine, a dihydropyridine calcium antagonist, has been approved for intravenous treatment of severe BP elevation.^{75,92} Intravenous nicardipine effectively lowers BP with minimal adverse effects, making it a reasonable first-line agent for most types of hypertensive crisis. It is particularly effective in treatment of postoperative hypertension.⁷⁵ By inhibiting the transmembrane influx of calcium ions, nicardipine facilitates the relaxation of cardiac and smooth muscle cells. The predominant effect is on arterial smooth muscle cells, causing reductions in systemic vascular resistance, afterload, and arterial BP. Cardiac output increases with little effect on left ventricular end-diastolic pressure. Nicardipine induces coronary artery dilation, thereby improving myocardial perfusion, but it also increases heart rate, thus tending to increase myocardial work and oxygen demand. Given this tendency and the overall worse outcome of patients receiving dihydropyridine calcium antagonists in the setting of acute myocardial infarction, it seems prudent to avoid the use of nicardipine to treat hypertensive crisis complicated by myocardial ischemia or infarction.

Phentolamine

Phentolamine is a competitive α -adrenergic receptor antagonist with greater affinity for the α_1 - than the α_2 -receptor subtype. Systemic vascular resistance is decreased, whereas heart rate,

cardiac output, and myocardial oxygen demand are increased during phentolamine administration.

Phentolamine is effective for treatment of severe hypertensive states associated with catecholamine excess, such as pheochromocytoma, clonidine withdrawal, and crack cocaine overdose. Adverse effects, including reflex tachycardia, fluid retention, and precipitous falls in BP, and its short duration of action, limit its use.⁷⁴ Because of associated increases in myocardial work and oxygen demand, phentolamine is contraindicated in situations of myocardial ischemia. A test dose of 0.5 to 1 mg infused over 1 minute is generally advised before starting a continuous infusion (see Table 28-3).⁷⁴

Esmolol

Esmolol is an intravenous ultra-short-acting β -adrenergic receptor antagonist that is used intraoperatively or postoperatively for short-term control of BP.⁹³ It should not be used in patients with second- or third-degree heart block, congestive heart failure, or a history of asthma. Esmolol selectively antagonizes the β_1 -adrenergic receptor. Like other β -blockers, it reduces heart rate and cardiac output through its negative inotropic properties without significantly affecting systemic vascular resistance.

Enalaprilat

Enalaprilat, an intravenous ACE inhibitor, is the active metabolite of orally administered enalapril.⁹⁴ Enalaprilat inhibits ACE, suppressing formation of angiotensin II, thus reducing systemic vascular resistance and arterial BP. As with other ACE inhibitors, the degree of BP reduction is directly related to circulating renin levels, such that persons with low renin levels may develop only minimal decreases in BP during enalapril treatment, whereas persons with high levels of renin, as in volume depletion secondary to diuretic treatment or dialysis, may experience precipitous hypotensive effects.⁹⁵ Intravenous enalaprilat is effective in conditions of severe hypertension complicated by high renin levels—in particular, scleroderma and other forms of renal vasculitis—but otherwise its efficacy is variable, precluding its general use in most hypertensive emergencies.

Hydralazine

Hydralazine is a direct arterial vasodilator that has little effect on venous capacitance, thus it preferentially relaxes arterial smooth muscle cells with little effect on veins. This reduces peripheral vascular resistance, afterload, and arterial BP with little or no change in preload or venous capacitance. The decrease in BP provokes a profound reflexive increase in sympathetic activity, causing reflex tachycardia and increased cardiac output, myocardial work, and myocardial oxygen demand. The increase in sympathetic activity also causes significant sodium and fluid retention, resulting in volume expansion.

The clinical use of hydralazine is limited by an associated reflexive increase in cardiac output and heart rate that increases myocardial oxygen demand, and by marked fluid retention. The only advantage of hydralazine is that it improves uterine blood flow and maintains fetal perfusion better than other antihypertensive agents and so is recommended for reduction of BP during preeclampsia or eclampsia.^{70-72,74} Hydralazine is specifically contraindicated in myocardial ischemia and aortic dissection because of its reflex increase in sympathetic nervous system

tone and myocardial inotropic activity. Hydralazine tends to increase intracranial pressure and should not be used to treat hypertensive crisis complicated by stroke or subarachnoid or intracerebral hemorrhage.

Fenoldopam

Fenoldopam is a selective dopamine-1 receptor agonist that effectively lowers BP while improving renal function.^{63,64,96} It provides selective vasodilation of renal, splanchnic, and coronary beds, and has specific benefits in patients with chronic kidney disease, providing short-term increases in natriuresis, diuresis, and creatinine clearance.^{64,65} Fenoldopam is approved for inpatient short-term management of severe hypertension. Headache, dizziness, reflex tachycardia, excessive hypotension, and flushing are reported side effects of fenoldopam.

Acute Aortic Syndromes: Diagnosis and Management

Peter C. Spittell

CHAPTER 29

Introduction Acute Aortic Dissection

Penetrating Aortic Ulcer Aortic Intramural Hematoma

Introduction

Acute thoracic aortic syndromes comprise a spectrum of medical and surgical emergencies, including acute aortic dissection, penetrating aortic ulcer, and aortic intramural hematoma. All of these conditions are potentially life-threatening and warrant prompt diagnosis and emergent management. The clinical presentation of acute aortic syndromes is highly variable, ranging from occult disease to classic clinical presentations. Numerous etiologic factors, acting singly and in combination, have been identified. Diagnosis is possible by noninvasive imaging in the majority of patients, but in some patients complementary noninvasive tests (transesophageal echocardiography [TEE], computed tomography [CT], and magnetic resonance imaging [MRI]) are required for diagnosis. The management of acute aortic syndromes continues to be a therapeutic challenge, while diverse surgical and percutaneous strategies for the treatment of aortic syndromes are continuously evolving. As a result of increasing knowledge and better management strategies in this area, the outcomes of patients treated for acute aortic syndromes have improved. Therefore, awareness of the clinical features of acute aortic syndromes and familiarity with currently available diagnostic techniques is basic to their effective treatment.

Acute Aortic Dissection

Acute dissection of the thoracic aorta is one of the most common catastrophic aortic conditions encountered in clinical practice. The incidence of aortic dissection has been reported to be approximately 2.9/100,000/yr.¹ The variable clinical presentations of aortic dissection, in combination with a mortality rate in untreated cases as high as 1% per hour during the first 48 hours after the onset of symptoms, underscore the importance of a high index of suspicion and prompt diagnosis and therapy.²⁻⁴ Noninvasive testing (TEE, CT, and MRI) allows an accurate diagnosis to be made in the majority of patients.⁵ Effective treatment exists so that future improvements in initial and long-term survival in acute aortic dissection depend on increased clinical awareness, rapid noninvasive diagnosis, and the early institution of appropriate medical and/or surgical therapy.

Pathogenesis

Aortic dissection originates at the site of an intimal tear in more than 95% of patients.^{2,6} The resultant intimal tear exposes the media to pulsatile aortic flow, creating a second or “false” aortic

lumen that then dissects in the outer layer of aortic media, propagating distally and, occasionally, proximally. One feature differentiating proximal and distal aortic dissection is the greater frequency of hypertension in patients with distal dissection, a possible factor in pathogenesis.⁷

The primary intimal tear is located, in decreasing order of frequency, in the ascending aorta 1 to 5 cm above the right or left sinus of Valsalva (65%), in the proximal descending thoracic aorta just beyond the left subclavian artery origin (20%), in the transverse aortic arch (10%), and more distally in the thoracic aorta or abdominal aorta (5%).^{2,6}

Once initiated, the dissection usually extends distally and, occasionally, proximally for a variable distance. As the dissecting process encounters branches of the aorta it may pass around their origins, extend into their walls, or occlude them.^{2,6} Reentry of the dissection through a second, more distal intimal tear may occur, usually in one of the iliac arteries. External rupture of the dissecting process into the pericardial space is the most common cause of death in aortic dissection; congestive heart failure, usually due to aortic regurgitation, is the second most common cause of death.

Predisposing Factors

Multiple risk factors for aortic dissection have been identified, the most common being advanced age, systemic hypertension, congenital abnormalities of the aortic valve, and heritable disorders of connective tissue.

Aortic dissection most frequently affects patients in the fifth to seventh decades of life (mean age 63 years) and is more common in men (65.3% male).⁸ In patients younger than 40 years, the incidence between men and women is equal due to the occurrence of aortic dissection in women during pregnancy, with approximately 50% of all aortic dissections occurring during the third trimester of pregnancy.⁹

Systemic hypertension is the most frequently encountered predisposing factor for aortic dissection, being present in more than 70% of patients.^{2,3,10-12} Hypertension may play a role in initiating the intramural hematoma along with having a direct weakening effect on the aortic media.^{6,12} The causative role of systemic hypertension is further supported by the finding that coarctation of the aorta predisposes to aortic dissection.¹³

Other major risk factors for aortic dissection, especially proximal aortic dissection, are congenitally bicuspid or unicommissural aortic valves,^{10,12} and the congenital disorders of connective tissue such as Marfan syndrome¹⁴ and Ehlers-Danlos

syndrome. Additional predisposing factors for acute aortic dissection include pre existing aortic aneurysm¹⁵ and a positive family history (as many as 19% of patients).

Iatrogenic aortic dissection is an uncommon but potentially serious complication of invasive angiographic procedures and cardiac surgery. Angiographic procedures such as coronary angiography, percutaneous transluminal coronary angioplasty, intra-aortic balloon insertion, and translumbar aortography have been complicated by aortic dissection.^{12,16-19} Catheter-induced dissection can originate at any location, and it is most common in the sinus of Valsalva, brachiocephalic arteries, descending thoracic aorta, abdominal aorta, and iliac or femoral arteries. The majority of catheter-induced dissections are retrograde dissections and tend to decrease in size over time due to thrombosis of the false lumen, whereas anterograde dissections tend to persist on follow-up. Nearly all iatrogenic aortic dissections can be treated medically with serial clinical examinations and noninvasive testing used to identify those in need of surgical therapy.¹⁷

Cardiac surgical procedures complicated by aortic dissection include those that require cross-clamp or cannulation of the ascending aorta, such as aortic valve replacement^{12,20,21,15} and/or coronary artery bypass grafting.^{12,22,23} Dissection can arise at the site of ascending aortic cannulation, aortosaphenous vein anastomosis, aortic cross-clamp, or as a result of direct arterial injury. Dissection in association with these procedures usually occurs intraoperatively and is promptly diagnosed and treated, but chronic dissection in the postoperative period has been reported.²¹

Aortic dissection has also been reported in association with inflammatory diseases (giant cell aortitis,^{12,24} Takayasu aortitis, rheumatoid arthritis, syphilitic aortitis, systemic lupus erythematosus,²⁵ Noonan syndrome,²⁶ Turner syndrome,²⁷ fibromuscular dysplasia,¹¹ annuloaortic ectasia,¹¹ aortic coarctation, cocaine use,^{28,29} methamphetamine use, polycystic kidney disease,³⁰ polyarteritis nodosa,³¹ trauma,³² high-intensity weight lifting.³³

Classification

There are two different anatomic systems—the DeBakey and Daily (Stanford) systems—used to classify aortic dissection. The DeBakey system³⁴ is based on the site of origin of the dissection and recognizes three types of dissection (Fig. 29-1): type I—the dissection arises in the ascending aorta and extends distally; type II—the dissection is limited to the ascending aorta; and type III—the dissection arises at or just distal to the origin of the left subclavian artery and extends distally or, rarely, retrogradely into the arch of the ascending aorta.

For clinical purposes, because types I and II have a similar prognosis, aortic dissection can be broadly divided into those with the tear in the ascending aorta and those with the tear in the descending aorta, also called “proximal” and “distal,” respectively.³⁵ A similar classification system, proposed by Daily and associates,³⁶ designates all dissections involving the ascending aorta as type A, regardless of the site of the primary intimal tear. All other dissections are designated type B.

An important aspect of classification is the duration of the dissection at the time of first presentation. Dissections are categorized as “acute” if the diagnosis is made within 2 weeks of symptom onset and as “chronic” if more than 2 weeks have elapsed. The distinction is important due to the fact that

Figure 29-1. Classification of aortic dissection. Type I refers to a primary tear in the ascending aorta and dissection involving the aortic arch and descending thoracic aorta for a variable distance. Type II refers to dissection involving only the ascending aorta. Type III refers to a primary tear distal to the subclavian artery origin, extending distally for a variable distance. (Modified from DeBakey ME, Henly WS, Cooley DA, et al: *Surgical management of dissecting aneurysms of the aorta*. *J Thorac Cardiovasc Surg* 1965;49:130-149.)

approximately 65% to 75% of patients with untreated aortic dissection die in the first 2 weeks after the onset of symptoms.²

Intimal tear without hematoma is an uncommon variant of aortic dissection characterized by a localized intimal tear exposing the underlying media or adventitial layers to pulsatile aortic flow. There is no progression or separation of the medial layers.³⁷

Clinical Features

Due to variable involvement of the aorta and its branches by the dissecting process, the patient with acute aortic dissection may have clinical manifestations of ischemia of various organ systems, singly or in combination, and symptoms and signs of cardiac disease. The diverse presentations of aortic dissection can provide for difficult diagnosis, and misdiagnosis commonly occurs.^{2,12} Despite major advances in the noninvasive diagnosis of aortic dissection and in medical and surgical therapy, up to 55% of patients in reported series die without a correct antemortem diagnosis.^{1,2,12,38,39} For these reasons, a high index of clinical suspicion for acute aortic dissection in any likely setting is imperative.

The classic presentation of a patient with acute aortic dissection, occurring in more than 70% of patients, is the sudden onset of severe pain, usually beginning in the anterior chest, radiating to the back, and moving distally as the dissection progresses.^{1,35} The pain is most commonly described as sudden in onset with a “ripping,” “tearing,” or “stabbing” quality; this is in contrast to the crescendo nature of the discomfort of acute myocardial infarction. Chest pain is significantly more common in patients with proximal (type A, type I, and type II) dissection (79% versus 63% in distal [type B, type III] dissection). In contrast, both back pain (64% versus 47%) and abdominal pain (43% versus 22%) are significantly more common with distal (type B) aortic dissection.⁸

Patients with acute aortic dissection often appear to be in shock, although blood pressure is elevated in one half to two thirds of cases, especially with distal dissection.⁸ Hypotension in aortic dissection is usually attributable to rupture of the dissection into the pericardial space with resultant cardiac tamponade or, less commonly, the pleural space or mediastinum and is more common with proximal dissection.

It should be remembered, however, that painless dissection occurs in 14% to 21% of patients.^{2,12,40} Patients with painless aortic dissection tend to be slightly older, have a prior history of diabetes, aortic aneurysm, or prior cardiac surgery, and more often have type A dissection. Syncope, congestive heart failure, or stroke are also more common in this group. Importantly, in-hospital mortality was significantly higher than for patients having pain (33% versus 23%).⁸

A cardiac murmur may be present, usually at the cardiac base, and may be systolic, diastolic, or both. A diastolic decrescendo murmur of aortic regurgitation indicates involvement of the ascending aorta and is heard in one half to two thirds of patients with type A aortic dissection.⁸ Congestive heart failure, when present in association with proximal aortic dissection, is most often due to severe aortic regurgitation,^{10,35} but cases of congestive heart failure due to rupture of the dissecting process into the right or left atrium or right ventricle have also been reported.⁴¹⁻⁴³ Myocardial infarction, most commonly inferior infarction, occurs in 1% to 2% of patients and is due to compromise of the coronary ostium by a hematoma or intimal flap. Peripheral pulse deficits are noted in 19% to 30% of patients,^{3,8,35} more commonly with proximal aortic dissection, and is associated with a higher rate of in-hospital complications and mortality.⁴⁴ Pulse deficits may be transitory due to oscillation of the intimal flap or distal reentry of the hematoma into the true lumen. Acute lower extremity ischemia, with or without chest pain, as a result of dissection extending into the iliac arteries occurs in 6% to 12% of patients,^{3,45,46} and may provide an important clue to the diagnosis.⁴⁵ Other cardiovascular findings include a difference in systolic blood pressure between the arms (>20 mm Hg), tachycardia, friction rubs, bruits, pulsus paradoxus, and cardiac tamponade.

Syncope in a patient with aortic dissection is an important event as it is associated with a worse prognosis. Syncope most commonly results from rupture of the dissecting process into the pericardial space producing cardiac tamponade.^{12,35} Less commonly, rupture occurs into the left pleural space producing a left hemothorax.¹² Neurologic deficits, including cerebrovascular accident, disturbances of consciousness, ischemic paraparesis, and ischemic peripheral neuropathy, occur in more than 40% of patients, more commonly with proximal aortic dissection.^{1,47}

Other less frequent findings that occur in association with acute aortic dissection include Horner syndrome, a pulsatile sternoclavicular joint,⁴⁸ vocal cord paralysis, hemoptysis,⁴⁹ superior vena cava syndrome,⁵⁰ upper airway obstruction,⁵¹ hematemesis,⁵² pleural effusion, unilateral pulmonary edema,⁵³ signs of mesenteric or renal infarction, fever,⁵⁴ and deep venous thrombosis.¹²

As a general rule, aortic dissection should always be considered in the differential diagnosis of a patient with unexplained syncope, stroke, congestive heart failure, acute arterial occlusion, or an abnormal aortic contour on chest radiography, even in the absence of chest pain.

Diagnosis

Aortic dissection is usually suspected from the initial history and physical examination. The majority of patients with aortic dissection can be identified based upon some combination of three clinical factors: (1) sudden onset of chest or abdominal pain with a sharp, tearing, and/or ripping character; (2) mediastinal and/or aortic widening on chest radiograph; (3) a pulse variation (absence of a proximal extremity or carotid pulse) and/or blood pressure (>20 mm Hg difference between the arms).⁵⁵ The incidence of aortic dissection was 83% when a pulse or blood pressure differential or any combination of the three variables occurred.

Routine laboratory studies are nonspecific and play a minor role in the initial assessment of patients with suspected acute aortic dissection. Their main value lies in the exclusion of other diseases. A mild to moderate leukocytosis occurs in two thirds of patients, and anemia may occur as a result of leakage of the dissection or from sequestration of blood in the false lumen. Serum lactate dehydrogenase and bilirubin levels are sometimes increased because of blood sequestered within the false lumen, but serum glutamic oxaloacetic transaminase and creatine phosphokinase are usually normal.³⁵ Hematologic studies consistent with disseminated intravascular coagulation can also occur. In one small study, D-dimer was positive in all patients with proximal aortic dissection, suggesting a negative test makes the presence of disease unlikely.⁵⁶

The most common electrocardiographic abnormality in patients with aortic dissection is left ventricular hypertrophy from chronic systemic hypertension.³ Acute electrocardiographic changes occur in up to 55% of patients and include ST segment depression, T-wave changes, and ST segment elevation, in decreasing order of frequency.⁵⁷ Acute ischemic changes can occur when one or both coronary ostia become obstructed, either by the intimal flap or from external compression by the dissecting hematoma. The electrocardiographic changes of acute pericarditis may be seen if there has been leakage of blood into the pericardial space. Heart block resulting from proximal extension of the hematoma into the area of the atrioventricular node has also been reported.⁵⁸ The chief value of the electrocardiogram is in distinguishing aortic dissection from acute myocardial infarction, although the two conditions can coexist.

Chest radiography may be helpful in suggesting the diagnosis of aortic, with abnormalities of the aortic dissection silhouette being the most common finding.^{8,59} Additional findings include pleural effusion, mediastinal widening, displacement of intimal calcification greater than 6 mm inside the outer edge of the aortic shadow, and the radiographic findings of congestive heart failure (Fig. 29-2). Nonetheless, it is important to remember that normal chest radiographic findings (present in 11% to 16% of patients) do not exclude the diagnosis of aortic dissection.⁸

Currently available noninvasive imaging modalities that are accurate in the diagnosis of acute aortic dissection include echocardiography (combined transthoracic echocardiography [TTE] and TEE), CT, and MRI. The choice of test depends on which imaging modality is most readily available at a particular institution and the hemodynamic stability of the patient. Most patients have multiple imaging studies performed; in the initial IRAD review, the initial study performed was CT in 61%, echocardiography in 33%, aortography in 4%, and MRI in only 2%.⁸

TTE can be very useful in some patients with suspected aortic dissection (Fig. 29-3). When the findings of a dilated aortic root

Figure 29-2. Chest radiographs in a patient with aortic dissection. **A**, Baseline anteroposterior chest radiograph before presentation with aortic dissection. **B**, Chest radiograph 1 year later when the patient presented with acute aortic dissection. Note the increased diameter of the ascending aorta and aortic arch and new widening of the superior mediastinum.

Figure 29-3. Transthoracic echocardiogram (left parasternal long-axis view) shows severe dilation of the ascending aorta and an intimal flap originating in the right coronary sinus of Valsalva (arrow).

(end-diastolic diameter >42 mm), widening of the aortic walls (16 to 20 mm for the anterior wall and 10 to 13 mm for the posterior wall), and a linear undulating echo representing the intimal flap are present, the positive predictive value for TTE is 100%.⁶⁰⁻⁶² Advantages of TTE are its portability, rapid “online” diagnosis, and ability to identify associated aortic regurgitation and other valvular disease, and to assess left ventricular function, regional wall motion abnormalities, pericardial effusion, and cardiac tamponade. The diagnosis of cardiac tamponade in a patient suspected of having aortic dissection deserves special mention. Echocardiographically guided pericardiocentesis should be avoided in this setting because the rapid withdrawal of pericardial fluid can result in a prompt improvement in left ventricular systolic function, left ventricular dp/dt , and systolic blood pressure, producing aortic rupture.^{63,64} The patient with aortic dissection complicated by cardiac tamponade should be taken emergently to surgery for institution of cardiopulmonary bypass followed by evacuation of blood from the pericardial space. Disadvantages of TTE limiting its utility in the diagnosis

of aortic dissection include difficulty in adequately visualizing the descending thoracic aorta,⁵ and in patients with suboptimal echocardiographic “windows” due to obesity or chronic obstructive pulmonary disease. Overall, the sensitivity and specificity of TTE are inferior to TEE, CT, and MRI in the diagnosis of aortic dissection.⁶

Multiplane TEE, in combination with TTE, has a sensitivity of 99% and a specificity of 98% in the diagnosis of aortic dissection.⁶⁵ TEE is portable, minimally invasive, and can accurately determine the type and extent of dissection safely in an emergent setting, allowing rapid triage of patients to either surgical or medical therapy^{66,67} (Fig. 29-4). Color flow Doppler imaging significantly improves the sensitivity of TEE by allowing visualization of the intimal flap, dissection entry site, the true and false lumens, the presence of thrombus, associated aortic regurgitation, and the proximal coronary arteries⁶⁷ (see Fig. 29-2). In addition, multiplane TEE provides a comprehensive assessment of left ventricular systolic function, regional wall motion, pericardial effusion, and cardiac tamponade. The overall sensitivity of TEE is comparable with CT,⁶⁸ MRI,^{5,69,70,71} and aortography⁷² in the diagnosis of aortic dissection. Current multiplane TEE probes have largely overcome impediments in the ascending aorta having monoplane and biplane transducers, although artifacts in this region continue to be a diagnostic challenge.

CT with intravenous iodinated contrast enhancement is also an accurate noninvasive screening test in patients with suspected aortic dissection.⁷³ Advantages of CT include ready availability at most hospitals, even on an emergency basis, and improved accuracy with spiral (helical) CT and with electron beam (ultrafast) or multidetector (multislice) CT.⁷⁴ CT can reliably demonstrate the intimal flap, pericardial and pleural effusion, associated mediastinal hemorrhage, and involvement of the aortic arch vessels and branches of the abdominal aorta⁵ (Fig. 29-5). Disadvantages of CT include the need for iodinated contrast exposure and nonportability, limiting its use in patients with significant renal insufficiency and in hemodynamically unstable patients, respectively. In addition, the site of entry is rarely identified.

Although less commonly used,⁸ MRI is a highly accurate noninvasive technique in the evaluation of patients with suspected aortic dissection.⁷⁵ MRI is superior to TEE and CT in detecting

Figure 29-4. Transesophageal echocardiogram (125 degrees longitudinal plane) shows an intimal flap (*arrow*) in a markedly dilated ascending aorta.

Figure 29-5. CT scan in a patient with type A aortic dissection. Note the complex intimal flap seen within the distal ascending aorta and descending thoracic aorta (*arrows*), and differential opacification of the true and false lumens.

arch vessel involvement and in identifying the anastomosis in patients managed with surgical therapy and may facilitate comparison of serial studies.^{5,69,76} Gated spin-echo MRI accurately demonstrates the entry site and intimal flap,⁷⁷ and may be the optimal method for demonstrating thrombus formation and entry site location within all segments of the aorta⁷⁸ (Fig. 29-6). The ability to obtain oblique and longitudinal planes of section makes MRI especially valuable in demonstrating dissection without intimal tear.^{5,70,79} Disadvantages of MRI include cost, examination time, reduced availability, and standard contraindications to MRI. The most important limitation of MRI in acute aortic dissection is its nonportability, limiting its use in hemodynamically unstable patients.

Of the definitive noninvasive imaging modalities in suspected acute aortic dissection (TEE, CT, MRI), a systematic review of the diagnostic accuracy of these imaging techniques has demonstrated a pooled sensitivity (98% to 100%) and specificity (95% to 98%) that is comparable between the three imaging techniques.⁷¹

Figure 29-6. MRI in the sagittal plane shows type A aortic dissection with an intimal flap extending into the distal abdominal aorta (*arrow*).

Aortography, the traditional definitive diagnostic method in aortic dissection, is able to localize the site of origin of the dissection, delineate the extent of the dissection, and the circulation to vital organs. Diagnostic aortographic features include opacification of the false lumen, deformity of the true lumen by the false lumen, widening of the aorta, narrowing or occlusion of branches of the aorta, and the presence of an intimal flap⁸⁰ (Fig. 29-7). Disadvantages of aortography include nonportability, invasive technique, exposure to ionizing radiation, the use of intravenous iodinated contrast agents, and an inherent delay in diagnosis. False-negative aortogram results can occur if there is simultaneous and equal opacification of the true and false lumina or if the false channel is very faintly opacified.⁸¹ For these reasons, aortography has generally been replaced by noninvasive imaging tests in the diagnosis of acute aortic dissection. Intravascular ultrasound, in combination with standard aortographic technique, greatly improves the accuracy of aortography, can be performed rapidly and safely, and could serve as an accessory diagnostic procedure in selected patients with suspected aortic dissection.^{82,83}

In view of the increased early mortality of untreated acute aortic dissection, the screening test chosen depends on which test is most readily available at a particular institution and the patient's hemodynamic status. Noninvasive diagnosis of acute dissection by TEE, CT, or MRI, if readily available, is preferred as it avoids the risks and delays inherent in invasive angiography.⁸⁴

Management

Treatment for acute aortic dissection is initiated when the diagnosis is first suspected clinically. After the patient is stabilized, the diagnosis is pursued with definitive noninvasive imaging (Fig. 29-8).

Figure 29-7. Aortogram shows a spiraling intimal flap (arrows) in the ascending aorta and aneurysmal dilation of the ascending aorta.

The initial treatment objectives in suspected aortic dissection are to control pain, reduce systemic blood pressure, and lower the rate of change of pressure development (dP/dT) to the lowest level compatible with maintenance of adequate visceral, renal, and cerebral perfusion.⁸⁵ In hypertensive patients, treatment consists of an intravenous (IV) β -adrenergic blocking agent, often in combination with IV sodium nitroprusside. Beta-blockade before nitroprusside therapy is essential because the latter increases the velocity of left ventricular ejection, increases aortic shear stress, and may promote propagation of the dissection.⁸⁶ Intravenous labetalol in place of a β -blocker and sodium nitroprusside is an alternative, but it has the potential for hepatotoxicity with long-term therapy.⁸⁷ In normotensive patients, an intravenous (IV) β -adrenergic blocking agent may be used alone. Intravenous verapamil or diltiazem are an alternative in patients who cannot tolerate beta-blockers. To assist in monitoring blood pressure and renal perfusion, an intra-arterial cannula and in dwelling bladder catheter are advisable. Following initial patient stabilization, noninvasive diagnosis is pursued (as discussed in the previous section). If the patient continues to require close monitoring and support, an emergency bedside TEE is the test of choice.

Patients with acute type A (type I and II) aortic dissection should undergo emergent surgical repair.^{88,89} Coronary angiography before surgery is not indicated because it does not improve survival and it results in a delay to surgical intervention.⁹⁰⁻⁹² Resection of the ascending aorta and replacement with Dacron is the usual procedure in type I or type II aortic dissection.^{88,89} The objectives of surgery include excision of the intimal tear, obliteration of the entrance into the false lumen, repair of

Figure 29-8. Algorithm for initial management of suspected acute aortic dissection. Angio, angiography; CXR, chest radiography; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

aortic regurgitation (if present), and restoration of patency to any major arteries occluded by the dissection. With associated aortic regurgitation, resuspension of the valve, if possible, is preferred. Intraoperative TEE can define the severity and mechanisms of aortic regurgitation and can assist the surgeon in identifying patients in whom valve repair is likely to be successful.⁹³ If there is associated annuloaortic ectasia or destruction of the aortic wall, a valved conduit may be used. The coronary arteries are reimplanted, or if they are involved by the dissection, they are reattached using vein bypass grafts anastomosed proximally to the aortic graft and distally to the uninvolved coronary arteries.^{89,94,95} If compromise of a branch of the aorta supplying a vital organ is present and is not relieved by closing the false channel, then direct repair or surgical replacement of that branch is indicated. Aortic fenestration may be indicated in patients with severe organ or limb ischemia complicating either acute or chronic aortic dissection. Fenestration, either surgical and percutaneous techniques, can effectively relieve the ischemia and can be performed safely in chronic aortic dissection.^{96,97} Operative mortality for ascending aortic dissections at experienced centers varies from 7% to 36%, which is well below the more than 50% mortality with medical therapy.^{8,58,98,99} In-hospital mortality is approximately 14% to 27%, patients with cardiogenic shock and those requiring concomitant coronary artery bypass grafting being the highest risk subgroup.^{98,99}

With acute type B (type III) aortic dissection, urgent surgical intervention is reserved for patients who have a complicated course (rupture, acute expansion or impending rupture, or vascular occlusion).¹⁰⁰ Independent predictors of surgical mortality include those 70 and older, and hypotension or stroke

Figure 29-9. Pathologic consequences of penetrating atherosclerotic ulcer of the aorta. Atheromatous ulceration that burrows deeply into an atheroma can result in one of four potential outcomes (*from left to right*): true saccular aneurysm, medial hematoma, adventitial false aneurysm, or transmural rupture. An intramural (medial) hematoma is the most commonly observed consequence of a penetrating aortic ulcer.

on admission.¹⁰¹ The best treatment for uncomplicated type III aortic dissection is less well-defined, but the majority of patients are best treated with medical therapy.¹⁰² Overall in-hospital mortality for these patients is approximately 10%.¹⁰³ Long-term medical therapy focuses on control of blood pressure, using a beta-blocker if possible, and periodic evaluation for evidence of any progression of dissection, patency of the false lumen, progression of aortic diameter to greater than 5 cm, or development of saccular aneurysm.¹⁰⁴⁻¹⁰⁶ The reported long-term survival rate with medical therapy is approximately 60% to 80% at 4 to 5 years and approximately 40% to 45% at 10 years.¹⁰³ Survival is best in patients with noncommunicating and retrograde dissections. The proximal descending thoracic aorta is the major site of aneurysm development and an enlarged false lumen in this region predicts poor outcome and subsequent aneurysm development.¹⁰⁷ Furthermore, partial false lumen thrombosis (34% of patients) predicts a significantly worse 3-year mortality rate.¹⁰⁸ An alternate approach is 2 to 3 weeks of pharmacologic therapy followed by surgical repair if the dissection becomes stable and the patient's general condition does not contraindicate surgery.^{109,110} Transluminal placement of an endovascular stent-graft device in type III aortic dissection is being successfully performed with increasing frequency and will likely provide an alternative to surgery in highly selected patients in the future.¹¹¹⁻¹¹³

Postoperatively, continuation of a beta-blockade, if possible, is essential, as hypertension and left ventricular ejection velocity play an important role in the recurrence of aortic dissection. Following hospital dismissal, emphasis is placed on adequate blood pressure control, avoidance of strenuous physical activity, and serial clinical evaluations. Noninvasive testing is performed at periodic intervals to detect the development of an anastomotic aneurysm or saccular aneurysm, extension of the dissection, patency of the false lumen, or progressive aortic dilation.^{114,115} Initial follow-up noninvasive imaging at 3, 6, and 12 months is warranted. Subsequent follow-up is performed every 1 to 2 years if there is no evidence of disease progression. MRI is generally preferred for follow-up (a baseline MRI before hospital discharge should be performed).

Penetrating Aortic Ulcer

Penetrating aortic ulcer shares several clinical features with aortic dissection, especially type III aortic dissection, but the absence of certain clinical signs favors a diagnosis of penetrating aortic ulcer. Results of noninvasive imaging studies are usually distinctive, allowing differentiation of penetrating aortic ulcer from typical aortic dissection.^{116,117} Differentiation between the two disorders is important in view of the fact that the natural history of penetrating aortic ulcer is less well-defined; therefore, treatment may differ from that currently used for classic aortic dissection.^{116,117}

Pathogenesis

Penetrating aortic ulcer refers to an atherosclerotic lesion of the thoracic aorta that undergoes ulceration, which penetrates the internal elastic lamina of the thoracic aorta, resulting in formation of one of the following: intramural hematoma within the media of the aortic wall, a true saccular aneurysm, a pseudoaneurysm, or transmural aortic rupture¹¹⁸ (Fig. 29-9).

Predisposing Factors

Risk factors for penetrating aortic ulcer are similar to those for aortic dissection, the most common being advanced age, chronic systemic hypertension, and evidence of advanced atherosclerotic disease.¹¹⁹ In contrast to aortic dissection, men and women are equally affected. Long-standing hypertension is present in the majority of patients and likely contributes to the advanced atherosclerotic disease that is universally evident. More than one half of the patients with penetrating aortic ulcer have advanced atherosclerotic disease in other locations, including coronary artery disease, peripheral arterial occlusive disease, and cerebrovascular disease. An increased association of penetrating aortic ulcer and abdominal aortic aneurysm, and aneurysms in other locations, has also been reported.^{118,120}

Clinical Features

The clinical presentation of penetrating aortic ulcer and acute aortic dissection are similar, the most common presentation being an elderly patient with systemic hypertension and

the sudden onset of severe pain in the chest, back, and, less commonly, epigastrium. Unlike aortic dissection, the pain is rarely migratory. Since the most common site of penetrating aortic ulcer is in the descending thoracic aorta, a murmur of aortic regurgitation, pericardial friction rub, and peripheral pulse deficits are not seen. In addition, visceral vessel involvement has not been reported. Neurologic deficits are very rare, but acute lower-extremity paraplegia has been reported.¹¹⁸ In a patient with a history compatible with aortic dissection, it is the *absence* of physical findings that suggests the diagnosis of penetrating aortic ulcer. Asymptomatic penetrating aortic ulcer does occur and is usually incidentally discovered as enlargement of the descending thoracic aorta or a hilar mass on routine chest radiography or on CT done for another indication.^{118,120}

Laboratory Findings

Routine laboratory studies are nonspecific with penetrating aortic ulcer. The chest roentgenogram is the most helpful of the routine laboratory tests because it is often abnormal. It may demonstrate mediastinal widening, focal or diffuse enlargement of the descending thoracic aorta, a hilar mass, left apical mass, bilateral pleural effusion, or isolated left pleural effusion.^{116,117} However, normal chest radiographic findings do not exclude penetrating aortic ulcer. The most common electrocardiographic abnormality is left ventricular hypertrophy from chronic systemic hypertension.

Diagnosis

The findings on CT, MRI, TEE, and aortography in patients with penetrating aortic ulcer are characteristic, allowing for differentiation of penetrating aortic ulcer from classic aortic

dissection. In contrast to aortic dissection, an undulating flap or false lumen are not present and TEE will usually demonstrate significant, often advanced atherosclerotic disease of the aorta, most commonly the descending thoracic aorta. An echolucent intramural hematoma with overlying advanced atherosclerotic disease is the most common TEE finding in patients with acute penetrating aortic ulcer. A careful evaluation may demonstrate a crater-like ulceration with surrounding atheroma. When the intramural hematoma undergoes thrombosis it becomes echogenic, creating the appearance of an increase in aortic wall thickness. The intramural hematoma may extend proximally or distally for a variable distance from the entry site. Additional findings in patients with penetrating aortic ulcer may be an aortic pseudoaneurysm or saccular aneurysm. Using CT, penetrating atherosclerotic ulcer manifests as focal involvement with adjacent subintimal hematoma and is often associated with aortic wall thickening or enhancement. Magnetic resonance imaging is superior to conventional CT in differentiating acute intramural hematoma from atherosclerotic plaque and chronic intraluminal thrombus and allows unenhanced multiplanar imaging (Fig. 29-10). Spiral CT involves shorter examination times and allows high-quality two- and three-dimensional image reconstruction. CT angiography can demonstrate complex spatial relationships, mural abnormalities, and extraluminal pathologic conditions. It should be noted that penetrating aortic ulcer is strongly associated with abdominal aortic aneurysm, which is seen concomitantly in 42% of patients; therefore imaging of the abdominal aorta should be included in the initial evaluation.¹¹⁹

Figure 29-10. MRI in a patient with multiple penetrating aortic ulcers. **A**, Transverse imaging plane shows a penetrating aortic ulcer in the proximal descending thoracic aorta (arrow). **B**, MR angiogram with gadolinium enhancement shows severe atherosclerotic changes of the descending thoracic aorta and a penetrating aortic ulcer in the proximal descending thoracic aorta (arrow).

Management

The optimal treatment for penetrating aortic ulcer is not well-defined. Treatment is individualized as the natural history of penetrating aortic ulcer and indications for surgery are evolving. Although careful follow-up is necessary, many penetrating aortic ulcers involving the descending thoracic aorta can be managed nonoperatively in the acute setting. The natural history of an intramural hematoma involving the descending thoracic aorta has been shown by serial noninvasive imaging studies to follow a course of resorption of the hematoma and compensatory aortic dilation in the region of the involved aorta in 85% of patients over 1 year.^{117,118} Patients with an intramural hematoma should be treated medically initially, with special emphasis placed on control of blood pressure, preferably with a β -adrenergic blocking agent.¹²⁰ Ascending aortic involvement, progressive aortic dilation, persistent symptoms, or difficult to control hypertension are indications for surgery. When saccular or pseudoaneurysm is the result of a penetrating atherosclerotic ulcer of the aorta, surgery is also recommended. Thoracic endograft technology is being applied to patients with penetrating aortic ulcer involving the descending thoracic aorta with high procedural success and a low perioperative morbidity and mortality.¹²²⁻¹²⁵

Aortic Intramural Hematoma

Aortic intramural hematoma (IMH) is an acute, potentially lethal disorder that is similar to but pathologically distinct from acute aortic dissection. Although hemorrhage into the aortic media occurs in both disorders, an intimal tear with resultant false lumen is not present in IMH. The prevalence of IMH among patients with acute aortic syndromes has been reported to be 5.7%.¹²⁶ The clinical presentation and noninvasive diagnosis of IMH are similar to aortic dissection, as are the classification scheme and general principles of management.

Pathogenesis

Although hemorrhage into the aortic media occurs in both acute aortic dissection and IMH, an intimal tear with resultant false lumen is not present in IMH. Instead, hemorrhage occurs within the aortic wall either because of rupture of the vasa vasorum or, less commonly, because of an atherosclerotic penetrating aortic ulcer.¹²⁷ IMH evolves very dynamically in the short term to regression, dissection, or aortic rupture.¹²⁸ The most frequent long-term outcome of IMH is the development of aortic aneurysm or pseudoaneurysm. Lesions of the ascending aorta appear to represent the early stage of a classic dissection in some patients.¹²⁹ Complete regression without changes in aortic size is observed in one third of cases, and progression to classical dissection is less common. A normal aortic diameter in the acute phase is the best predictor of IMH regression without complications, and absence of echolucent areas and atherosclerotic ulcerated plaque are associated with evolution to aortic aneurysm.¹²⁸ IMH is most often associated with long-standing hypertension (50% to 84% of patients), but has also been reported in association with trauma (e.g., auto accident or iatrogenic) in 6% of cases in a meta-analysis.^{126,130,131}

Classification

The classification scheme for IMH is the same as is used for classic aortic dissection (please see section on aortic dissection above). Patients with IMH are more likely to have type B

lesions than in those with classic aortic dissection (e.g., 60% versus 35%).¹²⁶

Clinical Features

Clinically, patients with acute IMH have a similar presentation to those with acute aortic dissection. Sudden, severe chest and/or back pain, as occur in classic aortic dissection, are common in IMH.¹³⁰ Although not specific, anterior chest pain is more common with ascending (type A) lesions, whereas interscapular back pain is more common with descending (type B) lesions.¹³² In contrast to aortic dissection, manifestations associated with aortic branch vessel disease (e.g., myocardial infarction, stroke, aortic regurgitation, visceral vessel compromise, and paraplegia) are relatively uncommon with type A IMH.

Diagnosis

The noninvasive imaging methods used to diagnose IMH are the same as those used in the diagnosis of acute aortic dissection (TEE, CT, MRI). Exclusion of a dissecting intimal flap is a prerequisite for the diagnosis of IMH. Specific findings on TEE for IMH include: crescentic or circumferential regional thickening of the aortic wall exceeding 7 mm, echolucent areas within the involved aortic wall, displaced intimal Ca^{2+} , and absence of an intimal flap. CT and MRI will typically demonstrate a crescentic or circular high attenuation area along the aortic wall that does not enhance with contrast,¹³³ (Fig. 29-11).

Management

In general, the acute management of IMH and acute aortic dissection are similar. Initial treatment places emphasis on reduction of systolic blood pressure to the lowest level compatible with adequate cerebral and renal perfusion (please see section on initial management of acute aortic dissection). Beta-blockade is indicated in all patients without absolute contraindications to their use and presumably exert their beneficial effect by reducing both systolic blood pressure and decreasing aortic wall stress. Patients with ascending aortic involvement have a reduction in early mortality with surgical intervention as compared with medical management (14% versus 36%).¹³⁰ Patients

Figure 29-11. CT scan with contrast enhancement in a patient with sudden and severe chest pain shows a circumferential intramural hematoma involving the mid-descending thoracic aorta (arrow).

with type B lesions have a similar mortality with medical or surgical management (14% versus 20%). Therefore surgical intervention is usually recommended in patients with type A (ascending aortic) IMH, whereas aggressive medical therapy is the most common course for patients with type B (descending aortic) IMH.

Progression of disease in patients who are managed medically and survive the acute phase of the illness often occurs, although the rate of progression can be reduced in patients treated with beta-blocker therapy acutely.¹³² Aortic diameter at the time of initial presentation may also predict which patients are most likely to have disease progression (aortic diameter >5 cm predicting progression), potentially identifying a high-risk group that would benefit from early surgical intervention. Interestingly, in patients with ascending aortic IMH managed medically (due to advanced age and comorbid medical conditions), the mortality rate is much lower as compared with patients with classic ascending aortic dissection who do not undergo surgery.¹²⁹

Introduction

Pericardial disease is encountered much less often in cardiac intensive care units (CICUs) than in cardiology clinics and inpatient services. Acute pericarditis is nevertheless an entity that sometimes must be considered in the population of patients hospitalized in a CICU. Patients who in reality do not have, or are unlikely to have, myocardial ischemic pain may be wrongly treated as though they were having a myocardial infarction or another acute coronary syndrome. Only after they have endured discomfort and have been exposed to the slight risk of harm, and after considerable expense, is the diagnosis of pericardial disease recognized and appropriate treatment begun whereas, in reality, many of these patients did not require hospitalization, still less admission to a CICU.

The possibility of acute pericarditis should be remembered by physicians who receive requests for admission of patients to the unit when the cause of chest pain has not been established.

Similarly, cardiac tamponade rather than massive myocardial infarction may be the true cause of apparent cardiogenic shock. Treatment aimed at the supposed myocardial infarction, instead of relieving pericardial pressure, is harmful and can easily prove fatal under these circumstances. Cardiac tamponade should always be included in the differential diagnosis of patients who develop unexplained significant hemodynamic deterioration following an invasive cardiac procedure, especially an interventional one.

The clinical picture of constrictive pericarditis is the same as that of right heart failure. Constrictive pericarditis and right heart failure of other etiology share some hemodynamic abnormalities, such as peripheral edema, pleural effusion and ascites, increased left and especially right ventricular diastolic pressure, and reduced cardiac output.

This chapter will focus on the issues outlined above. References that are to review papers are indicated as such in the text or citations. Physicians in charge of patients in a CICU must be aware of disorders of the pericardium because pericardial disease may simulate disease of the heart itself and lead to incorrect diagnosis and treatment. In the most extreme cases, this error may have fatal consequences. It remains as true today as when Osler¹ first made the observation that pericardial disease is a frequently missed diagnosis. Especially in a CICU, pericardial disease is much less common than myocardial disease; therefore the best way to recognize pericardial disease is to maintain

a high index of suspicion for this possibility when the cause of right heart failure or precordial pain is not readily apparent. The principal manifestations of pericardial disease simulating ischemic heart disease are listed in [Table 30-1](#).

Pericardial Syndromes in Ischemic Heart Disease

Chest Pain

A significant proportion of patients experience some type of chest pain in the first day or so after acute myocardial infarction. The most important cause of recurring chest pain in patients in the CICU with a documented acute myocardial infarction is myocardial ischemia, which often demands therapeutic action; however, not all chest pain occurring under these circumstances is so ominous. Many episodes of such pain elude diagnosis, especially those that are the result of the patients' natural apprehension and the understandable way in which they become sensitized to any abnormal sensations in the chest. Pulmonary infarction, embolism, or other conditions associated with pleuritic or substernal pain are included in the differential diagnosis. The cause of pleuritic chest pain can often be established from the clinical examination and the chest radiogram, but pleuritic pain may be a symptom of post-myocardial infarction pericarditis. Unfortunately, the pain of pericarditis is not always pleuritic in nature, but may simulate or be indistinguishable from pain of myocardial origin. The symptom may also have characteristics

Table 30-1. Major Ways in Which Pericardial Disease May Simulate Ischemic Syndromes

Pericardial pain simulating ischemic pain
ST segment deviation suggesting myocardial ischemia
Dressler syndrome mistaken for reinfarction
Cardiac tamponade misinterpreted as heart failure
Severe tamponade mistaken for cardiogenic shock
Friction rub mistaken for murmur of acute mitral regurgitation
Friction rub mistaken for murmur of rupture of the ventricular septum

of both myocardial and pericardial pain; for instance, it may be a crushing sensation, yet be aggravated by inspiration, influenced by posture, or be referred to the trapezius ridge. It would be desirable to be able to rely on the electrocardiogram to distinguish with certainty between pericardial and myocardial pain, but the typical changes of acute pericarditis often are not recognizable against a background of the changes associated with acute myocardial infarction or active ischemia.²

Acute Pericarditis

A number of comprehensive reviews of this subject have been published in recent years.³⁻⁹ Acute pericarditis most commonly is an acute infection of the pericardium and superficial myocardium (epicardium) that is adherent to the visceral pericardium. Acute viral pericarditis is a self-limiting relatively short disease that responds rapidly to anti-inflammatory treatment and therefore is classified as low risk for an early complication, most importantly cardiac tamponade, although tamponade does complicate about 1% to 2% and requires drainage to prevent a fatal outcome. In striking contrast is acute pericarditis of other etiologies, including infection with any living organism. Of special relevance to this chapter are pyogenic and tuberculous infection and acute pericardial injury of etiology other than that caused by viral infection. Examples include trauma including surgical or percutaneous intervention. The only common *late* complication is unpredictable recurrence that occurs at various intervals repeated over a highly variable period of time in 15% to 30% of patients (recent review papers).^{8,9}

Almost all patients complain chiefly of chest pain, but they may have few if any risk factors for coronary disease. They are often quite young and report a prodrome described as very like the flu. This prodromal event is febrile and very different from the feeling of general malaise that may precede acute myocardial infarction. Once the receiving physician considers it likely that a patient has acute pericarditis, evaluation and initial management should be done in a same-day unit,¹⁰ otherwise, hospital admission is necessary. The initial assessment can be completed in 24 hours and comprises enquiry about the details of the chief complaint (chest pain), any other symptoms, past medical history, standard biochemical laboratory tests, including C-reactive protein, and the erythrocyte sedimentation rate, and markers indicating myocardial inflammation.

Biomarkers

Acute pericarditis is associated with increased levels of serum biomarkers for myocardial injury, including modest elevations of creatine kinase (CK-MB) and serum cardiac troponin I (cTnI).¹¹⁻¹³ Serum cTnI is detectable in 32% to 49% of patients and exceeds the threshold value of 1.5 ng/mL in 8% to 22%. Mild increases in cTnI often occur in the absence of elevations in CK-MB. The rise in serum cTnI in acute pericarditis is roughly related to the extent of concurrent myocardial inflammation and is transient, resolving within 1 week. Persistent cTnI elevation suggests ongoing epicardial inflammation. Patients with a rise in cTnI do not, however, have a higher incidence of complications. Laboratory signs of inflammation are diagnostic criteria for acute pericarditis. These include the elevated white blood cell count erythrocyte sedimentation rate and, most important, serum C-reactive protein concentration.

I believe that the initial evaluation, in addition to an ECG and chest radiogram, should include an echocardiogram, but

some authorities state that echocardiography is not needed in straightforward cases. At the conclusion of this evaluation, most patients can be classified as either low or high risk for an early complication. Continued care of patients at low risk can be provided in an outpatient clinic. Patients considered to be at high risk or in whom the risk remains in doubt, should be admitted to the CICU or a medical ward, whichever is appropriate in individual cases, to determine the cause of the acute pericarditis, treat the cause and the pericarditis itself, a complication such as cardiac tamponade, or a large, slowly resolving pericardial effusion, if present.

Features suggesting high risk for an early complication are:

- Insidious rather than the customary acute onset
- Failure to respond promptly to NSAID therapy, suggesting a nonviral etiology
- Evidence of cardiac tamponade
- Neoplastic pericarditis, because it often causes tamponade, and may be the presenting feature
- Patient receiving anticoagulant or immunosuppressive treatment
- High fever, shaking chills, and leukocytosis suggesting pyogenic pericarditis

Viral, idiopathic, or acute pericarditis of various other causes is seldom an indication for admission to the CICU. Therefore most pericarditis encountered in the CICU is related to myocardial infarction and, less commonly, a cardiac or coronary intervention. Patients with acute pericarditis unrelated to ischemic heart disease may, however, also be placed in the CICU. When receiving physicians are unsure of the nature of the patients' pain and/or suspect cardiac tamponade, they should admit them to the CICU. Rarely, acute pericarditis presents as severe cardiac tamponade. Patients with this presentation, or those who are clinically unstable for another reason, may also become CICU patients.

Two pericardiopathies may occur after an acute myocardial infarction. The more frequent but less ominous is acute pericarditis with or without a benign small effusion. This acute pericarditis occurs early in the course, the peak incidence being at 3 days. This is a manifestation of contiguous pericardial inflammation over the region of the infarction and is thus more a feature of Q-wave than non-Q-wave infarctions. Using clinical criteria, a pericardial friction rub used to be reported in about 10% of patients after acute myocardial infarction² but is considerably more common in autopsy series. Pericardial friction rubs are most commonly detectable on the third day after the onset of infarction but sometimes are heard as early as the first day postinfarction. The rub has a tendency to be evanescent; therefore, if it is to be detected reliably, frequent careful auscultation focused on its detection is necessary.

The second pericardiopathy associated with acute myocardial infarction usually occurs considerably later. It is not caused by pericardial inflammation over the contiguous infarction, but is an autoimmune response to prior myocardial injury. The CICU is not the ideal milieu for auscultation, which doubtless is a reason for the underrecognition of pericardial friction rub. Rubs that first appear later than 1 week after an infarction suggest the onset of post-myocardial infarction syndrome, a subset of the pericardial injury syndrome and formerly known as Dressler syndrome.

Pericarditis may exaggerate the degree of ST segment elevation in acute myocardial infarction.^{14,15} ST segment elevation

Figure 30-1. ECG of a patient with acute viral pericarditis. Characteristic features include ST segments elevated concave upward and not localized. T waves are upright in leads with ST segment elevation. Reciprocal repolarization changes are seen in aV_R and V_1 . PR segments are depressed.

in leads in which reciprocal depression would be anticipated is suggestive of complicating generalized pericarditis;¹⁶ thus ST elevation is concordant (Fig. 30-1). When pericarditis, with or without effusion, complicates myocardial infarction, evolution of the T-wave changes may be atypical, with the T wave remaining or becoming positive when T-wave inversion would be anticipated in an uncomplicated infarction.¹⁷

The standard treatment for acute pericarditis is administration of an anti-inflammatory agent, preferably nonsteroidal; corticosteroid treatment should be avoided, if at all possible. In the setting of acute myocardial infarction, however, the clinician should be aware that anti-inflammatory treatment, by inhibiting the normal healing process, may increase the risk of myocardial rupture.

Pericardial Effusion

Pericardial effusion after myocardial infarction, when specifically sought by serial echocardiography, is surprisingly common,¹⁸ occurring in about one fourth of the patients. Another unexpected feature of pericardial effusion as a sequel of myocardial infarction is that it persists for several weeks and bears no relation to pericardial friction rub. Pericarditis and pericardial effusion are associated with a worse prognosis, probably because they are more common after large infarctions, which tend to be anterior, and usually transmural.¹⁸⁻²⁰ It is accepted practice to avoid administering anticoagulants or thrombolytic agents to patients with active or recent inflammatory pericarditis,²¹ but both the Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardio (GISSI)^{20,21} and the Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) trials²² have shown that thrombolytic therapy for myocardial infarction reduces rather than increases the incidence of pericardial effusion, presumably as a secondary consequence of its ability to reduce infarct size. Delayed pericardial effusion is an example of postinfarction pericardial injury. This autoimmune syndrome tends to be recurrent; therefore patients may be readmitted to the CICU with a diagnosis of a myocardial ischemic syndrome when the diagnosis is actually postinfarction autoimmune

pericardial effusion, formally known as Dressler syndrome.^{23,24} The correct diagnosis can be established when the physician keeps this diagnostic possibility in mind and seeks the characteristic features that include fever, leukocytosis, and chest pain that is usually somewhat pleuritic in nature. The chest radiogram discloses new apparent cardiomegaly and pleural effusion, which is often bilateral. Pulmonary infiltrates are less common. The correct diagnosis can usually be confirmed by echocardiography because a large pericardial effusion is a common manifestation of this condition. A review of post-myocardial infarction syndrome was published quite recently.²⁵

The evidence that the syndrome is an autoimmune phenomenon includes its association with antibodies against myocardium, but immunologic studies are not part of standard clinical care. The syndrome is considerably less common today than in the decades following its first description. The reason for this decreased incidence is not known, but it is speculated that it may be associated with decreased use of anticoagulant therapy after myocardial infarction.

Treatment is with an NSAID, but prednisone may be required in refractory cases. Relapses may occur for several months or longer and require the same treatment. In these cases, the patient's prior history is of great help in making the diagnosis. Anticoagulant or thrombolytic therapy is contraindicated because of the likelihood of hemorrhagic cardiac tamponade. This contraindication does not apply to early postinfarction pericarditis.

Cardiac Tamponade

Physiology

Cardiac tamponade is the syndrome that develops when fluid accumulates in the pericardial space faster than it is absorbed. After the small physiologic reserve volume has been reached, further influx of fluid therefore must elevate pericardial pressure, because after its reserve volume has been used up, the pericardium is virtually inextensible because its stress-strain relation is J shaped. Total cardiac volume consequently cannot

Figure 30-2. Hyperacute cardiac tamponade caused by penetration of a saphenous vein graft during angioplasty of the graft. The radial arterial tracing shows tachycardia and extreme pulsus paradoxus. The right atrial and pericardial pressures are equilibrated at a very high level. The volume of blood in the pericardium was small.

vary; therefore, an increase in right heart volume must cause decreased left heart volume and vice versa. This interdependence or interaction between the left and right sides of the heart is the principal mechanism underlying many of the clinical and imaging abnormalities characteristic of cardiac tamponade. These include pulsus paradoxus and greatly increased respiratory variation of transmitral and transtricuspid filling velocities, and stroke output and input. Pulsus paradoxus is detected by bedside examination and imaging that shows inspiratory decrease in stroke volume far greater than in normal subjects. The latter is shown and quantified by echo Doppler. Cardiac catheterization quantifies pulsus paradoxus and documents that systolic and pulse pressures in the systemic circulation are maximum at the time of peak expiration, but in the pulmonary circulation they are maximum at peak inspiration. This 90 degree out-of-phase relationship is another manifestation of chamber interdependence.

Common Causes of Tamponade in the CICU

Cardiac tamponade may complicate both early postinfarction pericarditis and late autoimmune pericardial effusion (Dressler syndrome). Cardiac tamponade is most often immediately life-threatening when it occurs as a result of the rupture of an infarcted myocardium or the aorta. Many cases of myocardial rupture are immediately fatal but, less frequently, the pericardial hemorrhage is sufficient to cause tamponade but insufficient to kill the patient rapidly. This condition is called pseudoaneurysm and usually requires later elective surgical treatment. Management of mechanical complications of myocardial infarction. Victims of this catastrophe will not survive if the diagnosis is missed or significantly delayed. Cardiac tamponade is thus a condition that the CICU physician must be able to recognize and be competent to treat, sometimes as an emergency. When the cause is rupture in the area of infarcted myocardium, the resulting tamponade is almost always hyperacute because the pericardium is stiff and stretches only minimally when the

increase in volume load is virtually instantaneous or rapid. The characteristics, therefore, are a relatively small volume of pericardial hemorrhage, but an excessively elevated pericardial pressure that causes stroke volume and arterial systolic pressure to fall dramatically and pulsus paradoxus to be severe (Fig. 30-2). A CAT scan or MRI provide optimal images, but in most cases, the patient is too ill to wait and be transferred to the imaging facility for these procedures, therefore echocardiography is used instead. The images will show the intrapericardial blood and flow from a ventricular cavity to the pericardial space, and will exclude the differential diagnosis of rupture of the chordae causing severe acute mitral regurgitation.

In summary, a high index of suspicion for cardiac tamponade must be maintained. Thus, sudden unexpected hemodynamic collapse that is not otherwise readily explained must always trigger a differential diagnosis that includes cardiac tamponade. An emergency echocardiogram should be obtained as quickly as possible.

Recognizing Cardiac Tamponade

Cardiac tamponade must be considered in any patient with a condition that commonly affects the pericardium. Myocardial infarction and its sequelae have been discussed, but today's CICU is not the coronary care unit of yesteryear. Because of the expanded role of the CICU, cases of cardiac tamponade of various causes may be admitted for monitoring and treatment.

Diagnosis

Diagnosis is facilitated as described previously by considering the possibility of cardiac tamponade in any unexplained hemodynamically compromised patient. The symptoms depend on the severity of cardiac tamponade, which clinicians should not consider as an all-or-none phenomenon but rather as one that ranges from mild to severe.²⁶ Mild cases are usually asymptomatic, but with increasing severity comes dyspnea, oliguria, and impending syncope, and ultimately death.

Tamponade, when a complication of a noncardiac systemic illness, is often accompanied by symptoms and signs of the systemic illness in addition to physical signs that are more commonly associated with right heart failure, but these patients lack any apparent cardiac abnormality to explain why the heart is failing. These findings are more difficult to interpret in patients with recent or past myocardial infarction or in those receiving hemodialysis, in whom the index of suspicion must be raised.

The venous pressure is elevated in all except the mildest cases of tamponade and those in whom there is a complicating cause of hypovolemia (low pressure tamponade). Careful inspection of the jugular venous pressure is critical in patients who have not received a central venous catheter. In those who are catheterized, the magnitude of the venous pressure and a detailed analysis of its waveform are easily obtained from the superior vena cava or right atrial pressure tracing. A central venous pressure less than 7 mm Hg is consistent with mild tamponade. Moderate tamponade is usually associated with a pressure of approximately 10 to 15 mm Hg, and severe tamponade is associated with higher pressure, sometimes up to 30 mm Hg.

When the jugular pressure cannot be determined by inspection and the patient does not have a central venous catheter in place, it can be assessed from the dimension of the inferior vena cava and its change or lack of change during the respiratory cycle (Table 30-2). Evaluation of the inferior vena cava is an essential component of the echocardiographic assessment for cardiac tamponade.

In patients with heart disease, it is important to evaluate how much of the pressure elevation in the central venous circulation is pre-existing and the result of heart disease and how much is a manifestation of tamponade. The venous pressure in uncomplicated cardiac tamponade, even when greatly elevated, declines during inspiration; thus Kussmaul sign is not a feature of tamponade.^{27,28} The other important diagnostic feature of the contour of the venous pressure tracing is attenuation or absence of the y descent (Fig. 30-3). The most likely explanation for this phenomenon is that early rapid ventricular filling is increased by enhanced recoil, but later filling is absent because cardiac volume, and therefore tamponade, are maximal at end-diastole. These features of the venous pulse can often be observed at the bedside. The x descent is synchronous with the carotid pulse and is prominent in tamponade.

In patients with severe tamponade manifested by tachycardia and respiratory distress, respiratory variation and the waveform of the jugular venous pulse become difficult or impossible to detect by simple inspection.

Table 30-2. Using the Dimension of the Inferior Vena Cava and Its Decrease with Inspiration to Estimate Central Venous Pressure

Inferior Vena Cava	Decrease with Inspiration	Right Atrial Pressure
Small: <1.5 cm	Collapse	0-5 mm Hg
Normal: 1.5-2.5 cm	<50%	5-10 mm Hg
High normal: 2.5 cm	< or >50%	11-15 mm Hg
Dilated: >2.5 cm	50%	16-20 mm Hg
Dilated: >2.5 cm	Zero change	20 mm Hg

When the clinician suspects cardiac tamponade, two other diagnostic tools are called into play: echocardiography and simultaneous recording of the central venous and pulmonary wedge pressures. Which of these to perform first depends on the circumstances. The echocardiogram provides definitive information in that if it shows that there is no pericardial effusion, the patient cannot be suffering from cardiac tamponade. Much other important diagnostic information is provided by the echocardiogram²⁹ (Fig. 30-4). Compression of the right atrium (Fig. 30-5) or right ventricular diastolic collapse³⁰ are both highly sensitive and reasonably specific signs of cardiac tamponade. Cardiac chamber collapse is caused by transient reversal of the normal ratio of right atrial to pericardial pressure.³¹

Doppler examination of ventricular inflow shows exaggerated respiratory variation.³¹ Additional information can be gathered from evaluation of cardiac chamber size and function. In

Figure 30-3. Equilibration of pressures in cardiac tamponade. The patient had severe cardiac tamponade. **A**, Right atrial and pericardial pressures are elevated to 20 mm Hg. Both pressure contours are monophasic with a prominent x but no y descent. **B**, Right atrial and pulmonary wedge pressures are also 20 mm Hg, and their contours are similar. (From Shabetai R: *Pericardial disease*. In Brown DL [ed]: *Cardiac Intensive Care*. Philadelphia, Saunders, 1988, pp 469-475.)

Figure 30-4. Echocardiogram showing a large circumferential pericardial effusion. Anterior (A) and posterior (B) aspects of the effusions are shown. (From Shabetai R: *Pericardial disease*. In Brown DL [ed]: *Cardiac Intensive Care*. Philadelphia, Saunders, 1988, pp 469-475.)

Figure 30-5. Echocardiogram showing severe right atrial compression (arrow) in a patient whose pericardial effusion had caused cardiac tamponade. (From Shabetai R: *Pericardial disease*. In Brown DL [ed]: *Cardiac Intensive Care*. Philadelphia, Saunders, 1988, pp 469-475.)

uncomplicated cardiac tamponade, the ventricles are of normal size, and their systolic function is normal.³² Demonstration of ventricular enlargement or systolic dysfunction calls for judgment regarding whether hemodynamic abnormalities are cardiogenic or manifestations of tamponade.

When cardiac tamponade is severe, pulsus paradoxus and, in more extreme cases, hypotension appear, at which stage tamponade is considered to be decompensated and is treated as an emergency. Right ventricular diastolic collapse develops earlier than pulsus paradoxus in the course of tamponade.³³

If a Swan-Ganz catheter is not already in place, one should be inserted to complete documentation and assessment of tamponade. The central venous pressure is measured at the proximal port and the wedge pressure is measured at the distal port. The two pressures are recorded simultaneously at precisely identical sensitivities and, if the apparatus permits, from a common baseline. In uncomplicated tamponade, the wedge and right atrial pressures are equal, so the tracings will be superimposed. This equilibration of right and left atrial pressures is a characteristic finding in tamponade. Records should be made during normal respiration and at expiration and with respiration arrested at end-tidal volume. The mean pressures should not differ by more than 2 or 3 mm Hg if scrupulous attention is paid to the recording technique (see Fig. 30-3).

Pulsus Paradoxus

Pulsus paradoxus develops when tamponade becomes moderately severe and is easily quantified if a systemic arterial line has been placed. Pulsus paradoxus is considered present when systemic arterial pressure drops 10 mm Hg or more during a normal inspiration (Figs. 30-2 and 30-6). The pulse pressure also falls during normal inspiration, reflecting decreased stroke volume. Respiration affects hemodynamics via a number of mechanisms, all of which contribute to pulsus paradoxus, but the most important is ventricular interaction.³⁵ In the absence of direct arterial monitoring, pulsus paradoxus can be estimated by

Figure 30-6. Low-pressure cardiac tamponade. The right ventricular pressure was only 10 mm Hg, but otherwise the characteristic hemodynamic abnormalities of severe tamponade were present, including pulsus paradoxus, which was out of phase between the right ventricle (RV) and the aorta (Ao), and absence of an early diastolic dip. (From Shabetai R: *Cardiac tamponade*. In Shabetai R [ed]: *The Pericardium*. Kluwer Academic Press Norwell, Massachusetts, 2003, pp 122-166.)

sphygmomanometry; the first blood pressure sound is initially heard only during expiration but, as cuff pressure is lowered, becomes audible consistently. Pulsus paradoxus is estimated as the difference in pressure between the levels at which the first heart sound is heard only in expiration and heard all the time. It is important when quantifying pulsus paradoxus to avoid requesting the patient to breathe deeply to bring out pulsus paradoxus because serial measurement of pulsus paradoxus is useful in monitoring the progress of patients monitored for tamponade.

The degree of pulmonary hypertension depends on the severity of tamponade. In mild cases, pulmonary arterial pressure is normal and, in the severe cases, pulmonary arterial systolic pressure is usually in the range of 40 mm Hg. In hyperacute cases, in which pulmonary diastolic pressure may be 50 to 60 mm Hg, pulmonary systolic pressure may be 70 to 80 mm Hg. Otherwise, pulmonary hypertension of substantially more than 40 mm Hg indicates that either the diagnosis is wrong or tamponade is superimposed on another cause of pulmonary hypertension. The right ventricular diastolic pressure does not show a dip-and-plateau configuration in tamponade, just as there is no γ descent of right atrial pressure. The dip-and-plateau configuration of ventricular diastolic pressure is a feature of constrictive pericarditis and restrictive cardiomyopathy in which early diastolic filling is abnormally rapid. In cardiac tamponade, filling in late diastole is attenuated or absent.

In a typical case of moderate-to-severe tamponade, all filling pressures are determined by the elevated pericardial pressure; thus right atrial, right ventricular diastolic, pulmonary wedge, and pulmonary arterial diastolic pressures are equal (see Fig. 30-3).

Exceptions to the classic findings of tamponade occur and are more common in CICU patients because these exceptions are manifestations of pre-existing heart disease. The mechanism of pulsus paradoxus is related to competition between the two sides of the heart for severely restricted intrapericardial space (ventricular interdependence) so that the inspiratory expansion

of right heart volume must impair left heart stroke volume during inspiration.³⁵ This mechanism implies that the external pericardial force, by rendering left and right ventricular pressures equal, equalizes left and right ventricular diastolic compliance. In patients who have heart disease with elevated left or right ventricular diastolic pressure, pericardial pressure can be lower than that in which whichever ventricle diastolic pressure is elevated by pre-existing heart disease, even when tamponade is severe. In that circumstance, ventricular diastolic compliance ceases to be equal on the two sides, and pulsus paradoxus is not present. Likewise, pulmonary hypertension or right heart failure can prevent the occurrence of echocardiographic right heart compression. Systemic arterial pressure should be monitored throughout pericardiocentesis, preferably by cannulation of an artery.

Low Pressure Cardiac Tamponade

Low pressure cardiac tamponade describes the condition in which cardiac tamponade is present without the characteristic elevation of central venous pressure.³⁶ Sometimes this phenomenon occurs simply because tamponade is mild. In these cases, hypotension, tachycardia, pulsus paradoxus and echocardiographic chamber compression and collapse are absent. The CCU staff should note it in the discharge summary, but no other immediate action is required. Low pressure cardiac tamponade may, however, be associated with hypovolemia, secondary to dialysis or ultrafiltration, highly aggressive diuresis, or acute hemorrhage as in cardiac tamponade caused by thoracic trauma. In these cases, chamber collapse, pulsus paradoxus (see Fig. 30-6) and hemodynamic compromise are very much in evidence. Treatment comprises pericardiocentesis and intravenous fluid replacement monitored by hemodynamics. Replacement should commence before a significant volume of fluid has been removed and be continued during pericardiocentesis.

Treatment

Cardiac tamponade is generally an indication for pericardiocentesis. Whenever possible, pericardiocentesis should be carried out in a cardiac catheterization or echocardiographic laboratory rather than in the CICU. In the catheterization laboratory, the physiologic recorder probably has considerably larger capacity and flexibility, and the technicians are usually more skilled at precise pressure recording than are their counterparts in the CICU. Likewise, the radiologic facility is apt to have far greater capability than the portable x-ray equipment available in the CICU. In the cardiac catheterization and echocardiographic laboratories, the inventory of catheters, guide wires, and cannulae immediately available to the operator is much larger. Contrast injection, be it with agitated saline or radio-opaque contrast agent, is a useful means of ensuring the proper position of a needle or catheter in the pericardial space and is more readily available in the catheterization or echocardiographic laboratory. An echocardiogram should be in the laboratory, and the machine should be available to give the operator the option of using echocardiographic guidance.

Pericardial pressure should always be measured, and simultaneous measurements of pericardial, right atrial, and pulmonary wedge pressures should be obtained at the outset to confirm the diagnosis, and serially during the procedure, or at its end, to monitor the hemodynamic response. By the time pericardiocentesis nears completion, pericardial pressure should have fallen to subatmospheric levels, at least during inspiration, and be

consistently below right atrial and pulmonary wedge pressures. When right atrial pressure remains elevated, consideration must be given to effusive-constrictive pericarditis, right heart failure, or tricuspid valve disease. Persistent elevation of the pulmonary wedge pressure, but normalization of the pericardial and right atrial pressures implies left heart failure or mitral valve disease. Systemic arterial pressure should be monitored throughout the procedure, preferably by cannulation of an artery.

Constrictive Pericarditis

Constrictive pericarditis is seldom an indication for admission to a CICU and therefore is not discussed in detail here. When patients with late stage disease are admitted, they have severe anasarca that should be ameliorated in a manner similar to that for patients with severe congestive heart failure, except that no attempt should be made to achieve a normal central venous pressure. This precaution is necessary because overly vigorous diuresis causes hypotension and low cardiac output and may lead to the patient's death, but enough fluid should be removed to make the patient comfortable and improve renal and hepatic function and protein-losing enteropathy. Patients not previously known by the CICU staff may be admitted for acute decompensated heart failure when the correct diagnosis is ultimately found to be constrictive pericarditis. A clue to the diagnosis of constrictive pericarditis is a patient who presents the findings usually associated with right heart failure but in whom there is no discernible cause or evidence of heart disease. Another clue is that the BNP level is significantly lower than expected. Suspicion that a patient has constrictive pericarditis rather than heart failure should lead to echo-Doppler evaluation, which would show elevated central venous pressure with absent respiratory variation, except for the y descent. As in cardiac tamponade, enhanced ventricular interaction is the cause of greatly increased respiratory variation of transmitral and transtricuspid velocity.

Imaging is very helpful in distinguishing heart failure, particularly when it is a manifestation of restrictive cardiomyopathy. Whereas the profile of mitral inflow velocity shows a severe restrictive pattern in both, the tissue Doppler findings in each are very different. Details are beyond the scope of this chapter, but are summarized in a review paper.³⁷

Acute Respiratory Failure

Marc Chalaby, Jay I. Peters

CHAPTER 31

Physiology of Gas Exchange Pathophysiology of Acute Respiratory Failure

Conclusion

RESPIRATORY FAILURE is defined as the inability to maintain either the normal delivery of oxygen to tissues or the normal removal of carbon dioxide from the tissues. From a physiologic perspective, respiratory failure can be caused by diffuse pulmonary dysfunction (ventilation/perfusion [$\dot{V}/\dot{Q}$] mismatch or pulmonary shunt), neurologic dysfunction (depression of the respiratory drive), cardiac dysfunction (low cardiac output or pulmonary edema), or a lack of hemoglobin to transport gases. Clinically this is seen as arterial hypoxemia leading to tissue hypoxia and/or arterial hypercapnia. Acute respiratory failure (ARF) may evolve over a period of minutes or hours to days depending on the clinical situation. ARF, therefore, is a generic term that encompasses a heterogeneous spectrum of diseases that eventually end with the same pathophysiologic outcomes, namely, arterial hypoxemia (usually with P_{aO_2} of less than 60 mm Hg) or hypercapnia (P_{aCO_2} of >45 to 50 mm Hg).

Physiology of Gas Exchange

In the lung, gas exchange occurs at the capillary-alveolar interface. Close examination of septal capillaries reveals that they are significantly thinner on the side that bulges into the air space. This conformation enhances the diffusion of oxygen from the air space into the blood and the elimination of carbon dioxide from the blood into the air space. Equilibration of partial pressures of gases between the two compartments occurs rapidly. Oxygen in the blood is carried by hemoglobin. Only a small percentage is transported as dissolved gas. The following equation describes the arterial oxygen content (CaO_2):

$$CaO_2 = (1.36 \times Hgb \times SaO_2) + (0.003 \times PaO_2)$$

where CaO_2 is the oxygen content of arterial blood in milliliters of O_2 per deciliter of blood; Hgb is the hemoglobin concentration in grams per deciliter of blood; SaO_2 is the fraction of hemoglobin sites bound by oxygen; and PaO_2 is the arterial partial pressure of oxygen.

Because the amount of dissolved oxygen is small in comparison to the amount transported by hemoglobin, in most clinical situations, CaO_2 depends primarily on the hemoglobin concentration and the oxygen saturation of the arterial blood, not on PaO_2 . Even in severe anemia, the contribution of dissolved oxygen in the overall CaO_2 is negligible despite very high PaO_2 . This principle is important clinically in patients with ARF for whom increasing CaO_2 can be accomplished by increasing hemoglobin

concentration and SaO_2 , but not necessarily by increasing PaO_2 . This follows from the sigmoid shape of the oxygen-hemoglobin dissociation curve, in which significantly higher PaO_2 is needed to increase the SaO_2 beyond 90% as the curve plateaus.

Carbon dioxide is transported in the blood mostly in the form of carbonic acid. Only approximately 5% is transported by binding with hemoglobin. Ten percent is transported as dissolved gas.¹ As the tissues extract more and more oxygen from the blood, the deoxygenated hemoglobin increases its ability to carry carbon dioxide (Haldane effect). Similarly, as more and more oxygen becomes available in the arterial and venous blood, less carbon dioxide may be carried by the oxidized hemoglobin. This effect has been implicated in the pathogenesis of worsening hypercapnia after oxygen supplementation in patients with baseline hypercapnia.

To achieve optimal gas exchange, local matching of ventilation and perfusion has to occur. The interrelationships between ventilation and blood flow are shown schematically in Figure 31-1 where imbalance (B) is typified by bronchospasm, shunt (C) is typified by dense pneumonia or severe acute respiratory distress syndrome (ARDS), and dead space (D) is typified by digestion of the capillaries in emphysema.

Normally, both ventilation and perfusion exhibit a gradient from the top to the bottom of the lung. However, the gradient is more pronounced in blood flow than in ventilation, such that in the upper portions of the lung there are predominantly high $\dot{V}/\dot{Q}$ areas and in the lower portions of the lung, low $\dot{V}/\dot{Q}$ areas. The overall $\dot{V}/\dot{Q}$ ratio of the normal lung is 0.8.²

The overall efficiency of gas exchange can be assessed in terms of maintenance of normal PaO_2 and $PaCO_2$. The assessment can be performed by calculating the alveolar-arterial partial pressure oxygen difference ($PAO_2 - PaO_2$), which is also known as the A-a gradient. The mean alveolar oxygen tension (PAO_2) is calculated by using the alveolar gas equation as follows:

$$PAO_2 = (P_B - PH_2O) \times FiO_2 - \frac{PaCO_2}{R}$$

where P_B is the barometric pressure of the atmosphere, which changes with altitude; FiO_2 is the fraction of inspired oxygen (approximately 0.21 in room air); $PaCO_2$ is the partial pressure of arterial carbon dioxide; and R is the respiratory quotient.

This equation gives an estimation of PAO_2 , which changes with altitude (P_B), with inspired oxygen concentration, and with $PaCO_2$. PaO_2 not only changes with changes in PAO_2 but also decreases

Figure 31-1. Schematic representation of various patterns of ventilation ($\dot{V}$) and perfusion ($\dot{Q}$). **A**, Normal $\dot{V}/\dot{Q}$ ratio in which the $P\dot{V}O_2 = 40$ mm Hg and $P\dot{C}O_2 = 46$ mm Hg. After equilibration, the capillary $PO_2 = 101$ mm Hg, $PCO_2 = 40$ mm Hg, and $P(A - a)O_2 = 0$ mm Hg. **B**, $\dot{V}/\dot{Q}$ imbalance caused by airway obstruction would decrease the PO_2 . This could be corrected with supplemental oxygen. **C**, A shunt allows mixed venous blood to traverse the capillary without any gas transfer. **D**, Dead space, the ventilated area of the lung that does not participate in gas exchange. (From Greene KE, Peters JI: Pathophysiology of acute respiratory failure. *Clin Chest Med* 1994;15:1-11.)

with age in normal individuals. Therefore $PAO_2 - PaO_2$ increases with age and can be estimated in most adults breathing room air to be approximately 4 mm Hg for each decade of life until the maximum of the seventh decade. This estimation is not valid for patients receiving oxygen supplementation. For these patients, assessment of efficiency of gas exchange can be obtained using the ratio of PaO_2 to FiO_2 (PaO_2/FiO_2 ratio normally is above 400 mm Hg). Although it is not as accurate as the $PAO_2 - PaO_2$ difference, it is useful clinically because most patients with ARF receive supplemental oxygen at the time blood gas analysis is performed. This ratio also forms one of the newer basic criteria for the diagnosis of acute lung injury or ARDS. By consensus acute lung injury is defined as noncardiogenic pulmonary edema with a PaO_2/FiO_2 ratio of less than or equal to 300 mm Hg; ARDS is diagnosed in the presence of a ratio of less than or equal to 200 mm Hg.³ This ratio is most helpful when used serially or when the ratio changes significantly with a therapeutic maneuver.

Pathophysiology of Acute Respiratory Failure

The three most important pathophysiologic mechanisms that cause ARF are hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunt. Diffusion abnormalities, which occur with mild pulmonary edema or early interstitial lung disease, may cause exercise-induced hypoxemia but rarely cause clinically significant hypoxemia. Reduction of inspired PO_2 and venous admixture are other potential but less common causes of hypoxemia.

Hypoventilation can be defined as the inadequate movement of fresh alveolar gas necessary for maintaining a normal $P\dot{C}O_2$. Pure hypoventilation is a relatively uncommon clinical event. In most cases, hypoventilation occurs along with other causes of hypoxemia.

When pure hypoventilation does occur, it is usually caused by depression of the respiratory center by sedative-hypnotic drugs or by neuromuscular diseases that affect the respiratory muscles.

Figure 31-2. Variations in PO_2 , PCO_2 , and O_2 content in a gas exchange lung unit as its ventilation-perfusion ratio is progressively increased. This lung is assumed to be breathing air, and the mixed venous blood PO_2 and PCO_2 are 40 mm Hg and 45 mm Hg. (From West JB: Ventilation-perfusion relationships. *Am Rev Respir Dis* 1977;116:919-943.)

The increase in $P\dot{C}O_2$ that accompanies pure alveolar hypoventilation invariably affects PAO_2 as predicted in the alveolar gas equation, causing a decrease in PAO_2 . This results in hypoxemia with a normal $PAO_2 - PaO_2$ gradient. In patients on room air, the PaO_2 will fall 5 mm Hg for every 3 mm Hg rise in $P\dot{C}O_2$. If the $PAO_2 - PaO_2$ gradient is abnormally increased, then other mechanisms may also be involved in the pathogenesis of hypoxemia. Hypoxemia resulting from pure alveolar hypoventilation usually responds adequately to increasing FiO_2 .

By far the most common cause of clinically important hypoxemia is $\dot{V}/\dot{Q}$ mismatching. $\dot{V}/\dot{Q}$ mismatching is present as a continuum from pure shunt $\dot{Q}$ without $\dot{V}$ to pure dead space ventilation $\dot{V}$ without $\dot{Q}$, with unlimited patterns of $\dot{V}/\dot{Q}$ mismatching in between. In young normal individuals, $\dot{V}/\dot{Q}$ ratios range from 0.6 to 3.0 and usually center around 1.0.⁴ Low $\dot{V}/\dot{Q}$ lung units can result from compromised ventilation such as obstructed airways or from partial alveolar filling with pneumonia or pulmonary edema. High $\dot{V}/\dot{Q}$ lung units most often occur with obstruction of blood flow due to pulmonary vascular disease or from a lack of capillaries due to lung parenchymal destruction such as that seen in emphysema.

$\dot{V}/\dot{Q}$ mismatching causes hypoxemia and hypercapnia. However, in most cases, an increase in minute ventilation stimulated by hypercapnia results in normalization of $P\dot{C}O_2$ with persistent hypoxemia. This is possible because the CO_2 dissociation curve is linear, allowing well-ventilated areas to compensate. The O_2 dissociation curve is sigmoid-shaped; therefore the increase in minute ventilation, despite producing higher end-capillary PO_2 , results in very modest changes in oxygen saturation, which in most cases is inadequate to reverse the hypoxemia (Figure 31-2). Hypoxemia due to $\dot{V}/\dot{Q}$ mismatching is usually correctable with increasing the FiO_2 . Local hypoxia in low $\dot{V}/\dot{Q}$ areas triggers reflex hypoxic pulmonary vasoconstriction in an attempt to correct the $\dot{V}/\dot{Q}$ imbalance. This reflex vasoconstriction can be abolished by a number of vasodilators, including nitroprusside, nitroglycerin, calcium channel blockers, and inhalational anesthetics. When

compensatory mechanisms fail in a patient with severe lung disease, the body may set a new steady state PaCO_2 and pH as an adaptive response to conserve the work of breathing.

Right-to-left shunt occurs when there is no ventilation into a lung unit while perfusion is preserved. It is one of the extreme ends in the spectrum of $\dot{V}/\dot{Q}$ mismatches. In a normal lung, the amount of shunt present is less than 5%. Shunt in the lung results from atelectasis, severe pulmonary edema, and air space consolidation such as pneumonia. In addition, right-to-left shunt can also occur as a consequence of arteriovenous malformation and intracardiac shunts from a patent foramen ovale, patent ductus arteriosus, or ventricular septal defect. Shunt causes significant hypoxemia due to the mixture of oxygenated blood with shunted, poorly oxygenated venous blood. Hypercapnia is usually not present until the shunt is greater than 50%. In contrast to other mechanisms of respiratory failure, hypoxemia due to shunting is not responsive to increases in FiO_2 . This feature of shunt can be conveniently used to separate it from other causes of hypoxemia. Calculation of shunt ($\dot{Q}_s/\dot{Q}_t$) is easily done by administering 100% oxygen for 15 minutes and then analyzing arterial blood gases. Percent shunt can be estimated using a nomogram or by using the following formula:

$$\dot{Q}_s/\dot{Q}_t = \frac{(C_{\text{CO}_2} - C_{\text{aO}_2})}{(C_{\text{CO}_2} - C_{\text{vO}_2})} \times 100$$

In this equation, C denotes content, and the lower case letters c , a , and v denote end-capillary, arterial, and venous blood, respectively. A simplified shunt equation assumes that the C_{vO_2} is normal and that the shunt is less than 25%. This simplified shunt equation states

$$\dot{Q}_s/\dot{Q}_t = \frac{\text{PAO}_2 - \text{PaO}_2}{20}$$

When the FiO_2 used is less than 1.0, the resulting calculation is called venous admixture instead of shunt. This reflects the contribution of severe $\dot{V}/\dot{Q}$ mismatching, including very low $\dot{V}/\dot{Q}$ ratios that approach zero, which may act like shunts when alveoli are not ventilated with 100% oxygen.

The hypoxemia of shunt is remarkably resistant to correction by increasing the FiO_2 . Patients with significant shunts may have the same arterial oxygen saturation when maintained on a relatively toxic FiO_2 (near 1.0) or when titrated down to relatively safe FiO_2 (0.6 to 0.7).

Clinical Assessment

Patients with ARF commonly have dyspnea. For those with underlying lung disease, dyspnea may be present chronically. Therefore mild changes in the degree of dyspnea may or may not be perceived. In the presence of significant hypoxemia and acidosis, patients may have symptoms of central nervous system depression ranging from irritability to coma. Patients may also have evidence of the effects of hypoxemia or acidosis on the cardiovascular system, such as arrhythmias, angina, or infarction. Depending on the underlying disease, other symptoms may also be present. Although they may be important and helpful in evaluating the underlying process causing the respiratory failure, they are not that helpful in evaluating the degree of respiratory dysfunction. For example, the additional symptoms of cough, sputum production, and fever may suggest pneumonia, whereas pleuritic chest pain with certain characteristics may

suggest pneumothorax or pulmonary embolism as the cause of the respiratory distress.

Initial physical examination of patients with ARF should focus on overall appearance, vital signs, and the ABCs (airway, breathing, circulation). In general, patients with ARF have tachypnea, tachycardia, and variable mental status. Assessment of mental status may help by anticipating the cooperation the patient will give in the process of evaluation and management. The degree of alteration of mental status may reflect the severity of the respiratory failure. Confusion or disorientation in the presence of dyspnea and tachypnea may reflect profound hypoxemia or hypercapnia with its attendant respiratory acidosis. Pulsus paradoxus, a decrease in arterial systolic pressure of greater than 10 mm Hg with inspiration, also suggests severe airway obstruction associated with significant negative intrathoracic pressures. Patients with severe respiratory distress are usually unable to speak in full sentences. Likewise, the presence or absence of adventitious breath sounds may assist the clinician in evaluating the degree and acuity of the respiratory distress. Crackles suggest alveolar flooding or early bronchopneumonia, whereas rhonchi often herald an increase in mucus production or an inability to clear secretions. Wheezing suggests airway obstruction, whereas wheezes located over the neck suggest upper airway stridor that may be associated with respiratory collapse. Decrease in breath sounds may be seen in patients with chronic obstructive pulmonary disease (COPD) or those with severe airway obstruction. The absence of wheezing and breath sounds in a patient with underlying obstructive lung disease and respiratory distress may suggest impending respiratory collapse as a result of very limited air movement. Absence of breath sounds may also be associated with pneumothorax. Subcutaneous emphysema usually indicates pneumomediastinum with or without accompanying pneumothorax.

Despite advances in noninvasive technologies in oxygenation assessment, arterial blood gas analysis remains the best and most accurate test in the initial assessment of patients with ARF. Pulse oximetry is acceptable as a method for following oxygenation once it has been calibrated to true blood gas co-oximetry saturation and the arterial PaO_2 is known. Pulse oximetry (SpO_2) carries $\pm 4\%$ error in measuring oxygen saturation. In patients with carbon monoxide poisoning, SpO_2 does not reflect true PaO_2 , and profound hypoxemia may be missed. With methemoglobinemia, the SpO_2 may falsely read the oxygen saturation at around 85%, irrespective of the true saturation. Furthermore, pulse oximetry does not give information on PaCO_2 and pH, which may be crucial in the differential diagnosis and management of the patient with ARF. The presence of hypercapnia is a marker of the severity of disease. Hypercapnia is more likely to complicate hypoxemic failure when the disease is superimposed on significant underlying lung or neuromuscular disease.

The presence of hypoxemia, hypercapnia, and respiratory acidosis can be used to define ARF, but it is difficult to set specific levels of PaO_2 or PaCO_2 because patients with underlying lung disease may have markedly abnormal baselines. Given these qualifications, generally patients with ARF have a PaO_2 less than 55 mm Hg or a PaCO_2 more than 50 mm Hg. The pH is very helpful in assessing the acuity of the hypoventilation. In cases of subacute or chronic hypoventilation, the patient usually has an elevated serum bicarbonate level and a mild depression of the pH. In acute respiratory acidosis without renal compensation, the pH drops by 0.08 for each 10-mm Hg rise in PaCO_2 .

Table 31–1. Radiographic Approach to Acute Respiratory Failure

Radiograph	Clinical Characteristics	Responses to Oxygen*
“White” Chest Radiograph		
Pneumonia	Fever, leukocytosis, sputum production	+ to + + +
Adult respiratory distress syndrome	Predisposing risk factors, wedge $\leq$ 18 mm Hg	+ to + +
Cardiogenic edema	Paroxysmal nocturnal dyspnea, orthopnea, edema	+ + + to + + + +
Interstitial lung disease	Prior chest radiographic abnormalities	+ + + to + + + +
“Black” Chest Radiograph		
Chronic obstructive pulmonary disease/asthma	Reduced flow on bedside spirometry	+ + to + + + +
Pulmonary emboli	Acute dyspnea, pleuritic pain	+ + + to + + + +
Right-to-left shunt	History and physical examination consistent with pulmonary hypertension	+
Microatelectasis	Postoperative or rib fracture, bronchial breath sounds	+ + to + + +

*Range from +, which is shuntlike (Po_2 increases 1 mm Hg for 1% rise in FiO_2), to + + + +, which is $\dot{V}/\dot{Q}$ imbalance (Po_2 increases 5 mm Hg for 1% rise in FiO_2)

Compensatory bicarbonate retention or wasting by the kidneys to buffer the pH changes usually takes 2 to 3 days to occur. After renal compensation, a change of 10 mm Hg of PaCO_2 will produce 0.03 change in pH in the opposite direction.

The chest radiograph is useful in sorting out the differential diagnosis of ARF during the initial presentation. The causes of hypoxemia can be classified based on radiographic appearance. Table 31-1 shows examples of diseases associated with “white” chest radiographs showing diffuse or patchy infiltrates and diseases associated with “black” chest radiographs showing normal or clear lung fields.

Differential Diagnosis

The clinical classification of ARF based on chest radiographic appearance provides a convenient algorithm in evaluating hypoxemic patients. PA and lateral films or CT of the chest provide better quality than portable films and can help visualize the retrocardiac space. Patients having a “white” chest radiograph usually have pneumonia, ARDS, cardiogenic pulmonary edema, or progressive interstitial lung disease. Patients having a “black” chest radiograph usually have obstructive lung disease, pulmonary emboli, a right-to-left shunt, or microatelectasis. Most patients with hypoxemic respiratory failure have radiographic infiltrates. The presence of additional compatible history and physical examination findings often allows the clinician to narrow the differential diagnosis. With fever, cough, sputum production, and lobar or patchy infiltrate, pneumonia is a likely possibility. Pneumonia often presents in an atypical fashion in older patients (those older than 65 years old).⁵ Up to 50% of older patients do not have a fever or specific respiratory complaints, and confusion or mild hypotension may be the primary findings on examination. Cardiogenic pulmonary edema superimposed on abnormal lung parenchyma such as in emphysema will often give bilateral patchy radiographic infiltrates and not necessarily the classic central batwing distribution. In such cases, a history of underlying heart disease and compatible physical examination may aid in arriving at the presumptive diagnosis of congestive heart failure. In recent

years, an increase in the use of brain natriuretic peptide levels (BNP) have been used to support the diagnosis of heart failure. A recent review by Korenstein pooled over 3000 patients and determined that BNP of less than 100 pg/mL essentially rules out the diagnosis of heart failure, whereas a BNP greater than 400 pg/mL has a sensitivity and specificity of 81% and 90%, respectively.⁶ Elevated levels do not distinguish between right and left ventricular failure and may be seen in patients having pulmonary emboli and cor pulmonale. BNP levels have also been noted to be elevated in patients with septic shock without evidence of clinical heart failure.

The most helpful feature in separating these disorders is the radiographic response to therapy. Radiographically, pneumonia resolves over 3 to 12 weeks, whereas cardiogenic pulmonary edema may clear over days. In the absence of supportive clinical evidence for left ventricular failure, diffuse infiltrates may represent noncardiogenic pulmonary edema, pulmonary hemorrhage, or interstitial pneumonitis. Noncardiogenic pulmonary edema (ARDS) most often occurs in hospitalized patients. If a patient presents to the hospital with ARDS, a diagnosis of severe bilateral pneumonia should strongly be considered. Most patients with ARDS have one of the common precipitating factors leading to this disorder. The common predisposing events include sepsis, hypotension, massive aspiration, severe pneumonia, and massive trauma or transfusions. Less common precipitating events include pancreatitis, drug overdose, and postcardiopulmonary bypass surgery. Revised criteria for ARDS are listed in Table 31-2.³ Low tidal volumes of 6 to 8 mL/kg of ideal body weight and plateau pressures less than 30 to 32 cm/H₂O have been shown to significantly reduce mortality in patients with ARDS.⁷ Comprehensive reviews of ARDS have been published⁸ and therapeutic trials and protocols are maintained on the ARDS-net website (www.AARDSnet.org). In a patient with a history of joint complaints, an undiagnosed rash, or unexplained renal insufficiency, a diagnosis of vasculitis or collagen vascular disease should be considered. In the presence of an acute drop in hematocrit, pulmonary hemorrhage syndrome may

Table 31–2. The American-European Consensus Criteria of Acute Lung Injury and Acute Respiratory Distress Syndrome.

Shared Criteria	
• Acute onset • Bilateral infiltrates on frontal chest radiograph • Pulmonary artery occlusion pressure ≤ 18 mm Hg or no clinical evidence of left atrial hypertension	
Specific Criteria	
• Acute lung injury: $P_{aO_2}/F_{iO_2} \leq 300$ mm Hg • Acute respiratory distress syndrome: $P_{aO_2}/F_{iO_2} \leq 200$ mm Hg	

be entertained, in which case, a definitive diagnosis including lung biopsy may be essential to allow proper treatment and management. In some cases, pulmonary hemorrhage is not accompanied by hemoptysis. The Infectious Diseases Society in conjunction with the American Thoracic Society has recently published consensus guidelines on the management of community-acquired pneumonia in adults. The antibiotics regimen chosen by the IDSA/ATS mainly relies on macrolides (with or without a β -lactam), or respiratory fluoroquinolones (e.g., levofloxacin or moxifloxacin), for outpatient therapy. They recommend respiratory fluoroquinolones or cephalosporins plus macrolides for hospitalized patients. In 2005, the IDSA/ATS also published evidence-based guidelines for hospital-acquired pneumonia (HAP), including health care-associated pneumonia (HCAP) and ventilator-associated pneumonia (VAP) that were again updated in 2007. The major goals of this evidence-based guideline for the management of HAP, VAP, and HCAP emphasize early, appropriate antibiotics in adequate doses, while avoiding excessive antibiotics by de-escalation of initial antibiotic therapy based on microbiologic cultures and the clinical response. If patients receive an initially appropriate antibiotic regimen, efforts should be made to shorten the duration of therapy from the traditional 14 to 21 days to periods as short as 7 days if the patient has a good clinical response with resolution of clinical features of infection and the etiologic pathogen is not *Pseudomonas aeruginosa*.^{9–10}

Pneumonia may be difficult to distinguish from atelectasis presenting as a localized infiltrate. Atelectasis can be seen with pulmonary embolism (PE), diaphragmatic dysfunction with volume loss, splinting from rib fracture or pleuritis, and in mechanically ventilated patients. Unfortunately, the presenting signs and symptoms may overlap in many instances, including dyspnea, chest pain, fever, and leukocytosis. High clinical suspicion is needed not to miss PE. Mortality of untreated PE has been reported to be about 30%, and with treatment approximately 8%.¹¹ High probability $\dot{V}/\dot{Q}$ scan carries a positive predictive value for PE of 88%.¹² With the addition of strong clinical suspicion, the positive predictive value is as high as 96%. About 12% of patients with low probability $\dot{V}/\dot{Q}$ scan may have angiographically proven PE. Therefore, if PE is clinically suspected, further evaluation after a low probability scan is needed. Evaluation of the lower extremities for deep venous thrombosis with Doppler ultrasonography is noninvasive and, if positive, obviates the necessity to perform pulmonary angiography. If the patient

does not have a high pretest probability of PE, some advocate repeating the Dopplers after 72 hours. If both Doppler studies are negative, there is a very low probability of significant PE. Pulmonary angiography has been shown to be safe in 755 patients enrolled in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study. The diagnostic utility of $\dot{V}/\dot{Q}$ scans for acute PE persists even in the presence of preexisting cardiac or pulmonary disease.^{13–14} In recent years there has been an increased use of D-dimer in patients presenting to the emergency department. D-dimer is formed from the degradation products of cross-linked fibrin by plasmin. It is very sensitive but nonspecific (elevated in almost all patients with carcinoma and most seriously ill hospitalized patients) for either DVT or PE. A negative D-dimer using enzyme-linked immunosorbent assays (ELISA) has a negative predictive value of 95%.¹⁵

Righini and colleagues showed that a diagnostic strategy including clinical probability, D-dimer, Doppler ultrasonography, and helical CT was highly cost-effective. A negative D-dimer in the setting of a negative Doppler ultrasound may obviate the need for further testing.¹⁶ Helical CT with a PE protocol has virtually replaced pulmonary angiography. The great benefit of CT is in providing an additional diagnosis to explain the patient's symptoms; its sensitivity and specificity ranges from 78% to 100%; its accuracy drops in the areas of atelectasis and segmental or subsegmental vessels. Multidetector scanning increases the sensitivity to 89% and can visualize thrombi up to the sixth pulmonary artery branch. The PISA-PED investigators recently published diagnostic algorithms based on their 40 years of experience that relies heavily on ventilation/perfusion lung scanning and only used multidetector scanning in 16% of the cases when there was discordance between pretest probability and lung scanning. This option may be very useful in patients who cannot tolerate IV dye secondary to renal insufficiency.¹⁷

Exacerbation of underlying obstructive lung disease is the most common cause of hypoxemic respiratory failure in patients who do not have infiltrates on chest radiography. The most important precipitants of ARF in patients with COPD are airway infection, congestive heart failure, anatomic interference with chest wall function (e.g., pleural effusion, pneumothorax, or rib fracture), and medication noncompliance.¹⁸ Additionally, PE and oversedation can also precipitate respiratory distress. The most common bacteria isolated from the airway and lungs of patients with COPD are *Haemophilus influenzae* and *Streptococcus pneumoniae*¹⁹ (and *Moraxella catarrhalis*). Antibiotics have been shown to be beneficial in patients having at least two of the following: dyspnea, increased sputum production, and sputum purulence.²⁰ Therefore a β -lactam antibiotic (e.g., amoxicillin, oral cephalosporin) or trimethoprim-sulfamethoxazole are frequently given during exacerbations of COPD. Recent studies have documented the benefit of oral corticosteroids in acute exacerbations of COPD. A large randomized controlled study of 271 patients with COPD exacerbation who were randomly assigned to receive either systemic corticosteroids or placebo for up to 2 weeks demonstrated that systemic corticosteroids reduced the 30-day treatment failure rate (23% versus 33%), the 90-day treatment failure rate (37% versus 48%), and hospital stay (8 versus 10 days), while improving lung function. Standard practice is to now treat all significant exacerbations with 7 to 10 days of oral corticosteroids.²¹

Another cause of respiratory failure with a normal chest radiograph is a right-to-left shunt. The presence of a significant shunt can be suspected when arterial hypoxemia is resistant to improvements with higher FiO_2 . An acute rise in right-sided cardiac pressures from PE or from right ventricular infarction may acutely open the foramen ovale and cause a right-to-left shunt. An echocardiogram with a bubble study may be used to detect a cardiac shunt. Finding radio-macroaggregated albumin in the brain or kidney after a lung perfusion scan is a sensitive and specific way of identifying the presence of a pulmonary or cardiac right-to-left shunt.

Microatelectasis is another cause of respiratory failure with a normal chest radiograph. This disorder almost always occurs in the setting of inadequate ventilation, usually seen in postoperative patients or in the setting of splinting secondary to chest wall pain. Diffuse alveolar collapse leads to bronchial breath sounds at the base of the lung without the infiltrate that is seen with obstructive atelectasis. The use of analgesics for pain, incentive spirometry, and the addition of positive pressure to the airway leads to resolution of this process. In hospitalized patients, inspiratory positive pressure breathing devices with nebulized therapy is often beneficial, especially in postoperative patients.

Hypercapnia may develop in patients with either a “black” (normal) chest radiograph or “white” (infiltrative) chest radiograph. Hypercapnic respiratory failure results usually from alveolar hypoventilation or severe $\dot{V}/\dot{Q}$ mismatching or a combination of the two. In patients with normal lungs, it generally occurs in the setting of reduction in central nervous system respiratory drive or acute neuromuscular weakness. In both cases, alveolar hypoventilation is the predominant mechanism. In patients with preexisting lung disease, hypercapnic respiratory failure usually occurs in the setting of severe lung disease and $\dot{V}/\dot{Q}$ mismatching. Whatever the triggering event may be, the patient is generally incapable of increasing the minute ventilation needed to compensate for the increased ventilatory workload requirements.

Reduction in central nervous system respiratory drive may be caused by sedative-hypnotic medications or depressed mental status from organic and metabolic or hypoxic encephalopathy. Although patients with stroke or brain hematoma rarely have clinically significant depression of respiratory drive, hypercapnia may still occur if the breaths are shallow with small tidal volumes, increasing dead space ventilation and resulting in alveolar hypoventilation. Acute hypoxemia that results in global brain hypoxia may also lead to depression of mental status and alveolar hypoventilation.

Neuromuscular weakness is a less common cause of clinically significant alveolar hypoventilation. Typically the tidal volume is reduced secondary to shallow breathing, with increased respiratory rate, in an attempt to restore minute ventilation. This type of shallow and rapid breathing increases dead space ventilation, and given the same minute ventilation, alveolar ventilation will be reduced. Amyotrophic lateral sclerosis, high cervical spinal cord injury, Guillain-Barré syndrome, myasthenia gravis, phrenic nerve paralysis, and muscular dystrophy may result in both hypercapnic and hypoxemic respiratory failure. Hypercapnia may also result from respiratory muscle fatigue after a period of sustained rapid breathing, such as seen in the later stages of acute exacerbations of asthma or COPD.

Hypercapnic respiratory failure that occurs in the absence of respiratory drive depression or neuromuscular weakness is usually caused by severe $\dot{V}/\dot{Q}$ mismatching and often associated with conditions that increase CO_2 production $\dot{V}/\dot{Q}$. Fever increases $\dot{V}\text{CO}_2$ by 13% for each degree Celsius.²² Patients with severe preexisting $\dot{V}/\dot{Q}$ abnormality, in particular those with large low $\dot{V}/\dot{Q}$ areas, may not be able to compensate for the increased workload. Therefore when compensatory efforts fail in a COPD patient with pneumonia and fever, hypercapnia ensues. Patients with severe lung disease, baseline hypoxemia, and hypercapnia are also at risk of worsening the hypercapnia when they receive oxygen supplementation. When these patients require oxygen therapy for hypoxemic exacerbation, extreme caution must be exercised to prevent too much oxygen. Low flow oxygen (1 to 2 L/min nasal cannula or 24% to 28% FiO_2 by mask) should be started and titrated up until the saturation is approximately 90%. If acute severe hypercapnia occurs, assisted ventilation is the treatment of choice. The pathophysiology of this process is still being debated and may involve three mechanisms.²³⁻²⁵ Worsening of $\dot{V}/\dot{Q}$ mismatching is believed by many to be the major mechanism. Additionally, displacement of CO_2 molecules from hemoglobin (known as the Haldane effect) has been proposed but probably plays only a small role. Finally, suppression of hypoxic ventilatory drive has long been debated and remains controversial.

Management

The initial approach to managing patients in acute respiratory failure is supportive. The essential first step remains assessment of airway patency, presence of breathing, and adequacy of circulatory function. Once this is ensured, specific treatments must be directed at the underlying disease that initiated respiratory failure. Specific therapy for each of these disorders is beyond the scope of this chapter but has been reviewed.²⁶

In most cases, administration of supplemental oxygen is required. The ultimate goal of oxygen therapy is to provide adequate oxygen to the tissues, thereby preserving tissue and organ function. Because there is no clinically useful measure of cellular oxygen tension, tissue hypoxia can only be indirectly predicted from overall organ function and oxygen transport. The critical level of hypoxemia that compromises organ function varies depending on the organ system and local factors. Clinical studies in patients without adaptive mechanisms suggest that short-term memory is adversely affected at PaO_2 less than 55 mm Hg.²⁷ Generally, PaO_2 of about 60 mm Hg, usually corresponding to SaO_2 of about 90%, is considered as an adequate target. Further increase in PaO_2 offers little additional benefits because of the shape of the oxygen-hemoglobin dissociation curve and determinants of arterial oxygen content and may potentially increase the risk of hypercapnia in some patients. Therefore hypoxemic patients with severe lung disease, especially those with baseline hypercapnia, must be monitored closely with serial blood gases for correction of hypoxemia and prevention of worsening hypercapnia. The use of pulse oximetry to follow the adequacy of oxygenation may be appropriate if the pulse oximetry saturation (SpO_2) has been properly calibrated to accurately reflect co-oximetry saturation (SaO_2) of the patient when hypercapnia is not a concern.

Once the decision for oxygen supplementation has been made, the next step is to choose the method of delivery. In patients who are intubated, delivery of oxygen can be accomplished through a ventilator or through a T-piece, the latter if

mechanical breaths are not needed. For patients who are not intubated, there are several choices of oxygen delivery systems.

Nasal cannula is the most commonly used low-flow system. It delivers pure (100%) oxygen at various rates up to 5 to 6 L/min. Rates beyond this are associated with nasal mucosal and septal complications. This system is simple to use and comfortable, allowing the patient to speak, eat, and drink without much interference. As is true with all low-flow systems, the FiO_2 is not accurate, depending on several factors, including total minute ventilation. Investigators have measured an FiO_2 of 48% with 6 L/min and high-flow heat humidified nasal cannulas may go up to 15 L and achieve FiO_2 in the 75% range.²⁸⁻²⁹ A simple face mask also delivers low-flow oxygen with a somewhat higher FiO_2 than a nasal cannula because of the presence of 100 to 200 mL of reservoir space between the mask and the patient's face. It must be removed transiently when the patient eats or drinks. Face masks with reservoir bags come in two varieties. A partial rebreather mask has a reservoir that is filled with pure oxygen mixed with a small amount of early exhaled gas that mainly comes from high oxygen tension dead space. This mask is able to achieve FiO_2 of 0.6 to 0.8. A non-rebreather mask has a reservoir containing pure oxygen and is not mixed with exhaled gas. In addition, there are one-way exhalation valves allowing exhaled gas to leave the mask without inhaling air. This mask allows the achievement of FiO_2 close to 0.9, but not quite 1.0, because of the presence of small amounts of exhaled gas in the space between the mask and the face.

Venturi masks are low-flow masks that use the Bernoulli principle to entrain room air when pure oxygen is delivered through a small orifice, resulting in a large total flow at predictable FiO_2 . The size of the orifice determines the FiO_2 . This oxygen delivery system is useful in patients with ARF who require oxygen supplementation, but in whom there is substantial risk for development or worsening of hypercapnia because the FiO_2 does not fluctuate significantly even with considerable changes in the patient's minute ventilation. Venturi masks or a Venturi device in a humidifier-mixer is accurate only to 40% to 50% FiO_2 ; above this range, many patients overbreathe the system. When a higher FiO_2 is required, a high-flow mask (e.g., Misty-Ox) and a high-flow regulator (that can go up to 30 L/min) is recommended. With all these masks, there is significant deterioration of oxygen delivery as the respiratory rate increases, as when the patient is in respiratory distress. At 30 breaths/min, the FiO_2 delivered by a 15-L oxygen mask can drop from 95% to 60% due to entrainment of ambient air and dilution of the inspired oxygen concentration. In a recent study by Wagstaff, the high levels of inspired oxygen concentration was achieved by a 15-L nasal cannula using a Vapotherm system that humidifies and warms the oxygen-air mix and makes it more tolerable to the patient.²⁸ An alternative is to use a non-rebreather mask where a reservoir bag with a one-way flap is connected to the mask and fills during the patient's expiration.

Aside from the risk of hypercapnia, there are other risks associated with oxygen therapy. High FiO_2 decreases the amount of inert nitrogen that fills and stabilizes peripheral airways and alveoli while oxygen is being rapidly removed from the alveoli, resulting in atelectasis. Absorption atelectasis causes a decrease in vital capacity and an increase in right-to-left shunt, which leads to worsening of hypoxemia. This is more frequently seen at FiO_2 above 0.7. High FiO_2 can also lead to tracheo-bronchitis and acute lung injury with capillary leak syndrome.³⁰ When this happens it is often difficult to distinguish from worsening of the

underlying condition that initially precipitated ARF. In general, FiO_2 of 1.0 can be used for 24 hours and FiO_2 of 0.9 can be used for 72 hours without significant sequelae. FiO_2 of 0.6 or less is usually well tolerated without significant long-term histologic and physiologic changes. If a patient requires very high FiO_2 with the above methods, ventilatory-assist devices should be considered to allow the FiO_2 to be lowered, thereby decreasing the risks of atelectasis and oxygen toxicity. These include non-invasive ventilation using continuous positive airway pressure through nasal or face mask and invasive mechanical ventilation through an endotracheal tube.

Over the past few years there has been a renewed interest in the use of noninvasive ventilation in the management of ARF. Several pilot studies have shown useful applications of these techniques in avoiding intubation in some patients with ARF. Larger clinical trials are needed to further define the role of noninvasive mechanical ventilation in ARF, especially in those patients with advance directives for no intubation and with potentially reversible processes causing ARF.

Although positive airway pressure can be applied to nonintubated patients, these techniques may lead to gastric distention and vomiting. Continuous positive airway pressure is best tolerated at low levels (10 cm H_2O) and for brief periods. Bi-level positive airway pressure allows for the inspiratory pressure to be set at a higher level (e.g., 10 to 20 cm H_2O) than the expiratory pressure (e.g., 0 to 10 cm H_2O). There have now been 14 meta-analyses to date on noninvasive positive pressure ventilation (NPPV), which range from bilevel positive airway pressure machines applied via a full face mask, all the way to a conventional ventilator connected to a mask device that covers the whole face. Its success varies according to the purpose and the diagnosis for which it is used. The best survival data and earliest applications were in exacerbations of COPD and acute cardiogenic pulmonary edema. In COPD, the application of NPPV decreased both mortality and length of hospital stay with a number needed to treat of five. Intubation risk was reduced by 28% in a meta-analysis by Keenan and colleagues. In cardiogenic pulmonary edema, mortality was reduced by 45%.³¹ Other trials proved its effectiveness in acute respiratory failure following lung resection, acute asthma, solid organ transplantation, and in immunocompromised patients. NPPV has also been used in weaning patients from mechanical ventilation and the application of NPPV in one study shortened mechanical ventilation days.³² Other studies, however, have shown increased mortality when NPPV is used in patients requiring vasopressors, lack of improvement of respiratory acidosis, refractory hypoxemia, fatigue, and inability to clear secretions. These clinical parameters should be evaluated after 1 hour of initiation of NPPV, when the first arterial blood gas is obtained. Confalonieri developed a chart predicting the success of NPPV that included APACHE score, acidosis, level of consciousness, and respiratory rate.³³ As can be imagined, patients with a depressed level of consciousness, a pH less than 7.25, and a respiratory rate greater than 35 are more likely to fail and probably benefit from urgent intubation without a trial of NPPV. All studies evaluating NPPV published exclusion criteria that may very well be deemed as contraindications: cardiac or respiratory arrest, hemodynamic instability, the uncooperative patient, patients with facial trauma, copious secretions, or significant risk of aspiration. Those patients should undergo intubation and conventional mechanical ventilation. Intubation facilitates

the delivery of higher tidal volumes and the application of positive end-expiratory pressure needed to avert oxygen toxicity.

Mechanical Ventilation

Mechanical ventilation is a method of supporting intubated patients during illness when spontaneous ventilation is inadequate to sustain life or to achieve a therapeutic target. The clinical objectives are as follows³⁴: (1) to correct hypoxemia; (2) to correct acute respiratory acidosis; (3) to relieve respiratory distress; (4) to prevent or reverse atelectasis; (5) to rest respiratory muscles or prevent fatigue; (6) to allow sedation and neuromuscular blockade; (7) to decrease systemic or myocardial oxygen consumption; (8) to reduce intracranial pressure through controlled hyperventilation; and (9) to stabilize the chest wall.

In general, mechanical ventilators can be divided into two categories: negative pressure ventilators and positive pressure ventilators. The iron lung is the prototype of negative pressure ventilators that gained its popularity during the polio epidemics. Today, newer generations of negative pressure ventilators are still available under different names, such as cuirass, body suit, Porta Lung, pneumobelt, pneumowrap, pneumosuit, and so on. They function by creating a negative pressure outside the chest wall, causing chest wall expansion and subsequent inspiration, simulating physiologic breathing. On release of the negative pressure, exhalation is passively accomplished. In the hospital setting, positive pressure ventilators are the mainstay of mechanical ventilation owing to various features and adjunctive modes that allow for more sophisticated delivery of conditioned gas and assistance in ventilation.

Positive pressure inflation of the lung can be achieved with machines that terminate inspiration according to volume, pressure, or time. The latest generation of positive pressure ventilation allows the physician to select among these options and allows for pressure support (a flow cycled mode of ventilation) and reverse inspiratory to expiratory (I/E) ratio ventilation.

Volume-cycled ventilators deliver preset inspiratory flow to achieve a target volume, regardless of the pressure required. This system guarantees the tidal volume unless the peak pressure during inspiration exceeds the high pressure limit, in which case the resulting volume is less than the preset volume. High pressure delivered to diseased, noncompliant lungs may predispose to barotrauma. Pressure-cycled ventilators deliver preset positive pressure throughout inspiration; however, the resulting tidal volume is variable depending on the compliance of the lungs. A true time-cycled ventilator does not depend on the patient's lung characteristics or even whether the ventilator is attached to the patient to end inspiration; therefore it is important to recognize that a complete ventilatory cycle may occur without generating a tidal volume. Pressure support ventilation can be used either as a ventilatory mode or as an adjunctive mode. As a ventilatory mode, the pressure is set to produce a desired level of tidal volume similar to a pressure-cycled system, whereas in an adjunctive mode the pressure is set just high enough to overcome the tubing and circuit resistance during inspiration such that the level of pressure support does not increase the spontaneous tidal volume of the patient. A pressure support of 5 to 10 cm H₂O is usually adequate for the adjunctive mode.

Volume-cycled ventilators are most commonly used in the intensive care unit. In an assist-control (AC) mode, each patient breath that is recognized by the ventilator is assisted with a preset volume and flow rate in addition to a number of mandatory

breaths per minute. In an intermittent mandatory ventilation (IMV) mode, the patient can take spontaneous unassisted breaths between the mandatory breaths. A synchronized IMV (SIMV) mode synchronizes the machine mandatory breaths to the patient's spontaneous breaths to avoid breath stacking. A pressure support system can be used to augment the spontaneous breaths of patients in the SIMV mode, while at the same time guaranteeing a minimum number of mandatory breaths.

AC mode allows the patient to rest because each recognized spontaneous breath is assisted. Patients with respiratory muscle fatigue should be allowed to rest on this mode. Patients with sepsis and hypotension benefit from this mode by decreasing respiratory muscle work, which accounts for a significant portion of oxygen consumption during hypoperfusion states. Similarly, in patients with cardiogenic pulmonary edema, decreased work of breathing translates to decreased myocardial work demand. However, in patients with abnormal homeostatic mechanisms, such as hepatic encephalopathy, increased central respiratory drive may result in respiratory alkalosis. The SIMV mode is more homeostatic because the patient can determine the tidal volume needed; however, the work of breathing is higher and proportional to the amount of spontaneous ventilation relative to the assisted ventilation. The SIMV mode is primarily used in patients with severe air flow obstruction who tend to air trap when each breath is a relatively large, positive pressure breath. When the mandatory rate is set beyond the patient's spontaneous rate, or if the patient is completely paralyzed, the two modes are practically indistinguishable and the patient will receive only the mandatory breaths. Newer modes of ventilation include airway pressure release ventilation and bilevel modes. The first one allows for continuous positive airway pressure with an intermittent pressure release phase. A P_{high} (high pressure) and P_{low} (low pressure) are set and the patient is allowed spontaneous breathing independently of the ventilator cycle. Rather than continuously distending and deflating the alveoli, the P_{high} keeps them inflated during the entire respiratory cycle and only briefly releases them to P_{low}, thus aiding in ventilation and CO₂ removal. Ventilation can be improved by increasing the T_{high}—the time spent at P_{high}—and reducing the T_{low}. Therefore the APRV mode may result in lower peak airway pressures and less sedation for the patient.³⁵

In addition to ventilator modes, prone positioning has been extensively studied. Most research shows indeed an improvement in oxygenation and P_{aO₂} to F_{IO₂} ratios, but studies fail to show an increase in survival or less ventilator days; however, a French study showed a decreased incidence of ventilator-associated pneumonia in the prone ventilation group. Papazian and colleagues studied a combination of prone ventilation and inhaled nitric oxide, in patients with ARDS. This study demonstrated an additive improvement in the P_{aO₂} to F_{IO₂} (P/F) ratio, but the study was small and not powered to show survival outcome differences.³⁶

After the mode of ventilation is decided, the tidal volume, respiratory rate, F_{IO₂}, and inspiratory flow rate must be set on the ventilator. The range of tidal volumes used in mechanical ventilation is between 5 and 15 mL/kg of ideal body weight. When low tidal volumes (6 to 8 mL/kg ideal body weight) are used, positive end-expiratory pressure (PEEP) or sighs (generally each sigh volume is 2 to 3 × tidal volume) should be given at set intervals to prevent microatelectasis. As a general rule, with severe airway obstruction or ARDS, 6 mL/kg up to 8 mL/kg tidal volume is reasonable [refer

to ARDSnet.org ventilator chart]. Postoperative patients with normal lungs are frequently started on 8 to 12 mL/kg, whereas patients with neuromuscular disease receive 10 to 15 mL/kg. It is generally safe to select a tidal volume that generates a peak alveolar pressure less than or equal to 35 cm H₂O (with plateau pressures less than 30 to 32 cm H₂O). The rate should be chosen in conjunction with the tidal volume to provide minute ventilation that maintains a normal pH. A rate of 12 to 18 breaths/min will usually be adequate. Once the patient is stable, the ventilator rate is often adjusted 2 to 4 breaths/min below the total respiratory rate. This prevents excessive work of breathing in the SIMV mode and provides an adequate backup rate in the AC mode.

In emergent situations, the FIO₂ should be set at 0.9 or 1.0 with later adjustments guided by arterial blood gases. The FIO₂ can be titrated down to achieve an SaO₂ of more than 90% (usually a PaO₂ of 60 mm Hg). More than 24 hours with an FIO₂ greater than or equal to 0.9, or prolonged use of an FIO₂ greater than or equal to 0.6, requires the addition of PEEP for prevention of oxygen toxicity. In general, this can be achieved with a PEEP of 5 to 15 cm H₂O. The inspiratory flow rate is usually set by the respiratory therapist at a level of 40 to 55 L/min. It is mandatory for the peak flow setting (inspiratory flow rate) of the ventilator to be greater than the patient's inspiratory flow demand. Otherwise the patient breathes against the resistance of the ventilator circuitry, and this results in the patient "fighting the ventilator." The flow setting should be three and one half to four times the minute ventilation to achieve an I/E ratio of 1:1.2 to 1:1.5. In patients with severe obstructive lung disease, I/F ratios of 1:4 to 1:6 may be necessary.

Complications may arise during the course of mechanical ventilatory support. A deliberate and stepwise approach should be followed in the management process. Patient distress may arise from general discomfort or, frequently, from inadequate ventilation or the feeling of dyspnea. If hypoventilation is part of the overall strategy, then the patient needs to be sedated. Accidental hypoventilation may result from kinking of the endotracheal tube, mucus plugging, accidental mainstem intubation, pneumothorax, ventilator circuit leak, or ventilator disconnection. If the ventilator alarms have been set properly, they are frequently the first indicator of the acute problem, especially in a comatose, sedated, or paralyzed patient. A high pressure alarm is usually caused by obstruction of the airway or acute change in lung compliance, whereas a low volume alarm suggests decreased respiratory drive, a leak within the system, or a disconnected ventilator. During a high pressure alarm distress, the patient should be disconnected from the ventilator and hand ventilated with an ambu bag at an FIO₂ of 1.0, while a systematic search for the cause is being done. Unequal breath sounds may suggest a pneumothorax or slippage of the endotracheal tube into a mainstem bronchus. Acute changes in hemodynamics are more suggestive of the former. Difficulty in hand ventilation should suggest kinking of the tube or mucous plugs; therefore a suction catheter should be passed for diagnostic and therapeutic purposes. Chest radiography may aid the diagnosis and demonstrate lobar or complete collapse of the lung. If aggressive chest physiotherapy and inhaled mucolytics (e.g., Pulmozyme) are not effective, bronchoscopy may be required. If tension pneumothorax is strongly suspected, placement of a 14-gauge needle [angiocatheter] into the second intercostal space along the mid-clavicular line can relieve the tension immediately. Once this is done, a chest tube should always be placed whether a tension

pneumothorax was present or not since the patient is receiving positive pressure ventilation and the catheter may have punctured the visceral pleura.

When a leak in the circuit is suspected, the ventilator tubing can be changed. If the leak is from the endotracheal tube, it can happen anywhere from the valve of the pillow to the cuff. A three-way stopcock inserted into the valve may correct the problem if the leak comes from the valve, obviating the need to change the endotracheal tube. If it does not stop the leak, then the site of the leak may be in the pillow, the pilot line, or the cuff itself and may necessitate replacement of the endotracheal tube over a flexible stylet.

Pneumonia occurs in approximately 30% of patients receiving ventilator support. The risk increases with the duration of ventilator support at a rate of about 1% per day.³⁷ Pneumonia may be difficult to diagnose in patients with a "white" chest radiograph and may require either empirical therapy with a presumptive diagnosis or the use of bronchoscopy with a sterile brush with greater than or equal to 10³ colony forming units/milliliter on quantitative culture considered a significant finding [or 10⁴ on bronchoalveolar lavage or 10⁵ on endotracheal aspirate].

Physiologic measurements such as maximum inspiratory pressure (P_Imax = -20 cm H₂O), vital capacity (VC = 10 mL/kg), and minute ventilation (MV = 15 L/min) are used to determine when a weaning trial should be done. Recently, the ratio of respiratory frequency (f) to tidal volume (V_T) during 1 minute of spontaneous breathing was found to be more accurate.³⁸ If f/V_T is less than 100 breaths/min/L, a weaning trial is likely to be successful. The usual method of weaning includes trials of increased spontaneous breathing through a T tube or on pressure support ventilation (PSV, up to 10 cm H₂O). When patients can breathe spontaneously for more than 30 minutes to 2 hours without a significant change in their hemodynamics, respiratory rate, or minute ventilation, they can usually be successfully extubated.³⁹

Conclusion

Acute respiratory failure implies an inability to maintain adequate oxygenation for tissues or adequate removal of carbon dioxide from tissues. The differential diagnosis should be suggested by the radiographic appearance of the chest radiograph and by the patient's history and physical examination. A specific diagnosis should be pursued and frequently requires ancillary studies such as blood or sputum cultures, bedside spirometry, pulmonary artery catheterization, perfusion lung scan, or a CT angiogram using multidetector scanners. This allows the physician to initiate specific therapy for the underlying cause of acute respiratory failure. These patients often require supportive therapy.

Massive Acute Pulmonary Embolism

Guy Meyer

CHAPTER 32

Definition	Thrombolytic Agents
Diagnosis of Massive Pulmonary Embolism	Pulmonary Embolectomy
General Medical Support	Conclusion

IN-HOSPITAL MORTALITY of clinically stable patients without major comorbidity receiving anticoagulant treatment for pulmonary embolism (PE) has been reported to vary between 1% and 2% in recent controlled trials.^{1,2} By contrast, more than 25% of patients having a pulmonary embolism and low blood pressure die in the hospital.³⁻⁵ A subgroup of patients with normal blood pressure who have right ventricular failure on admission as detected by echocardiography may have a higher mortality rate than patients with normal echocardiographic findings.⁶ Recent data further suggest that cardiac biomarkers, such as troponin and brain natriuretic peptide (BNP), also help identify patients with adverse outcomes among those with normal blood pressure.^{7,8} Accordingly, it has been suggested that PE be classified into two main categories: (1) massive PE defined by a systolic blood pressure of 90 mm Hg, or a pressure drop of 40 mm Hg for at least 15 minutes, and (2) nonmassive PE.⁹ An additional category, submassive PE, is considered to be a subcategory of nonmassive PE with evidence of right ventricular dysfunction.⁹ Suspected cases of massive PE require prompt confirmation using bedside tests. In these patients, supportive measures are needed and thrombolytic therapy is indicated.¹⁰ Pulmonary embolectomy is useful in a small subset of patients with massive PE, whereas catheter embolectomy requires additional evaluation. The clinical benefit of thrombolytic therapy in patients with submassive PE is less clear and international experts currently advise against using thrombolytic therapy in these patients.¹⁰

Definition

Pulmonary vascular obstruction has long been considered the main criteria for defining massive pulmonary embolism; however, recent studies strongly suggest that clinical tolerance rather than vascular obstruction is the main determinant of hospital mortality in patients with PE. As a result, massive PE is now defined as PE with persistent systemic hypotension (i.e. systolic blood pressure of 90 mm Hg for at least 15 minutes or a drop of systolic blood pressure of at least 40 mm Hg).⁹ Alpert and associates reported on 144 patients with angiographically proven PE: they found that PE-related mortality was 5% in patients with a vascular obstruction below 50% and 16% in those patients with a pulmonary vascular obstruction exceeding 50%. However, the excess mortality in the latter group was limited to patients with cardiogenic shock as a result of PE. The mortality rate was

greater in this group of patients (32%) than in those with high vascular obstruction but normal blood pressure (6%).⁴ More recently, 1001 patients with pulmonary hypertension because of PE were grouped into four categories by Kasper and associates: (1) those with normal blood pressure; (2) those with isolated arterial hypotension; (3) those with cardiogenic shock; and (4) those who sustained cardiopulmonary resuscitation.⁵ Hospital mortality was 8% in group 1, 15% in group 2, 25% in group 3, and 65% in group 4. The mortality rate listed in the International Cooperative Pulmonary Embolism Registry (ICOPER) was 58% for patients who were hemodynamically unstable at the time of presentation, and 15% for those who were hemodynamically stable.³ In that study, systolic blood pressure below 90 mm Hg was used as an independent predictor for early death (hazard ratio: 2.9 [95% confidence interval: 1.7 to 5.0]). Those patients represented only 4.2% of the total population included in the study.

Patients with normal blood pressure have a much better clinical outcome and are considered as having nonmassive PE.⁹ However, several studies have identified a subgroup of patients considered as having submassive PE with normal blood pressure who may have an increased risk of mortality. Ribeiro and colleagues were the first to suggest that patients with right ventricular failure may have increased mortality. In that study, 126 consecutive patients with PE were examined with echocardiography on the day of diagnosis. Patients were divided into two groups: group A ($n = 56$) with normal or slightly reduced RV function and group B ($n = 70$) with moderately or severely reduced RV function. Four deaths occurred in group A and 15 in group B ($p = 0.04$).⁶ However, the patient population was composed of stable and unstable patients, and the outcome of patients with normal blood pressure with and without right ventricular dysfunction was not specified. Five studies have evaluated the value of echocardiography as a prognostic tool in hemodynamically stable patients with PE.¹¹⁻¹⁵ Right ventricular dysfunction was associated with a 2.4-fold (95% CI: 1.3 to 4.4) increased risk of hospital mortality. Criteria used to define right ventricular dysfunction differed from one study to another and the risk of death was not adjusted for major confounding factors. More recently, the role of cardiac biomarkers as early predictors of outcome has been investigated in several studies. Four studies assessed brain natriuretic peptide in clinically stable patients with PE.^{8,13,14,16} A high BNP level was associated with a ten-fold increase in the risk of hospital death (95% CI: 3.2 to 35.3).

Similarly, increased values of pro-brain natriuretic peptide and troponin are associated with a 5.7-fold (95% CI: 2.2 to 15.1) and 7.5-fold (95% CI: 3.1 to 18.1) increased fatality risk.^{8,12,17} However, most studies were carried out in individual medical centers and included a small number of patients. Also, the threshold values for each biomarker differed from one study to another and the risk was not adjusted for major confounders. As a result, the role of these biomarkers in selecting patients at risk requires further evaluation in larger multicenter cohorts.

Diagnosis of Massive Pulmonary Embolism

The risk of death in patients with massive PE is maximal during the first few hours following their admission to the hospital and prompt diagnostic confirmation and treatment are mandatory. In addition, in-hospital transportation of hemodynamically unstable patients is associated with an increased risk of morbidity and mortality; thus every effort should be made to confirm the diagnosis of suspected massive PE using bedside diagnostic tests. No specific literature is available on the diagnosis of massive PE; however, the basic principles for diagnosing clinically stable patients with suspected PE can probably be applied to unstable patients.¹⁸ Indeed, evaluating the clinical probability of PE should be the first step in the diagnosis process. Several rules have been published, but clinical probability can also be based on the clinical gestalt of risk factors, clinical signs and symptoms, chest radiography, blood gas analysis, and ECG.^{19,20} If the clinical probability is high, which is often the case when massive PE is suspected, a D-dimer test result is of little value.^{18,21,22} The positive likelihood ratio of bedside transthoracic echocardiography demonstrating right ventricular dilation (5.0; 95% CI: 2.3 to 10.6) is high enough to confirm PE when the clinical probability is high.¹⁸ Presence of clots in the right heart chambers is rare and is not required to confirm PE. In addition, echocardiography can rule out left ventricular dysfunction and pericardial tamponade,

which may clinically mimic massive PE. Conversely, the negative likelihood ratio of a normal echocardiography (0.6; 95% CI: 0.4 to 0.9) is not low enough to rule out PE when the clinical probability is high.¹⁸ If echocardiography is normal, spiral computed tomography of the pulmonary arteries is required to confirm or rule out PE after the patient's hemodynamic status has been stabilized (Fig. 32-1).

General Medical Support

Oxygen

Arterial hypoxemia is a common finding in patients with acute PE. The degree of hypoxemia is usually moderate; in 81 patients submitted to pulmonary embolectomy, the mean arterial partial pressure of oxygen breathing room air was 51 ± 12 mm Hg at the time of admission.²³ Oxygen administration by nasal cannula or facemask is usually sufficient for maintaining arterial oxyhemoglobin saturation within the normal range. Mechanical ventilation is only rarely required and positive pressure must be applied very cautiously because of its detrimental effects on cardiac output in right ventricular failure.

Fluid Loading

Acute pulmonary artery obstruction increases right ventricular afterload and end-diastolic and end-systolic right ventricular volumes and decreases right ventricular stroke volume. These changes may reduce left ventricular preload and impair left ventricular function as a result of ventricular interdependence, and a decrease in cardiac output with circulatory failure may ensue. Fluid loading increases the right ventricular end-diastolic volume and may increase cardiac output by the Frank-Starling mechanism, but it may also increase the leftward septal displacement, thereby worsening left ventricular diastolic function. Animal studies have addressed this issue with conflicting results. The effect of fluid loading in patients with PE and circulatory failure has been evaluated in two studies.^{24,25} In 13 mechanically ventilated patients with massive PE, the cardiac index increased

Figure 32-1. Suggested diagnostic algorithm for patients with suspected massive pulmonary embolism (PE). RV, right ventricular.

from 1.7 ± 0.6 L/min/m² to 2.0 ± 0.7 L/min/m² after a 600-mL fluid challenge.²⁵ More recently, we observed a significant 25% increase in the cardiac index from 1.7 ± 0.2 to 2.1 ± 0.2 L/min/m² in 10 patients after a 500-mL fluid challenge was administered over 15 minutes.²⁴

Inotropic Support

Inotropic support is required when shock persists despite fluid loading. Isoproterenol, dobutamine, dopamine, and norepinephrine all improve the hemodynamic status in animals with experimental massive PE and hypotension. However, severe hypotension is rarely observed in patients with massive PE and most of these drugs have not been evaluated in clinical studies. In 10 patients with massive PE, Jardin and colleagues found a 35% increase in the cardiac index during dobutamine infusion as a result of stroke volume increase, whereas the heart rate decreased significantly.²⁶

Thrombolytic Agents

Hemodynamic Effects

Thrombolytic treatment induces a rapid decline in pulmonary artery resistance in patients with acute PE and pulmonary hypertension. Alteplase, given as a 100 mg dose over 2 hours, reduces the mean pulmonary artery pressure from 30.2 ± 7.8 mm Hg to 21.0 ± 6.7 mm Hg and increases the cardiac index from 2.1 ± 0.5 L/min/m² to 2.4 ± 0.5 L/min/m² after 2 hours, whereas no significant change is observed with heparin.²⁷

Reduction of Pulmonary Vascular Obstruction

Thrombolytic treatment reduces vascular obstruction quicker than heparin alone. Pulmonary vascular obstruction as assessed by the Miller index decreased significantly from 28.3 ± 2.9 to 24.8 ± 5.2 two hours after the start of alteplase infusion, whereas no significant difference was observed in patients who received heparin alone.²⁷ Importantly, however, the differences between the thrombolysis and the heparin group disappeared after 7 days of follow-up.²⁷ Thus thrombolytic therapy restores

pulmonary vascular flow and right heart hemodynamics faster than heparin alone, but both treatments result in a similar degree of improvement after 1 week.

Effects of Thrombolysis on Recurrent PE, Major Bleeding, and Mortality

Eleven controlled studies compared thrombolytic therapy with heparin in patients with PE (Table 32-1).²⁷⁻³⁷ Only one small study included patients with massive PE alone,³² four studies included some patients with massive PE and a majority of patients with submassive PE,^{28,30,35,37} and six trials included clinically stable patients with or without right ventricular dysfunction.* To date, no study has compared thrombolytic therapy and heparin in patients with submassive PE. Eight studies had an open design and three were placebo controlled. PE diagnosis was confirmed using invasive procedures in seven trials.^{27-30,35-37} Recurrent PE was objectively confirmed in only two trials.^{28, 33} Criteria for major bleeding were not explicitly given in some studies and differed significantly among other studies. Overall, only 748 patients were included in these studies, and their outcome was analyzed in four meta-analyses.³⁸⁻⁴¹ The overall death rate was lower for patients who had thrombolytic therapy (4.3%) when compared with those that received heparin alone (5.9%; OR, 0.70; 95% CI, 0.37 to 1.30). The overall rate of major bleeding was 9.1% in patients who were allocated to thrombolytic treatment and 6.1% in those who received heparin. The relative risk for major bleeding associated with thrombolysis was 1.42 (95% CI, 0.81 to 2.46).³⁸ Most major bleeding cases occurred in studies that used central venous access for angiography and invasive hemodynamic monitoring (Table 32-2). Overall, the rate of major bleeding averages 20% in patients receiving fibrinolytic therapy and 12.5% in those receiving heparin. The rate of major bleeding reported in the most recent studies using noninvasive diagnostics and monitoring is far lower, averaging 2% in patients who were receiving thrombolytic treatment and 3% in patients who were receiving heparin.³¹⁻³⁴ Intracranial bleeding remains a major concern in patients receiving thrombolytic treatment for PE, with an estimated incidence of intracranial bleeding of 1.9%

*Some events (recurrent PE or bleedings) were fatal and counted both as events and in the deaths.

(95% CI, 0.7 to 4.1).⁴² Risk factors for major bleeding include old age and invasive diagnostic procedures.⁴³

Massive Pulmonary Embolism

One single small randomized trial has compared streptokinase with heparin in patients with massive PE. Although 40 patients were expected to be recruited, the trial was terminated early after only eight patients had been included. All patients had cardiogenic shock on inclusion; four were allocated to streptokinase and survived, and four were allocated to heparin and died during the 72 hours following randomization.³² These results prompted the ethics committee to stop the trial. In a recent meta-analysis of the controlled studies comparing thrombolytic therapy with heparin in patients with PE, a subgroup analysis was performed on the five studies that included patients with massive PE and shock.³⁸ The patients allocated to thrombolysis had a mortality rate of 6.2% and those who were receiving heparin alone had a rate of 12.7% (odds ratio, 0.47; 95% CI, 0.20 to 1.10). The difference was significant if recurrent PE and deaths were considered: odds ratio, 0.45; 95% CI, 0.22 to 0.92.³⁸ Notably, however, only a minority of the patients included in those trials had massive PE (see Table 32-1).

The high mortality rate seen in patients with massive PE who receive heparin alone, the early hemodynamic improvement observed with thrombolytic therapy, the results of the small randomized study by Jerjes-Sanchez and colleagues, and the recent meta-analysis all suggest that thrombolytic therapy is associated with significant clinical benefit in patients with massive PE. Thus most authorities recommend the use of thrombolytic therapy in this setting.^{9,10}

Submassive Pulmonary Embolism

To date, the largest randomized study assessing thrombolytic treatment for submassive PE included 256 patients with PE and normal blood pressure who were allocated to receive either heparin alone or both alteplase and heparin.³³ The primary end point consisted of the combination of in-hospital death or clinical deterioration requiring the escalation of treatment. This was

reached in 11% of the patients in the alteplase group and was reached in 24.6% in the heparin group ($p = 0.006$). The difference was mainly due to the use of secondary open-label thrombolytic therapy, which was more frequent in the patients assigned to receive heparin (23.2%) than in those receiving alteplase (7.6%; $p = 0.001$). The death rate did not differ significantly between the groups. The unexpected low mortality rate in patients receiving heparin (2%) may be related to the low (30%) proportion of patients with right ventricular dysfunction, or to the early use of rescue thrombolytic treatment for those patients who did not improve with heparin. Overall, thrombolytic therapy was compared with heparin in six studies, in which 494 clinically stable patients with submassive or nonmassive PE were included.* The death rate was 3.3% for those receiving thrombolytic therapy and was 2.4% for those allocated to heparin (OR, 1.16; 95% CI, 0.44 to 3.05). Thus the current evidence from controlled studies does not indicate that patients with submassive PE receiving thrombolytic treatment have a lower in-hospital mortality risk. As mentioned above, however, most of these studies included patients with nonmassive PE resulting in a low death rate in both groups. In addition, the number of patients remains low. As a consequence, the available clinical trials and meta-analyses are underpowered and are unable to detect clinically important differences between thrombolytic therapy and heparin in patients with submassive PE.

Some indirect evidence may suggest that thrombolytic therapy may improve the short-term outcome of patients with submassive PE, despite negative results from controlled studies. Goldhaber and coworkers did a post hoc analysis on a subgroup of 36 patients with right ventricular hypokinesia, who were included in their controlled study comparing alteplase and heparin. They observed five PE recurrences (two of them fatal) among 18 patients who were treated with heparin, whereas no deaths or recurrent PE occurred among the 18 patients who received alteplase.³¹ In the MAPETT study, the death rate was lower for patients receiving thrombolytic treatment, which

*References 27, 29, 31, 33, 34, 36.

was the only independent predictor of a favorable outcome.⁴⁴ However, this was an observational study and treatments were not randomly allocated. Experts have expressed contradicting opinions on indications for thrombolytic therapy in patients with submassive PE.^{4,41,45,46} A large international investigator-initiated randomized study comparing thrombolysis to heparin in 1000 patients with submassive PE, defined by elevated troponin and right ventricular failure (assessed by echocardiography or spiral CT), is under way to clarify this issue.

Results of Various Thrombolytic Regimens

Various thrombolytic regimens have been evaluated in controlled trials. Urokinase, given as a bolus dose of 4400 IU/kg followed by a 12-hour or 24-hour maintenance infusion of 4400 IU/kg/hr, was compared with streptokinase, given as a 250,000 IU bolus dose followed by a 100,000 IU/hr infusion given over 24 hours, in a large randomized trial.⁴⁷ The three regimens produced the same degree of hemodynamic and angiographic improvement with no significant differences in terms of major hemorrhage. Recombinant tissue-type plasminogen activator (rtPA) given as a 2-hour 100 mg infusion was compared with a 4400 IU/kg/hr infusion of urokinase, given over 12 or 24 hours.^{48,49} rtPA led to a faster hemodynamic and angiographic improvement, but the two drugs yielded similar hemodynamic results by the end of the urokinase infusion. Patients receiving rtPA had a nonsignificant reduction in major bleeding.^{48,49} A similar rtPA regimen was subsequently compared with a shorter urokinase regimen, given as a 3 million IU infusion over 2 hours.⁵⁰ No differences in hemodynamic improvement and bleeding between the groups were observed, suggesting that when the two drugs are given over the same time period they share similar efficacy and safety. The 2-hour rtPA regimen resulted in faster hemodynamic improvement than a 12-hour streptokinase infusion, whereas no difference was observed when the two drugs were given over the same 2-hour period.^{51,52} The rate of major bleeding was lower for patients receiving the 2-hour streptokinase infusion than the 2-hour rtPA regimen, but the difference was not significant.⁵¹ Two studies compared a rtPA dose of 0.6 mg/kg body weight given over a period of 15 minutes with the 100 mg regimen given over 2 hours.^{53,54} Hemodynamic improvement was slightly but significantly faster for the 2-hour regimen, but the 0.6 mg/kg dosage was associated with a nonsignificant reduction in major bleeding.^{53,54}

Contraindications to Thrombolytic Therapy

For patients with hemodynamic compromise who do not improve with anticoagulation and pressure support, the benefit of thrombolytic treatment outweighs its risk of bleeding, even in the presence of minor contraindications. The main contraindications to thrombolytic therapy are given in Table 32-3.

Additional Measures

As most bleeding episodes occur at the puncture site, it is mandatory to avoid invasive diagnostic procedures, such as pulmonary angiography, if thrombolytic treatment is being considered. Thrombolytic therapy can be given through a peripheral line. Central venous lines should be avoided. Heparin should be interrupted during thrombolysis and resumed as soon as the activated partial thromboplastin time is within the target range. There are still no data for the combination of thrombolytic and low-molecular weight heparin therapy in PE.

Table 32-3. Contraindications to Thrombolytic Therapy in Pulmonary Embolism

Major contraindications to thrombolytic therapy in patients with massive PE

- Active bleeding
- Stroke within the last 2 months
- Spontaneous intracranial bleeding at any date

Minor contraindications to thrombolytic therapy in patients with massive PE

- Major surgery within the past 10 days
- Major trauma within the past 15 days
- Ophthalmologic surgery or neurosurgery within 30 days
- Platelet count less than 100,000/mm³

Pulmonary Embolectomy

Surgical Pulmonary Embolectomy

Pulmonary embolectomy using cardiopulmonary bypass was first reported in 1961 and is now considered to be the best operative technique. In 17 large studies, the operative mortality averages 36%.⁵⁵ Ideally, pulmonary embolectomy should be attempted only in those patients who will not survive without surgery because of the high mortality rate in patients that have undergone this procedure. However, an unequivocal set of criteria that accurately identifies these patients remains elusive. As a result, the role of surgical embolectomy in the treatment of PE has been the subject of much discussion but few definitive conclusions. According to the last ACCP consensus, the candidate should meet the following criteria: (1) massive PE; (2) shock despite heparin and resuscitation efforts; and (3) failure of thrombolytic therapy or a contraindication for its use.¹⁰ In our experience, these patients represent only 3% of those referred for massive PE.²³

Percutaneous Procedures

Several transvenous procedures have been proposed for pulmonary embolectomy, including suction, clot fragmentation with angiography catheters, ultrasound-assisted aspiration, laser-assisted embolectomy, and clot fragmentation using several other devices.⁵⁶ Most of these procedures have been evaluated in vitro or in animal experiments, but clinical evaluation is still limited to small retrospective case series for most devices.⁵⁷ In addition, most devices were used with concomitant fibrinolytic treatment and the respective roles of catheter embolectomy and thrombolytic therapy in the patient's outcome is difficult to ascertain.^{56,57}

Conclusion

Patients who have massive PE with systemic hypotension and cardiogenic shock have a high mortality rate when receiving heparin alone. Available evidence strongly suggests the use of thrombolytic treatment in these patients. Recent data indicate that patients with so-called submassive PE may have a higher mortality risk than patients with normal right ventricular

function. Controlled studies available to date are insufficiently powered to confirm or exclude the clinical benefit of thrombolytic therapy in those patients. A large randomized controlled trial is currently under way to address this issue. Pulmonary embolectomy should be considered in the few patients with PE and cardiogenic shock receiving full hemodynamic support and who do not improve while receiving thrombolytic treatment or for whom thrombolytic treatment is contraindicated.

Pulmonary Hypertension

Peter F. Fedullo, William R. Auger

CHAPTER 33

Pulmonary Vascular Anatomy and Physiology Classification of Pulmonary Hypertension Postoperative Pulmonary Hypertension

Chronic Thromboembolic Pulmonary Hypertension Conclusion

SUBSTANTIAL ADVANCES have occurred over the past decade in understanding the pathophysiologic and pathobiologic basis of pulmonary hypertensive disorders. In concert with these advances, dramatic improvements have occurred in the diagnostic approach and therapeutic options available to patients afflicted with this disorder. The resulting development of both pharmacologic and surgical interventions has fundamentally transformed the natural history of a number of disease processes once considered uniformly fatal.

The purpose of this chapter is to review the normal physiologic control of the pulmonary vascular bed and to provide guidelines for a systematic approach to both diagnosis and therapy in patients with pulmonary hypertensive disorders.

Pulmonary Vascular Anatomy and Physiology

Starting from the main pulmonary arteries and proceeding distally towards the pulmonary capillaries, five structural regions can be identified.¹ These include: (1) the large elastic arteries with a diameter greater than 3200 μm ; (2) transitional arteries with diameters ranging from 2000 μm to 3200 μm ; (3) muscular arteries with diameters ranging from 150 μm to 2000 μm ; (4) partially muscularized arteries; and (5) nonmuscular arterioles with diameters ranging from 30 μm to 75 μm . The smallest muscular arteries and the partially muscularized arteries are felt to represent the resistance vessels of the pulmonary circulation.

The adult pulmonary circulation is a low resistance circulatory system that accommodates the whole cardiac output. Under normal circumstances, the resting pulmonary arterial pressure in man is fairly constant throughout life. The normal pulmonary artery pressure at sea level has a peak systolic value of 25 mm Hg, an end diastolic value of 10 mm Hg, and a mean value ranging from 12 to 16 mm Hg. By consensus, pulmonary hypertension is present when mean pulmonary arterial pressure exceeds 25 mm Hg at rest or 30 mm Hg with exercise.² By definition, pulmonary hypertension is considered mild when the mean pulmonary artery pressure is 26 to 35 mm Hg, moderate when it is 36 to 45 mm Hg, and severe when it exceeds 45 mm Hg.

Exercise-related increases in pulmonary blood flow are associated with only minimal increases in pulmonary arterial pressure. As flow increases, therefore, pulmonary vascular resistance decreases. This response is primarily the result of recruitment of

previously unperfused pulmonary vessels and, to a lesser extent, distention of already perfused vessels. Occasionally, especially in older subjects, pulmonary arterial pressure can increase to 50 mm Hg during exercise. This increase in pulmonary artery pressure is the result of an increase in pulmonary arterial wedge pressure, the probable result of decreased left ventricular diastolic compliance, rather than an increase in the pulmonary artery to pulmonary artery wedge pressure gradient.³

The hemodynamic evolution of pulmonary hypertensive disorders has been well described.⁴ Initially, the ability of the pulmonary vascular bed to dilate and to recruit unused vasculature is lost, resulting in increases in pulmonary artery pressure at rest and further elevations with exercise. In response to this increased afterload, the right ventricle undergoes hypertrophy. Early in the disease, the right ventricle is capable of sustaining a normal cardiac output at rest, although the ability to augment cardiac output with exercise is impaired. With disease progression, the right ventricle becomes incapable of maintaining a normal cardiac output at rest. As progressive right heart dysfunction develops, right heart diastolic and right atrial pressure increase, and right ventricular failure becomes clinically apparent. Although the left heart is not directly affected by pulmonary vascular disease, progressive right ventricular dilation can impair left ventricular compliance, leading to increased left ventricular end-diastolic and pulmonary capillary wedge pressures.

The main vascular changes in pulmonary arterial hypertension are vasoconstriction, smooth-muscle cell and endothelial-cell proliferation, and thrombosis. The endothelial cell plays a major role in the maintenance of normal pulmonary hemodynamics through the release of a variety of vasoactive substances, including nitric oxide (NO), prostanooids, and endothelin (ET), that contribute to vascular tone.⁵⁻⁷ Nitric oxide, previously known as endothelium-derived relaxing factor (EDRF), appears to play a central role in the modulation of pulmonary vascular tone. In addition to being a powerful vasodilator, nitric oxide acts as a bronchodilator, neurotransmitter, anticoagulant, anti-proliferative, and antimicrobial substance and inhibits platelet aggregation. Continuous release of nitric oxide from pulmonary endothelium appears to determine the characteristically low pulmonary vascular resistance in man. Prostacyclin (PGI_2), a product of cyclooxygenase metabolism of arachidonic acid, is a powerful vasodilator and inhibitor of platelet aggregation. Although it has been suggested that release of PGI_2 by the endothelium modulates vasoconstriction, the continuous

release of PGI₂ does not appear necessary to maintain pulmonary arterial vasodilation. Endothelin, consisting of three discrete isoforms, represents one of the most powerful pulmonary arterial vasoconstrictors.

A wide array of other mediators has been found to be involved in pulmonary vascular remodeling, including transforming growth factor receptors (TGF- β), bone morphogenic protein receptor 2 (BMPR2), vascular endothelial growth factor (VEGF), vasoactive intestinal peptide, 5-hydroxytryptamine (5-HT), adrenomedullin, and natriuretic peptides among others. Although an imbalance among these mediators has been implicated in the initiation and progression of certain variants of idiopathic and secondary forms of pulmonary hypertension, their respective effects on smooth muscle cells and the circumstances under which one class of mediators predominates remain undefined and the subjects of intense investigation.

Classification of Pulmonary Hypertension

Pulmonary hypertension results when there is an absolute loss of pulmonary vascular cross-sectional area or an increased resistance to flow at any point within the pulmonary circulation. The pulmonary circulation is defined as extending from the pulmonic valve to the left atrium and consists of the pulmonary outflow tract, the right and left main pulmonary arteries and their lobar branches, the intrapulmonary arteries, the pulmonary arterioles, capillaries, venules, and large pulmonary veins. As a result, a diverse group of disease processes affecting any aspect of this circulation can result in pulmonary hypertension (Table 33-1). The term *primary pulmonary hypertension* (PPH) has been abandoned in favor of *idiopathic pulmonary arterial hypertension* (IPAH). The term *pulmonary arterial hypertension* (PAH) is reserved for those with a genetic basis for pulmonary hypertension, those with collagen vascular disease or other conditions associated with pulmonary arterial hypertension (APAH), and for the idiopathic variant (IPAH).

Pulmonary hypertension can result from a variety of obstructive and restrictive pulmonary parenchymal disorders.⁸⁻¹⁰ The basis for pulmonary hypertension in these disorders involves both an absolute loss of pulmonary cross-sectional area (bronchiectasis, emphysema) and, of greater importance, the chronic alveolar hypoxia, acidosis, and polycythemia that accompanies these disease states.

Independent of pulmonary parenchymal disorders, pulmonary hypertension is a frequent hemodynamic complication associated with a range of respiratory system disorders whose common physiologic abnormality are alveolar hypoxia and arterial hypoxemia of longstanding duration.¹¹ Such disease processes include the obesity-hypoventilation syndrome, chest wall disorders, and neuromuscular disease.

Small-vessel pulmonary arterial changes may ultimately develop from an augmented pulmonary flow state (Eisenmenger syndrome), from vasculitides or toxic injuries affecting the small pulmonary arteries, or as a consequence of idiopathic pulmonary hypertension.

There is also a group of disorders for which occlusion or narrowing of the large to medium-size pulmonary arteries is the site of increased resistance to flow. Included in this category is chronic thromboembolic disease, Takayasu arteritis, primary

Table 33-1. Classification of Pulmonary Hypertension⁷⁵

Group I: Pulmonary arterial hypertension (PAH)
Idiopathic PAH (IPAH)
Familial PAH
Associated with PAH (APAH)
Collagen vascular disease
Congenital systemic to pulmonary shunts (large, small, repaired, or nonrepaired)
Portal hypertension
HIV infection
Drugs and toxins
Other (glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasis, hemoglobinopathies, myeloproliferative disorders, splenectomy)
Associated with significant venous or capillary involvement
Pulmonary veno-occlusive disease (PVOD)
Pulmonary capillary hemangiomatosis (PCH)
Persistent PH of the newborn (PPHN)
Group II: Pulmonary venous hypertension
Left-sided atrial or ventricular heart disease
Left-sided valvular disease
Group III: Pulmonary hypertension associated with intrinsic lung disease or hypoxemia
Chronic obstructive pulmonary disease (COPD)
Interstitial lung disease
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Group IV: Pulmonary hypertension caused by chronic thrombotic or embolic disease
Thromboembolic obstruction of proximal pulmonary arteries
Thromboembolic obstruction of distal pulmonary arteries
Pulmonary embolism (tumor, parasites, foreign material)
Group V: Miscellaneous
Sarcoidosis
Histiocytosis X
Lymphangiomatosis
Compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

pulmonary artery tumors, and compression from mediastinal or hilar processes (carcinoma, fibrosis).¹²⁻¹⁵ Although it might be assumed that the progressive nature of the pulmonary hypertension in this group is primarily the result of the initiating disease process, there is increasing evidence that small vessel changes in the unobstructed vascular bed resulting from high pressure or flow, or mediator imbalance, may contribute significantly to the progression of the disease.¹⁶

Increased resistance to pulmonary venous drainage is a mechanism common to a number of diverse processes in which pulmonary hypertension occurs. Altered resistance to pulmonary venous drainage may be the result of diseases affecting the left atrium, the left ventricle (both systolic and diastolic), mitral or aortic valvular disease, or the large (mediastinal fibrosis) or small (pulmonary veno-occlusive disease) pulmonary veins. Additional

Table 33–2. Functional Assessment of Patients with Pulmonary Hypertension⁷⁶

Class I: Patients with pulmonary hypertension but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near syncope.
Class II: Patients with pulmonary hypertension resulting in slight limitation of physical activity. These patients are comfortable at rest, but ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near syncope.
Class III: Patients with pulmonary hypertension resulting in marked limitation of physical activity. These patients are comfortable at rest, but less than ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near syncope.
Class IV: Patients with pulmonary hypertension resulting in inability to perform any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnea and/or fatigue may be present at rest, and discomfort is increased by any physical activity.

vascular remodeling or vasoconstriction may contribute to the elevated pulmonary artery pressures and increased transpulmonary gradient, especially when left heart filling pressures have been markedly and protractedly increased.¹⁷

Finally, there is a group of disorders in which the association between pulmonary hypertension and the primary disease state remains obscure. Included among these is the pulmonary hypertension associated with HIV infection, and with cirrhosis and/or portal vein thrombosis.^{18–20}

Clinical Presentation

The first challenge in the diagnostic evaluation of a patient with pulmonary hypertension is recognizing that pulmonary hypertension is, in fact, present. Diagnostic delay, especially in the absence of a history of an associated disease process, occurs commonly. Symptoms specifically attributed to the presence of pulmonary hypertension are nonspecific and dependent on the stage of the disease at which the patient presents (Table 33–2). A gradual decline in exercise tolerance and exertional dyspnea represent the initial manifestation and are present in essentially all patients with significant pulmonary hypertension. Other symptoms may include cough, chest pain, hemoptysis, and easy fatigability. These symptoms are also nonspecific and may lead the clinician, in the case of isolated pulmonary hypertension, to ascribe them to other causes (coronary artery disease, chronic obstructive pulmonary disease, psychogenic dyspnea); and, in the case of secondary pulmonary hypertension, to mistakenly ascribe them to a progression of the underlying disease.

Findings on physical examination in pulmonary hypertension are similarly reflective of the stage of the disease at which the patient presents. Unless the pulmonary hypertension or accompanying right ventricular dysfunction is severe, findings on physical examination can be deceptively subtle. Before the development of significant pulmonary hypertension or overt right ventricular failure, physical examination abnormalities may be limited to narrowed physiologic splitting of the second heart sound or a subtle accentuation of its pulmonic component. In time, obvious findings such as a right ventricular heave, jugular venous distention with prominent A- and V-wave

pulsations, widened or fixed splitting of the second heart sound, a fourth or third heart sound of right ventricular origin, murmurs of tricuspid regurgitation or pulmonic insufficiency, hepatomegaly, and ascites may develop. The presence of digital clubbing can suggest the possibility of bronchiectasis, idiopathic interstitial fibrosis, or right-to-left intracardiac or intrapulmonary shunting. Cyanosis is a relatively late finding in pulmonary hypertension not resulting from pulmonary parenchymal disorders, chronic alveolar hypoxia, or right-to-left shunts. In pulmonary hypertension resulting from diseases of the large and small pulmonary arteries, cyanosis may develop late in the disease as a consequence of shunting through a patent foramen ovale secondary to elevated right atrial pressure.

One unique physical finding described in chronic thromboembolic pulmonary hypertension and congenital pulmonary artery stenosis is the presence of flow murmurs over the lung fields.²¹ The detection of these often subtle bruits, which appear to originate from turbulent flow through partially obstructed pulmonary arteries, can be instrumental in differentiating a large vessel from a small vessel etiology of pulmonary hypertension. These flow murmurs are detected over the lung fields rather than the precordium, are accentuated during inspiration, and are frequently heard only during periods of breath-holding.

Diagnostic Evaluation

In the evaluation of the patient with suspected pulmonary vascular disease, historical information should be gathered with the intent of identifying a disorder with a known association with pulmonary hypertension. In most instances, the presence or history of obstructive lung disease, restrictive lung disease, digital clubbing, obesity-hypoventilation syndrome, rheumatic fever, collagen vascular disease, HIV infection, or thromboembolism will antedate the occurrence of pulmonary hypertension and suggest a likely etiology. Intravenous drug use and the ingestion of certain anorexigenic medications (e.g., fenfluramine) have also been associated with the development of pulmonary hypertension.^{22–25} If the patient's place of residence is a region endemic for histoplasmosis, this information is useful in suggesting the possibility of fibrosing mediastinitis. Although familial pulmonary hypertension is extremely rare, a family history of pulmonary hypertension should be explored with any individual having suspected pulmonary hypertension.²⁶

Once an abnormality of the pulmonary vasculature has been considered as a basis for the patient's complaints, the diagnostic sequence, despite the diverse diagnostic possibilities, is relatively straightforward if an orderly approach is followed (Fig. 33–1).

Findings on standard laboratory tests are dependent on the point in the natural history of the disease at which they are obtained. Abnormalities usually reflect the hemodynamic and gas exchange consequences of the pulmonary vascular obstruction and accompanying cardiac dysfunction. Electrocardiographic findings can suggest the possibility of pulmonary hypertension but are unlikely to differentiate among the diverse cardiac and pulmonary etiologies. Routine hematologic and blood chemistry studies are often unremarkable. Secondary polycythemia, resulting from long-standing hypoxemia, may be encountered. Abnormalities of liver function studies may be a consequence of hepatic congestion or may suggest the possibility of portopulmonary hypertension. Elevations in blood urea nitrogen (BUN) or uric acid levels may reflect the depressed cardiac output present in the latter stages of the disease.

Figure 33-1. Guideline for evaluating pulmonary hypertension. A wide range of differential diagnostic possibilities must be considered, including conditions amenable to surgical and medical therapies. PVOD, pulmonary veno-occlusive disease.

Alterations in gas exchange may represent either an accompaniment of pulmonary hypertensive disorders or a causal factor. In disease processes not affecting the lung, chest wall, or respiratory control mechanism, hypoxemia is the consequence of a decreased mixed venous oxygen saturation (SvO_2) resulting from a depressed cardiac output or from right-to-left shunting at either a cardiac or pulmonary level. In those processes which do affect the respiratory apparatus and which result in chronic hypoxia, vasoconstriction and vascular remodeling occur as a result of the hypoxemia, resulting in reduction of the pulmonary vascular bed to the degree necessary for the development of pulmonary hypertension.²⁷ A central differential point is the presence of hypercarbia, which suggests advanced obstructive or restrictive parenchymal lung disease, disorders of the chest wall, or the presence of alveolar hypoventilation on either a central or neuromuscular basis.

Patients with chronic obstructive lung disease tend to have less severe pulmonary hypertension than other forms of pulmonary vascular disease although severe pulmonary hypertension may occur. The development of pulmonary hypertension in patients with chronic obstructive pulmonary disease represents a poor prognostic sign in terms of both mortality and quality of life. Mean pulmonary artery pressures rarely exceed 40 mm Hg,

even in the presence of severe hypoxemia. This differs greatly from idiopathic pulmonary arterial hypertension, thromboembolic pulmonary hypertension, and from pulmonary hypertension associated with left heart and congenital heart diseases. In the latter stage of these disease processes, mean pulmonary artery pressure often exceeds 50 mm Hg, and can reach levels comparable to those of the systemic circulation. For this reason, pulmonary hypertension out of proportion to the degree of gas exchange impairment, or a rapid worsening of previously mild pulmonary hypertension in a patient with obstructive lung disease, should raise suspicion for a superimposed process such as thromboembolism, left ventricular dysfunction, or sleep apnea.^{28,29}

The chest radiograph may provide useful clues in the evaluation of a patient with suspected pulmonary hypertension (Fig. 33-2). If pulmonary hypertension is severe, enlargement of the right ventricle and pulmonary arteries (>16 mm enlargement of right interlobar pulmonary artery) may be recognized. Chest radiography can also be useful in suggesting the presence of pulmonary parenchymal, mediastinal, or cardiac problems responsible for the pulmonary hypertension.

Two noninvasive studies, echocardiography and ventilation-perfusion scanning, can provide valuable information regarding

Figure 33-2. Chest radiograph in a patient with pulmonary hypertension. Right hilar structures are markedly enlarged. Asymmetry of the two hilar silhouettes and oligemia of the left lower lobe suggest chronic thromboembolic pulmonary hypertension.

the severity and etiology of pulmonary hypertension. Transthoracic echocardiography (TTE), although often technically difficult in patients with advanced lung disease, has evolved as an important noninvasive means of assessing the degree of pulmonary hypertension and right heart enlargement.³⁰ Echocardiography has proved to be sensitive although somewhat less specific in detecting the presence of pulmonary hypertension in appropriate populations. Correlation between the echo-derived estimate of pulmonary artery pressure and that obtained at right heart catheterization is quite good within the range of pulmonary artery systolic pressures of 50 and 100 mm Hg.^{30,31} Echocardiography is useful in detecting disorders of the left atrium, left ventricle, and aortic and mitral valves. Systolic and/or diastolic left ventricular dysfunction can result in pulmonary venous hypertension that may be responsible for elevated pulmonary artery pressure. The addition of a contrast study is useful in the detection of intracardiac shunts.

Right heart catheterization remains the gold standard for the diagnosis of pulmonary hypertension and in the evaluation of response to therapeutic measures. Analysis of mixed venous oxygen saturation can allow diagnosis of intracardiac shunts, provide information regarding prognosis and response to therapy, and provide an improved measure of cardiac output in patients with severe tricuspid regurgitation in whom thermodilution measurements might be inaccurate. An elevated pulmonary capillary wedge pressure in the setting of a normal transpulmonary gradient suggests pulmonary venous or left ventricular disease as the etiologic basis of the pulmonary hypertension.

Ventilation/perfusion ($\dot{V}/\dot{Q}$) scanning, although having been supplanted by computed tomography in acute pulmonary embolism diagnosis, continues to play a central role in helping define the etiology of pulmonary hypertension. High-probability $\dot{V}/\dot{Q}$ (segmental and larger defects) scan results are very sensitive for detecting chronic thromboembolic pulmonary hypertension.³² Segmental defects also occur in patients with large vessel vasculitides, pulmonary artery sarcoma, extrinsic compression of large pulmonary arteries or veins, and on occasion in pulmonary veno-occlusive disease.³³ Patients with pulmonary hypertension resulting from abnormalities of the distal pulmonary bed have scan results that are normal or exhibit a mottled appearance (Fig. 33-3).

The $\dot{V}/\dot{Q}$ scan findings can often dramatically understate the actual degree of central pulmonary vascular obstruction in patients with chronic thromboembolic pulmonary hypertension.³⁴ The presence of even a single segmental or larger mismatched defect in a patient with pulmonary hypertension should raise the possibility of chronic thromboembolic disease and should lead to consideration of right heart catheterization and pulmonary angiography.

Imaging of the pulmonary vascular bed is best achieved using pulmonary angiography. The appearance of the normal pulmonary vasculature is one of smoothly tapering branches that extend to the periphery of the lung fields (Fig. 33-4). Two types of branching have been described: bifurcational branching in which the parent artery divides into two branches at an angle of 10 to 60 degrees; and collateral branching in which the trunk divides into two branches, one of which is virtually the size of and continues in the same direction as the parent trunk, the other which comes off at an angle of 30 to 80 degrees. In both types of branching, the sum of the diameters of both branches is greater than the diameter of the trunks. Angiographic evaluation should involve attention to the capillary and venous phases of the study in addition to the arterial phase. Evidence of pulmonary venous obstruction or of anomalous venous return can provide critical information regarding the etiology of the pulmonary hypertensive disorder.

Because major-vessel chronic thromboembolic pulmonary hypertension has been shown to be surgically remediable, establishing this diagnosis has become increasingly relevant. It is important to recognize that the angiographic patterns created by organized thrombi (pouch defects, webs or bands, intimal irregularity, abrupt vascular narrowing) are distinct from the intraluminal filling defects of acute thromboembolic disease or from the distal hypovascularity of small-vessel pulmonary hypertension (Fig. 33-5).³⁵ Although there are risks in performing pulmonary angiography in pulmonary hypertensive patients, the National Institutes of Health registry, the PIOPED (Prospective Investigation of Pulmonary Embolism Diagnosis) study, and the University of California, San Diego, Medical Center's experience suggest that this procedure can be performed safely by experienced angiographers taking certain precautions.^{36,37}

Other imaging modalities can also prove valuable in the evaluation of pulmonary hypertension. Computed tomography imaging is particularly useful in defining abnormalities of the pulmonary hilum, the mediastinum, the lung parenchyma, and the pulmonary vascular bed that could account or be contributing to a patient's pulmonary hypertension (Fig. 33-6). Arch aortography or magnetic resonance angiography may detect evidence of systemic involvement in cases of suspected Takayasu arteritis or other vasculitides.³⁸⁻⁴⁰

Figure 33-3. **A,** Ventilation-perfusion scan in chronic thromboembolic pulmonary hypertension showing multiple mismatched segmental defects. **B,** Perfusion scan in small vessel variant of pulmonary hypertension showing diffuse mottled appearance without segmental defects.

Figure 33-4. Normal right-sided pulmonary angiogram showing normal tapering vessels extending to the periphery of the lung.

The clinical utility of lung biopsy in the overwhelming majority of patients with small-vessel pulmonary hypertension is quite limited.⁴¹ When considering such an intervention, the information to be gained must be carefully weighed against the morbidity and mortality of the procedure, which are not insignificant, and the effect of open biopsy on future transplantation decisions. Biopsy should be considered only when there is a suspicion of unusual disease processes (pulmonary hemosiderosis, alveolar proteinosis, interstitial fibrosis), when the diagnosis cannot be established by less invasive serologic or radiographic techniques, and when the possibility of effective therapeutic intervention is present.

Therapeutic Approach

Idiopathic Pulmonary Arterial Hypertension

Extraordinary advances have been made in the diagnostic and therapeutic approach to idiopathic pulmonary arterial hypertension (IPAH), once considered a rare, almost uniformly fatal disease, which pursued a progressive course with a median survival time of less than 3 years. These advances have been based on a better understanding of the pathobiologic mechanisms of the disease and the mediators involved in its progression, the development and introduction of several classes of vasodilating or antiproliferative agents, and on the use of lung transplantation in those patients in whom pharmacologic management is ineffective.

Although not systematically studied in patients with pulmonary hypertension, oxygen supplementation, diuretics, anticoagulation, and cardiac glycosides are routinely used but should be applied in a targeted fashion. The basis for each can be justified clinically given the physiologic consequences of the disease: oxygen therapy to reduce pulmonary vasoconstriction in

Figure 33-5. **A** and **B**, Biplane pulmonary angiograms showing several of the characteristic findings in chronic thromboembolic disease. Note segmental level cutoffs in upper lobe vessels and marked irregularity of lower lobe pulmonary artery. On the lateral view (**B**), complete obstruction of the lower lobe artery below a dilated right middle lobe branch and the superior segment branch is apparent (arrow).

Figure 33-6. CT scan showing filling defect in the pulmonary outflow tract, both main pulmonary arteries, and the left lower lobe artery consistent with pulmonary artery sarcoma.

patients with hypoxemia, diuretics for volume overload and its adverse effect on right and left ventricular function, anticoagulants for the prothrombotic state that accompanies the disease, and digoxin to enhance ventricular function in patients with evidence of right ventricular failure.⁴²

Four classes of drugs are currently available for pulmonary hypertension therapy: prostanoids (epoprostenol, treprostinil, iloprost); endothelin blockers (bosentan, ambrisentan); phosphodiesterase inhibitors (sildenafil); and calcium channel blockers. Each differs in terms of its indication for use, mechanism of action, and side-effect profile.⁴³⁻⁴⁵

Epoprostenol, the first drug approved by the FDA for the treatment of pulmonary artery hypertension, is a potent, short-acting vasodilator and antiproliferative agent. Administered by constant intravenous infusion, it is the only medication for PAH that has demonstrated a survival benefit in a randomized clinical trial.⁴⁶ Epoprostenol is stored as a dry powder, reconstituted with a sterile diluent, and then continuously infused via an ambulatory infusion pump worn by the patient. Common side effects include flushing, diarrhea, headache, arthralgias, tachycardia, and jaw pain. High doses may produce hypotension and heart failure, and, because of epoprostenol's potent vasodilatory properties, patients with coronary artery disease may develop a coronary steal phenomenon and experience cardiac ischemia with its administration. Sudden reductions in dose or abrupt cessation of the drug may result in severe rebound pulmonary hypertension or even sudden death. The necessity for a tunneled catheter places patients at risk for line infections and thrombotic complications.

Treprostinil is a stable prostacyclin analogue approved by the FDA for continuous subcutaneous administration, although it can also be delivered as a continuous intravenous infusion or by inhalation. Advantages of treprostinil include a longer half-life than epoprostenol (55 to 117 minutes vs. <5 minutes), its stability at room temperature, and its ability to be infused subcutaneously. Infusion site complications, most notably pain often associated with erythema and induration, limit its usefulness.

Iloprost, another prostacyclin analogue, has a half-life of approximately 30 minutes and is approved for inhalation therapy. The inhalational route theoretically provides the advantage of minimizing systemic side effects and of delivering the drug to

well-ventilated regions of the lung, thereby minimizing ventilation-perfusion mismatch in patients with parenchymal lung disease. Each iloprost treatment requires 5 to 10 minutes through a special nebulizer device and must be administered six to nine times a day, thereby limiting its utility.

Bosentan, the second drug approved by the FDA for the treatment of pulmonary artery hypertension, is a dual, nonselective endothelin receptor antagonist that has demonstrated improved exercise capacity and cardiopulmonary hemodynamics compared to a placebo in patients with IPAH and pulmonary hypertension associated with connective tissue disease.⁴⁷ Small trials have also demonstrated that bosentan has positive hemodynamic and symptomatic effects in patients with HIV-related pulmonary hypertension and in those with Eisenmenger syndrome.^{48,49} The most important adverse effect associated with bosentan is hepatocellular injury, which occurs in 5% to 10% of patients. The injury appears to be reversible on withdrawal of the drug and the FDA requires that liver function studies be performed monthly in patients receiving the drug. Bosentan is a pregnancy category X drug. Therefore pregnancy must be excluded before the start of therapy and a second form of birth control used in addition to hormonal therapy because bosentan can affect hormone levels.

Ambrisentan has recently been approved for pulmonary hypertension treatment. Unlike bosentan, ambrisentan is an ET (A)-selective endothelin receptor antagonist. In phase 3 clinical trials in patients with PAH, ambrisentan (2.5 to 10 mg daily) improved exercise capacity, Borg dyspnea index, time to clinical worsening, World Health Organization (WHO) functional class, and quality of life compared with the placebo.⁵⁰ Advantages of ambrisentan include a lower incidence and severity of hepatocellular injury and decreased interference with P450 enzymes, thereby lowering the risk of certain drug-drug interactions.

Sildenafil, a phosphodiesterase-5 inhibitor, functions through the nitric oxide/cyclic GMP (NO/cGMP) pathway by slowing the metabolism of cGMP and increasing delivery of nitric oxide to the lung. The SUPER trial demonstrated significant improvement in symptomatic, functional, and hemodynamic status in patients in WHO class II and III status when compared with the placebo.⁵¹ The optimal dose of sildenafil has not been determined but seems to be in the range of 60 to 240 mg daily. In the SUPER trial, 20 mg every 8 hours was as effective as 40 or 80 mg during the initial 12 weeks of the study. Patients in the extension study were treated with 80 mg three times daily and demonstrated stability in functional status as defined by the 6-minute walk distance after 1 year. Whether a lower dose would have been effective is not known. In another trial, sildenafil administered at a dose of 50 mg three times daily was equivalent to bosentan at improving a 6-minute walk distance and pulmonary hemodynamics in WHO class III patients with IPAH or pulmonary arterial hypertension associated with a connective tissue disease.⁵² The role of the longer-acting phosphodiesterase-5 inhibitors, tadalafil and vardenafil, in the therapy of pulmonary arterial hypertension remain to be determined.

The use of combination therapy is an appealing concept in that it would allow different pathogenic pathways to be targeted and minimize the toxicity associated with higher doses of individual agents. To date there have been few prospective trials conducted to appraise the benefit of combination therapy although a number of trials using a variety of drug combinations are planned or underway.⁵³ Until the development and approval

of bosentan and sildenafil, calcium channel antagonists were the only class of oral agents demonstrated to provide long-term benefit in this patient population. In 1992, Rich and coworkers reported their experience with 64 IPAH patients receiving high-dose calcium channel blockers.⁵⁴ Seventeen patients (26%) experienced a decline in pulmonary vascular resistance of 20% or more, a response that was maintained up to 5 years in all but one patient. In the patients who had a response, not only were quality-of-life measures improved, but 5-year survival was considerably higher (94% vs 38%) relative to patients who did not manifest an acute response to vasodilator challenge.

The risks of empirically initiating calcium channel antagonist therapy in patients with IPAH cannot be overemphasized. Patients being considered for treatment of IPAH should be referred to specialized centers where an acute vasodilator challenge study can be performed under hemodynamic monitoring. This recommendation is based on several considerations. Less than 10% of patients with IPAH will demonstrate a degree of vasodilator responsiveness, defined as a decrease in the mean pulmonary artery pressure of at least 10 mm Hg to less than 40 mm Hg with a normal cardiac output, predictive of a satisfactory long-term outcome when treated with calcium channel blockers alone.⁵⁵ For those who do not meet these stringent response criteria, the failure rate of calcium channel blocker therapy is substantial and the negative inotropic and systemic vasodilating effects of calcium channel antagonists can result in a number of adverse consequences, which include worsening right ventricular failure, hypotension, and sudden death.⁵⁶ The dose of calcium channel antagonists used in idiopathic pulmonary arterial hypertension is considerably higher than that used in other disease states.

An acute vasodilator challenge can be performed using a number of agents. Intravenous epoprostenol in a dose of 2 to 12 ng/kg/min has been used as a vasodilator-challenging agent. It is particularly useful because of its potency and short biologic half-life (around 3 minutes), making it easy to titrate and minimizing the duration of any adverse hemodynamic consequence. Side effects include headache, flushing, abdominal pain, diarrhea, and systemic hypotension, all of which resolve quickly after the infusion is discontinued. Because of its short serum half-life, adenosine is a desirable agent to use as a vasodilator in the assessment of PH. Schrader and colleagues studied 15 patients (11 patients with IPAH) with IV adenosine administered at a dose of 50 g/kg/min and increased by 50 µg/kg/min every 2 minutes to a maximum dose of 500 µg/kg/min to acutely assess vasodilator response. Inhaled nitric oxide also has been used as a vasodilator challenging agent. Significant advantages of this agent compared with intravenous prostacyclin and adenosine include its short duration of activity and its lack of systemic hemodynamic effects. Channick and coworkers examined the effects of inhaled nitric oxide (40 ppm) in 16 patients with IPAH and demonstrated a response in 5 (31%). With one exception, patients who responded to nitric oxide also responded to epoprostenol. A significant decline in mean arterial pressure and systemic vascular resistance occurred with epoprostenol, an effect not seen with inhaled nitric oxide.⁵⁸

Patients having right ventricular decompensation represent a medical emergency. The role of vasopressors and inotropes in this population must be guided by an understanding of their effect on cardiac output and pulmonary and systemic vascular resistances. The goals of enhancing cardiac output and reducing

pulmonary vascular resistance while avoiding disproportionate decreases in systemic vascular resistance can be problematic and may require combination therapy. Dobutamine, norepinephrine, and dopamine have been used successfully in conjunction with more specific pulmonary vasodilating/antiproliferative agents, such as epoprostenol, nitric oxide, and sildenafil. The role of diuresis in patients with intravascular volume overload cannot be emphasized too strongly. Volume overload can result in overdistention of the right ventricle, thereby increasing right ventricular wall tension and oxygen demands, decreasing contractility, impairing left ventricular filling and compliance, and reducing systemic cardiac output and oxygen delivery.

The role of atrial septostomy in patients with idiopathic pulmonary arterial hypertension remains undefined.^{59,60} Preliminary observations suggest that it may represent a potential, albeit high-risk option as a bridge to transplantation in patients with severe pulmonary hypertension whose clinic status is deteriorating despite maximal pharmacologic management. The purpose of the procedure is to “unload” the right ventricle and to improve left ventricular function, cardiac output, and systemic oxygen delivery. These benefits, however, come at the price of significantly worse gas exchange as the result of the newly created or enlarged right-to-left shunt, which may result in refractory and life-threatening hypoxemia. The procedure can be performed by blade septostomy or, preferably, by graded balloon dilation, which allows the hemodynamic benefit to be balanced against the gas exchange consequence.

For IPAH refractory to medical therapies, lung transplantation has become a therapeutic option.⁶¹ With an awareness that the right ventricle is capable of resuming normal function once reduction in right ventricular afterload has been achieved, single lung transplantation has become an alternative to double lung or heart-lung transplantation.⁶² Recently published data from the Registry of the International Society for Heart and Lung Transplantation demonstrated, however, that 90% of the lung transplant procedures for pulmonary hypertension between 1995 and 2006 were double lung rather than single. During that time frame, transplantation for “primary pulmonary hypertension” represented only 3.6% of the total number of lung transplant procedures. This decrease in both the absolute and relative number of lung transplant procedures performed for pulmonary hypertension is a tribute to the substantial gains that have been made over the past decade in the pharmacologic management of the disease. Primary pulmonary hypertension remains the second most frequent indication for heart-lung transplant. Early survival (3 months and 1 year) in patients undergoing lung transplantation for pulmonary hypertension is below that for other indications, such as cystic fibrosis and chronic obstructive pulmonary disease. However, at 10 years, pulmonary transplant recipients recover to an intermediate survival position among the diseases. Four-year survival for both lung and heart-lung transplantation remains less than 60%. For this reason, organ transplantation must still be considered a treatment of last resort in patients with IPAH.

Chronic Lung Disease

Recent reviews have discussed the therapeutic approach to pulmonary hypertension complicating chronic lung disease.⁶³ Although the degree of baseline pulmonary hypertension is generally mild to moderate in patients with chronic respiratory disease, significant worsening can occur during acute

exacerbations, exercise, and sleep. Furthermore, it has been demonstrated that the development of pulmonary hypertension adversely affects prognosis. In selected cases, the pulmonary hypertension and right ventricular dysfunction can dominate the clinical picture.²⁹

The primary approach to therapy involves optimization of lung function and gas exchange. The only form of therapy demonstrated to improve survival in chronic lung disease has been the administration of supplemental oxygen. Although no clear relationship between improved survival with supplemental oxygen and an improvement in pulmonary hemodynamics has been demonstrated, results from the British MRC and the NOTT suggest that oxygen therapy may prevent any further increases studies in pulmonary arterial pressure.^{64,65} In addition to improving survival, oxygen therapy has been demonstrated to improve neurologic function and exercise performance.

Guidelines for oxygen therapy, based on the NOTT entry criteria, include the administration of oxygen to patients with PaO_2 less than 55 mm Hg while breathing room air or those with a PaO_2 less than 60 mm Hg with peripheral edema, a hematocrit greater than 55%, and/or electrocardiographic evidence of right ventricular hypertrophy. In terms of survival and neuropsychologic function, continuous oxygen therapy appears more efficacious than that administered for shorter daily durations.

Except for measures designed to specifically improve arterial oxygenation, it is difficult to demonstrate the benefit of adjunctive measures used in patients with chronic obstructive lung disease. Although commonly used, cardiac glycosides have not been demonstrated to improve right ventricular function in patients with chronic obstructive lung disease. Digitalis, therefore, should be used with great care in hypoxic individuals, especially those being treated with sympathomimetic amines because of the threat of induced arrhythmias. Digitalis may be indicated, however, in patients with supraventricular arrhythmias and in those with coexisting left ventricular dysfunction. Likewise, care should be taken in the use of diuretics in patients with chronic lung disease and normal left ventricular function. Excessive diuresis can induce a metabolic alkalosis and worsen carbon dioxide retention, increase pulmonary vascular resistance through an increase in hematocrit and blood viscosity, adversely affect right ventricular preload and cardiac output, and predispose the patient to electrolyte abnormalities and the risk of superimposed arrhythmias.

The use of prostanoids, endothelin blockers, or phosphodiesterase inhibitors has not been demonstrated to be of proven benefit in patients with obstructive or restrictive lung disease. Although a reduction in pulmonary vascular resistance may accompany their use, the use of vasodilators in chronic obstructive lung disease may worsen gas exchange by relieving hypoxic vasoconstriction and thereby shunting blood to poorly ventilated areas of the lung. The use of agents such as calcium channel blockers may worsen cardiac output as a result of their negative inotropic effect and reduction in right ventricular preload.

In pulmonary hypertension associated with certain types of parenchymal lung disease, specific therapies can be directed to improve vascular resistance and right ventricular function. For example, if vessel inflammation is felt to be a substantive contributor to an increase in pulmonary vascular resistance (i.e., idiopathic interstitial fibrosis, sarcoidosis, Takayasu arteritis), a trial of corticosteroids, or other immunosuppressants, is indicated. The use of assisted ventilator devices in patients with

chronic alveolar hypoventilation, or of nasal continuous positive airway pressure devices in patients with obstructive sleep apnea, can effectively prevent the hypoxemia and hypercarbia responsible for the pulmonary vasoconstriction and right ventricular dysfunction present in these disease processes.

In patients with end-stage chronic lung disease, particularly when complicated by pulmonary hypertension, single or double lung transplantation represents a viable intervention. In addition to improvement in lung function and gas exchange following transplantation, pulmonary hemodynamics may return to normal levels and even severe right ventricular dysfunction appears to be reversible with alleviation of the increased right ventricular afterload.

Postoperative Pulmonary Hypertension

Cardiothoracic surgical procedures may be complicated by postoperative pulmonary hypertension. The etiology of this phenomenon is uncertain but may be related to endothelial injury associated with cardiopulmonary bypass or ischemic-reperfusion injury. In small series, both inhaled iloprost and nitric oxide have been demonstrated to have positive hemodynamic effects although a mortality benefit has not been confirmed in a prospective study.⁶⁶⁻⁶⁸

Portopulmonary hypertension represents a major risk factor for perioperative mortality in patients undergoing liver transplantation, which approaches 100% when the mean pulmonary artery pressure exceeds 45 mm Hg. Case reports and series have described successful transplantation in selected patients using intravenous epoprostenol or oral sildenafil as a bridge to transplantation.^{68,69}

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension (CTEPH) represents a potentially curable form of pulmonary hypertension. Based on recent data, it appears to be more common than idiopathic pulmonary arterial hypertension, occurring in approximately 1% of patients after an episode of acute pulmonary embolism.⁷⁰ In the majority of surgically treated patients, marked improvement in pulmonary hemodynamics and functional status can be achieved following pulmonary thromboendarterectomy.^{12,13}

Patient selection for thromboendarterectomy is essential to assure an optimal surgical outcome. The decision to proceed to thromboendarterectomy is based on several objective factors. First, the presence of pulmonary vascular obstruction should result in hemodynamic or ventilatory impairment at rest or with exercise. The majority of operated patients have a pulmonary vascular resistance in excess of $300 \text{ dynes} \cdot \text{sec} \cdot \text{cm}^{-5}$, at rest or with exercise. Occasional patients, especially those with involvement of one main pulmonary artery, have a significant exercise impairment due to high minute ventilation demands, without substantially altered pulmonary hemodynamics. Surgery is also indicated in those patients with only mild or modest degrees of pulmonary hypertension at rest but who develop striking levels of pulmonary hypertension with exercise-related increases

in cardiac output. Because this hemodynamic response reproduces events during the patient's activities of daily living, it may reflect the true work load of the right ventricle. Furthermore, there is increasing evidence to suggest that the small vessels of the "open" pulmonary vascular bed, if exposed to these high pressures and flows over a sufficient period of time, will develop secondary hypertensive changes, thereby perpetuating the cycle of pulmonary hypertension. Surgical intervention, before fixed, small-vessel changes or right ventricular failure occurs, results in improved operative mortality risk and long-term hemodynamic and functional status.

Although a thoracotomy approach has been used in the past, sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest appears to be the procedure of choice. Sternotomy allows access to both pulmonary arteries and assures more complete removal of the obstructing material. The use of cardiopulmonary bypass allows periods of complete circulatory arrest, necessary to provide the bloodless operating field essential for meticulous lobar and segmental dissections. It should be emphasized that thromboendarterectomy bears no resemblance to acute pulmonary embolectomy. The neointima in chronic thromboembolic disease is deceptive and is often not easily recognizable as chronic thrombi. The procedure is a true endarterectomy of chronic, endothelialized material from the native intima to restore pulmonary arterial patency (Fig. 33-7).

The operative and perioperative mortality rate in the 1959 patients who have undergone thromboendarterectomy at UCSD Medical Center, San Diego, has been 6.0%. Over the last 5 years, during which 720 patients have undergone surgery, 32 patients have died, for an in-hospital mortality of 4.4%. In addition to the complications common to other forms of cardiac surgery, patients undergoing pulmonary thromboendarterectomy face two additional and potentially fatal risks: postoperative lung injury (reperfusion pulmonary edema) and persistent postoperative pulmonary hypertension and right ventricular failure.

Reperfusion pulmonary edema, biochemically and clinically, appears to represent a localized form of high-permeability lung

injury. It may appear up to 72 hours after surgery and is highly variable in severity, ranging from a mild form of edema to an acute, hemorrhagic, and fatal complication. Management of reperfusion injury, as with other forms of acute lung injury, is supportive until resolution occurs. Investigations are ongoing to determine the basis for reperfusion lung injury and to find effective means of prevention or therapy.

In terms of residual postoperative pulmonary hypertension, this most commonly occurs in patients with longstanding disease in whom a secondary pulmonary arteriopathy has developed or in patients with a distal location of the occluding thromboembolic material. Residual postoperative pulmonary hypertension represents a significant cause of postoperative mortality with the mortality rate thirtyfold greater in patients with a postoperative pulmonary vascular resistance (PVR) greater than 500 dynes·sec·cm⁻⁵ than those in whom the postoperative PVR is less than 500 dynes·sec·cm⁻⁵.¹³

Lung transplantation remains a therapeutic alternative for patients not deemed candidates for thromboendarterectomy and for those who have undergone thromboendarterectomy with an inadequate hemodynamic outcome. Case series suggest that patients not deemed candidates for thromboendarterectomy by nature of the distal location of their disease and those who have residual postoperative pulmonary hypertension may benefit from the endothelin receptor antagonists sildenafil or prostanooids.⁷¹⁻⁷³ Epoprostenol has also been used as a bridge to thromboendarterectomy in patients with thromboembolic pulmonary hypertension and severely altered hemodynamics. Although such an intervention is capable of improving pulmonary hemodynamics, it remains to be established whether it reduces postoperative mortality or complications.⁷⁴

The need for a coordinated, experienced, multidisciplinary team dedicated to managing the complex problems often associated with the care of these patients cannot be emphasized too strongly. The often intricate details of the evaluative, surgical, and postoperative phases of care require an extensive experiential base to master. However, compared with lung transplantation, the only therapeutic alternative, thromboendarterectomy has much to recommend it in terms of long and short-term mortality, quality of life, and lack of need for immunosuppressant therapy.

Conclusion

Advances during the past decade in the pharmacologic and surgical management of several forms of pulmonary hypertension, namely chronic thromboembolic pulmonary hypertension and idiopathic pulmonary arterial hypertension, have been evolutionary, transforming disease processes once considered uniformly fatal into those consistent with a normal quality and duration of life. With an increasing understanding of pathophysiologic and pathobiologic mechanisms, and the role of various mediators in the initiation and progression of pulmonary arterial hypertension, new and innovative therapies can be envisioned. The progress that has been achieved in the diagnostic and therapeutic approach to patients with idiopathic and thromboembolic pulmonary hypertension, therefore, should not be considered the culmination of research and clinical efforts, but rather a model to apply to other forms of pulmonary hypertensive disease.

Figure 33-7. Surgical specimens obtained at the time of thromboendarterectomy. Note organized thrombotic material involving multiple branches beyond the area of central obstruction.

Hemodynamically Unstable Presentations of Congenital Heart Disease in Adults

David Gregg, Melvin D. Cheitlin, Elyse Foster

CHAPTER 34

Anatomic and Pathophysiologic Classification
of Congenital Heart Disease
Heart Failure in the Adult with Congenital
Heart Disease

Other Catastrophic Emergencies
Conclusion

AMONG THE large number of patients with cardiac emergencies, the patient with congenital heart disease is a rarity. However, with growing numbers of patients with complicated congenital cardiac lesions surviving childhood and with larger numbers with serious, but more common lesions palliated by surgery, the cardiologist increasingly is seeing more patients with congenital heart disease, some of whom will have cardiac emergencies. Between 1985 and 2000, the number of adults with congenital heart disease has doubled, resulting in approximately 1 million adult survivors in the United States who are increasingly having late complications.¹ Although the anatomy and nomenclature of congenital heart disease is often intimidating to an adult cardiologist, the care in most cases is analogous to that of other adult patients. For example, the care of a young adult with heart failure from a failing systemic right ventricle is modeled after the deep clinical experience caring for patients with left heart failure. Being aware of congenital anatomy and the complications that are frequently seen in common congenital lesions, however, is important to help focus on the likely diagnosis and optimal treatment plan.

In general, patients with congenital heart disease are seen as adults because they have one or more of the following conditions²:

1. Simple lesions that may escape early diagnosis (native disease) or have had early repair:

Native lesions in this category include:

- Congenital aortic stenosis
- Isolated mitral valve disease
- Isolated patent foramen ovale or small atrial septal defect
- Isolated small ventricular septal defect
- Mild pulmonary stenosis

Repaired conditions in this category include:

- Previous ligated or occluded PDA
- Repaired isolated ASD
- Repaired isolated VSD

2. Moderately complex lesions that were asymptomatic in childhood and not repaired (e.g., atrial septal defects [ASD], patent ductus arteriosus [PDA], Ebstein disease, coarctation of the aorta) or underwent palliative repair (e.g., tetralogy of Fallot, coarctation of the aorta).

3. Lesions of great complexity including lesions that were palliated in childhood (e.g., single ventricle D-transposition of the great vessels with atrial or arterial switch, tricuspid atresia with Fontan operation) or were not amenable to a surgical procedure. (Severe pulmonary vascular disease [Eisenmenger syndrome] or patients with very small pulmonary arteries located where focalization or shunts are not possible). Even these patients are now often candidates for lung or heart-lung transplant.

The majority of these lesions never present as cardiac emergencies. However, with incisions in the atrium affecting the pacemaker or conduction system; with incisions in the ventricle forming fibrous scars as the basis for re-entrant ventricular arrhythmias, with anatomic right ventricles functioning as a systemic ventricle; and with residual lesions forming the substrate for developing infective endocarditis, cardiac emergencies do occur and form the content of this chapter (Table 34-1).

There are emergencies that are unique to the patient with congenital heart disease: For example, the occurrence of pregnancy in the patient with Eisenmenger syndrome. The drop in systemic vascular resistance in these patients increases the right-to-left shunt and results in arterial desaturation. However, most emergent complications seen in congenital heart disease are similar to the emergency situations seen in cardiovascular problems of other more common etiologies. The diagnosis of ventricular tachycardia in a patient with repaired tetralogy of Fallot is treated in a manner similar to the patient with coronary disease and ventricular tachycardia and, unfortunately, with the same uncertain efficacy. It is important to remember that a patient with repaired tetralogy of Fallot is at risk of developing ventricular tachycardia and to recognize the importance of investigating palpitation and presyncope and syncope. Substantial analogies to the care of general cardiac patients exist, but this needs to be combined with knowledge of what complications to expect with what lesion and management needs to be tailored to a congenital patient's unique anatomy (Table 34-2).

In the patient with a cardiac emergency, congenital heart disease can predispose the patient to certain complications that may be responsible for the cardiac emergency. For example, in a patient with L-transposition of the great vessels and shortness

Table 34–1. Cardiac Emergencies

	Life-Threatening*	Not Life-Threatening
Arrhythmia	AF with bypass tract Atrial flutter Mustard Frontan CHB with hypotension or CHF and/or ventricular escape Ventricular tachyarrhythmias with symptoms	AF without bypass tract CHB: normal hemodynamics and nodal escape Isolated PVCs Asymptomatic, nonsustained VT
Ischemia	Ongoing chest pain with ischemic ECG changes	Chronic nonischemic chest pain
Ventricular failure	New murmur + fever Compromising pleural effusion or ascites	
Cyanosis	Loss of continuous murmur in patient with BT or central shunt Acute pulmonary infection	Chronic cyanosis
Noncardiac	Hemoptysis Transient ischemic attacks or seizures (new onset)	Gout Biliary colic

*Warrants admission to CICU.

Abbreviations: AF, atrial fibrillation; BT, Blalock-Taussig shunt; CHB, complete heart block; VT, ventricular tachyarrhythmias.

of breath, the right ventricle is acting as the systemic ventricle and is prone to failure. The diagnosis of heart failure is not difficult, and treatment of congestive heart failure in these patients is similar to the treatment of congestive heart failure in those with other conditions.

Anatomic and Pathophysiologic Classification of Congenital Heart Disease

During the formation of the heart and cardiovascular system, there are many opportunities for the development of the lesions of congenital heart disease. The large variety of lesions forming the body of congenital heart disease can be confusing. It is helpful for the cardiologist seeing adult patients to think of these lesions in an organized manner. The following classification is helpful in that all congenital heart patients fit into one or more of these categories.

1. Predominant left-to-right shunt. Blood that has gone through the lungs, recirculates to the right side of the heart, and as a result the pulmonary blood flow is greater than the systemic blood flow. The shunt can occur at any level (e.g., at the venous level, anomalous pulmonary vein to the superior vena cava; at the atrial level, ASD; at the ventricular level, VSD; at the arterial level, PDA).
2. Predominant right-to-left shunt, or “cyanotic disease.” The blood is shunted from the right heart to the systemic circulation, bypassing the lungs. The arterial blood is therefore desaturated. If the amount of desaturated hemoglobin is 5 g/dL or greater, cyanosis can be observed. The systemic blood flow is greater than the pulmonary blood flow. This shunt also can occur at any level of the cardiovascular system (e.g., at the venous level, superior vena cava draining into the left atrium; at the atrial level, tricuspid atresia with an ASD; at the ventricular level, tetralogy of Fallot; at the arterial level, truncus arteriosus).
3. Stenotic or atretic valves and hypoplastic or atretic ventricles. The valves can also be incompetent. Either ventricle may be hypoplastic or atretic.

4. Great vessel abnormalities. Transposition of the great vessels, coarctation of the aorta, PDA, vascular rings, and truncus arteriosus.
5. Abnormalities of position. Transposition of the great vessels, L-transposition, dextroposition, and dextrocardia.

Arrhythmias

Arrhythmias are some of the more common emergencies seen in patients with congenital heart disease. There are two types of arrhythmias: bradyarrhythmias (e.g., sick sinus syndrome, sinus arrest, varying degrees of heart block including complete heart block) and tachyarrhythmias (e.g., atrial fibrillation, atrial flutter, ventricular tachycardia, and fibrillation).

The arrhythmic patient may have palpitations, presyncope, or syncope. With atrial tachyarrhythmias, the patient usually complains of palpitations, which sometimes are severe enough to frighten the patient. Presyncope or syncope occurs with extremely rapid ventricular response, raising pulse rates to 200 beats/min or more. If the left ventricle is noncompliant with an atrial tachyarrhythmia, especially atrial fibrillation—in which there is no atrial contraction—stroke volume can fall dramatically, and the patient may develop syncope. The diagnosis of this type of arrhythmia can be made by electrocardiogram (ECG) if the arrhythmia is persistent. However, even if the patient having syncope or presyncope is in sinus rhythm at the time of the examination, it is most important to consider the patient with congenital heart disease, with or without repair, as having a potentially fatal arrhythmia.

The atrial bradyarrhythmias and tachyarrhythmias encountered in patients with congenital heart disease may result from hemodynamic alterations of the atrium or involve areas of slowed conduction in the areas of scar associated with prior surgery. These may include surgery for ASD repair,³ both ostium secundum and ostium primum defects, Fontan procedures for tricuspid atresia or single ventricle,^{4,5} and the Mustard or Senning procedure for transposition of the great arteries.^{6,7}

Lesions affecting the conduction system and causing AV block have become less common since surgeons have learned to avoid the conduction system during surgery. However, with any

Table 34–2. Complications of Congenital Heart Disease

Lesion	Special Considerations
Tetralogy of Fallot	Ventricular tachycardia Atrial fibrillation Right ventricular dysfunction Pulmonary regurgitation (late complication usually associated with moderate to severe regurgitation)
Fontan	Ventricular dysfunction Sinus node dysfunction Atrial flutter/intra-atrial re-entrant tachycardia (IART) Fontan obstruction or leak Pulmonary embolus
D-transposition of great arteries	Atrial flutter/IART Systemic right ventricular dysfunction AV block (uncommon late) Baffle systemic AV valve regurgitation Sinus node dysfunction with junctional rhythm (usually asymptomatic)
L-transposition of great arteries	Systemic ventricular failure AV block Systemic AV valve regurgitation WPW (2%–4%)
Coarctation	Dissection Bicuspid valve with endocarditis, regurgitation, or stenosis Early coronary artery disease or heart failure Cerebral aneurysm
Left-to-right shunt	Pulmonary hypertension (Eisenmenger syndrome) Atrial fibrillation Endocarditis (VSD or PDA, rare with ASD)
Right-to-left shunt (cyanotic)	Paradoxical embolus Worsening cyanosis Brain abscess Bleeding diathesis Hyperviscosity syndrome with erythrocytosis Protein-losing enteropathy
Marfan	Dissection Aortic valve regurgitation Mitral valve prolapse

VSD repair, immediate injury or later injury as a result of fibrosis is a possible cause of progressive heart block. With advances in surgical technique and knowledge of the path of the conduction system, heart block after repair of VSD is increasingly rare with persistent heart block seen in less than 1% of patients.⁸

L-transposition, or corrected transposition of the great vessels, is a lesion in which ventricular inversion has occurred without inversion of the atria or great arteries. In this condition, the anatomic right ventricle is the systemic ventricle and the anatomic left ventricle is the pulmonic ventricle, but the physiologic passage of blood is normal (i.e., the systemic venous return is pumped to the lungs, and the pulmonary venous return is ejected into the aorta). The conduction system is also inverted

and the AV node is abnormally located and often dual with elongation of the bundle of His.⁹ As a result, these patients have a high rate of AV block, which can occur at all levels of severity—from first to third degree—and which increases in incidence with age at a rate of about 1% to 2% per year.

Atrial Tachyarrhythmias

The diagnosis and treatment of bradyarrhythmias and tachyarrhythmias are the same in patients with congenital heart disease as for those with other lesions. When symptomatic bradycardia and hemodynamic instability, such as hypotension or syncope, are present, a pacemaker is indicated.

Atrial fibrillation, tachycardia, and flutter, when they occur in patients with congenital heart disease, are usually relatively not life-threatening.^{10,11} These arrhythmias occur in about 20% of patients with ASDs and can recur even after the ASD is repaired, especially when the repair is performed late in life (after the age of 40).³ In some defects, atrial fibrillation or atrial flutter can be very serious and even life-threatening. The treatment is similar to that of atrial fibrillation or atrial flutter due to other causes; with rapid atrial tachycardia in patients with hemodynamic instability, immediate cardioversion is indicated. In patients who are hemodynamically stable with noncontracting atria, which may be seen in conditions such as atrial fibrillation and atrial standstill, anticoagulation therapy for 3 weeks before cardioverting is indicated. In such cases, the patient should receive anticoagulation for 3 weeks after cardioversion until mechanical atrial contraction is well established. If the patient is hemodynamically stable, the ventricular response can be slowed with amiodarone, β -blockers, verapamil, or diltiazem. If it is necessary to cardiovert before achieving stability, a period of anticoagulation can be provided. Transesophageal echocardiography (TEE) to rule out evidence of atrial thrombus is desired and allows safe cardioversion. With atrial tachycardia, 6 mg adenosine given intravenously usually converts the patient to sinus rhythm. If this treatment is unsuccessful, another 6 to 12 mg of adenosine can be given.

Atrial flutter or intra-atrial re-entrant tachycardia occurs frequently in patients who have undergone a Fontan procedure, with the prevalence estimated as high as 50% in adult patients. The presentation is usually subacute but occasionally hemodynamic instability and even sudden death especially in the setting of 1:1 conduction.¹² The patient should be converted to normal sinus rhythm either pharmacologically or by cardioversion with the caution that antiarrhythmics may exacerbate sinus node dysfunction, AV conduction, or promote 1:1 conduction of an atrial arrhythmia. If atrial flutter recurs, the patient should be referred to an electrophysiologist to map the pathways of flutter, if possible. If this can be done, catheter ablation of the pathway is possible. If atrial flutter or atrial tachycardia recurs incessantly and ablation attempts fail, then ablation of the AV node with placement of a dual-chamber (DDD) pacemaker should be considered. If the patient does not remain in sinus rhythm, then a physiologically responsive (VVIR) pacemaker is the treatment of choice.

Another atrial arrhythmia that can be fatal is atrial tachycardia and subsequent atrial fibrillation in a patient with an antegrade conducting bypass tract. In this condition, the impulse conducts from the atrium to the ventricle over the bypass tract. Especially with sympathetic stimulation or increased conductivity induced by digitalis, the ventricular response can approach

250 to 300 beats/min, and the patient may develop ventricular fibrillation. In patients with a possible AV bypass tract, digoxin should always be avoided. Patients with Ebstein anomaly have 25% incidence of bypass tracts in the posteroseptal location and a bypass tract may be present in 2% to 4% of patients with L-TGA.

In patients with atrial fibrillation and an AV bypass tract (i.e., Wolff-Parkinson-White syndrome), digoxin should always be avoided. In these patients, the ventricular response is controlled with a β -blocker or calcium channel blocker. When present, the AV bypass tract should be ablated.

Ventricular Tachyarrhythmias

Ventricular tachyarrhythmias can occur as a result of incisions in the right or left ventricle with fibrous scar forming the basis for re-entrant arrhythmias or more commonly with progressive ventricular enlargement with decreased left or right ventricular function, or a hypertrophied left or right ventricle.

The development of ventricular tachyarrhythmias late after surgery is not uncommon. This is especially true in patients with tetralogy of Fallot; sudden death later after surgery is seen in about 6% of patients in long-term follow-up.¹³ Late sudden death and ventricular arrhythmias in tetralogy correlate well with the degree and duration of pulmonary regurgitation, with arrhythmias increasing as continued pulmonary regurgitation results in progressive right ventricular enlargement.¹⁴ As the right ventricle enlarges, there is increased fibrosis, QRS prolongation, and Q-T dispersion that appears to provide the substrate for ventricular tachycardia.^{15,16} Fortunately, it appears that timely pulmonary valve replacement may decrease the incidence of arrhythmias.¹⁷

The patient may have palpitations, presyncope, or syncope. The diagnosis of ventricular tachycardia can be made on ECG, either on presentation or on the 24-hour ambulatory ECG. If the arrhythmia is frequent but short-lived, an event recorder, which allows continuous ECG monitoring and activating capture of the rhythms when symptoms occur, can be worn for several days.

Any patient with congenital heart disease, either before or after surgery, with presyncope or syncope must be considered as having had a potentially life-threatening arrhythmia. In such patients, if the diagnosis cannot be made on an ECG, electrophysiologic testing should be considered for prognostication and to potentially assist with therapy. As with degenerative cardiac disease, anti-arrhythmic therapy has not been shown to be of life-sustaining benefit in congenital heart disease, although it may be important for symptom control. The use of an implantable cardioverter-defibrillator (ICD) should, therefore, be considered in patients considered at high risk for sudden death. Randomized trials of congenital heart patients, however, do not exist to guide selection.

Ischemic Complications

In adult patients with congenital heart disease, ischemic complications causing cardiac emergencies are rare. More commonly, the anomalous origin of the left coronary artery from the pulmonary artery causes acute severe ischemia and myocardial infarction in infants who usually have heart failure due to an extensive antero-lateral myocardial infarction. Occasionally, the murmur of mitral regurgitation or "angina" manifested by poor feeding or suckling or crying at times of exertion (such as feeding) and consequently brings the infant to the attention of the physician. By the age of 1 year, most of these children have been diagnosed or died.

The potential reasons for the occurrence of myocardial ischemia in adults with congenital heart disease include the following:

1. Anomalous left coronary artery arising from a pulmonary artery (ALCAPA) with late presentation or with complications resulting after repair in infancy.
2. A left coronary artery arising from the right sinus of Valsalva or the right coronary artery arising from the left sinus of Valsalva when these malformations are associated with an inter-arterial course between the aorta and the pulmonary artery.
3. Coronary arteries transposed in the arterial switch operation for transposition of the great vessels, with subsequent compromise.
4. Coronary aneurysm, with congenital or postinflammatory, such as Kawasaki disease or panarteritis nodosa with associated thrombosis.¹⁸
5. Coronary artery compressed by myocardial muscle bridge.
6. Coronary arteriovenous or coronary-cameral fistula.
7. Aortic stenosis with myocardial ischemia or pulmonary stenosis with right ventricular ischemia.

Rarely, the cardiologist sees an adult patient with a coronary artery anomalously arising from the pulmonary artery that was transplanted or repaired with a tunnel repair, or occasionally, with simple ligation of the left coronary artery. Prior to surgical repair, when the entire coronary circulation is dependent on the right coronary artery and collaterals, patients can develop progressive ischemia with growth, resulting in angina or heart failure. If there are symptoms or signs consistent with myocardial ischemia, the patient should have an estimation of ventricular function by echocardiography or radionuclide scanning and some measure of myocardial viability by positron emission tomography, dobutamine echocardiography, or resting thallium-201 scanning. If ischemic myocardium is found, then revascularization of the left coronary artery should be performed.

Rarely, adult patients have unrepaired ALCAPA. Presentations include ischemia, sudden death, dilated cardiomyopathy with heart failure, and progressive mitral regurgitation. Extensive collateral flow from a dilated coronary right artery permits survival into adulthood but the resulting left-to-right shunt and a coronary steal place a significant hemodynamic burden on the left ventricle. Prompt repair is indicated.

An uncommon condition causing myocardial ischemia is the left coronary artery arising from the right sinus of Valsalva. This lesion may not, and probably usually does not, cause myocardial ischemia in most patients. However, in some patients, usually young adults, most often during or just after exercise, sudden and usually transient occlusion of the left coronary artery can occur. This causes profound ischemia to the left ventricle and is usually manifested by sudden death or syncope and occasionally by profound angina, with or without myocardial infarction.

The reason for the sudden ischemic episode is not known. The usual course of such a vessel is obliquely posterior, between the right ventricular outflow tract and the aortic root. This could result in a kinking or compression of the artery during exercise, or possibly in collapse of the orifice of the coronary ostium. However, coronary spasm cannot be ruled out. This type of event occurs only rarely because patients on many previous occasions have exercised as or more vigorously without difficulty. Furthermore, in a few patients who have exercised after an event has occurred, frequently no ischemia can be precipitated.

Less commonly, the right coronary artery arises from the left sinus of Valsalva and causes sudden death, syncope, or inferior

myocardial infarction. This is less often a cause of sudden death because sudden occlusion of the right coronary artery generally leads to inferior myocardial infarction.

Any patient under age 30 years who has presyncope or syncope during exercise or a life-threatening ventricular arrhythmia with an apparently normal heart on echocardiogram should be suspected of having an anomalous origin of the left or right coronary artery from the opposite sinus of Valsalva. At present, cardiac CT and MRI may provide the best spatial resolution to define coronary anomalies¹⁹; however, transesophageal echocardiography (TEE)²⁰ or definitive identification with invasive catheterization can be useful. If such an anomaly is identified, bypass grafting should be considered.

Heart Failure in the Adult with Congenital Heart Disease

The underlying mechanisms for the development of congestive heart failure in the setting of congenital heart disease are similar to those in acquired disease. Broadly defined, congestive heart failure can result from:

1. Primary pump failure involving either the right or left ventricle.
2. Ventricular hypertrophy and fibrosis leading to diastolic dysfunction.
3. Mechanical dysfunction, usually on the basis of valvular disease or failure of palliative procedure.

The onset of heart failure in adults with congenital heart disease is usually gradual; thus patients usually have chronic or subacute symptoms. Acute presentations are most common in those with sudden valvular incompetence, ischemia (discussed previously), new onset of arrhythmia, or sudden exacerbations of chronic congestive heart failure. Identifying the cause of congestive heart failure in these patients requires an accurate and detailed clinical history and physical examination, a systematic noninvasive evaluation, and frequently a referral for an invasive hemodynamic evaluation when information remains incomplete.

The clinical history is an essential key in diagnosing the cause of heart failure in adults with congenital heart disease. Critically important are knowledge of the primary lesion and the presence of associated lesions. One example is coexistence of a bicuspid aortic valve that becomes clinically manifest with stenosis or insufficiency many years following a repair for aortic coarctation. Second, the timing and nature of both palliative procedures and surgical repairs strongly influence late manifestations. Occasionally, a palliative procedure may produce residual long after primary repair has been performed; for example, congenital aortic stenosis treated with surgical valvotomy may have recurrent stenosis or progressive aortic regurgitation. Third, the specific procedure performed to achieve the primary repair influences late outcome; for example, a patch placed across the pulmonary annulus (i.e., transannular) to alleviate pulmonary stenosis in teratology of Fallot is associated with progressive pulmonary insufficiency, whereas other procedures are more likely associated with residual stenosis. Finally, the development of acquired disease may influence the natural history of congenital heart disease, such as accelerated atherosclerotic coronary disease in patients with coarctation of the aorta.

The physical examination should be directed toward identifying signs of systemic venous congestion (e.g., elevated jugular venous pressure, leg edema, ascites, pleural effusion) and pulmonary venous congestion (e.g., pulmonary rales). Evidence of ventricular enlargement will be evident on precordial palpation, but the right and left ventricles may be transposed. Murmurs of valvular stenosis and insufficiency should be carefully noted. When present, prosthetic valve sounds should be crisp and constant in their intensity; dampened or irregular clicks may reflect valve dysfunction or arrhythmia. The absence of a continuous murmur in a patient with a Blalock-Taussig shunt may herald obstruction or pulmonary vascular disease and explain worsening cyanosis.

The approach to the noninvasive diagnosis of heart failure in the adult with congenital heart disease is similar to that for patients with acquired disease, except that knowledge of the anatomy unique to the primary congenital lesion and to the surgical repairs is required. Inspection of the ECG for conduction defects and arrhythmias occasionally reveals the cause of heart failure. Echocardiography should be considered early in the presentation of these individuals, with the following specific goals:

1. Establishing or confirming the primary and secondary diagnoses.
2. Establishing the adequacy of prior surgical repairs, including patch competency and shunt patency.
3. Evaluating ventricular systolic and diastolic function.
4. Identifying hemodynamically significant valvular dysfunction, either native or prosthetic, and intracardiac shunts.

TEE may be superior to surface imaging, especially in evaluation of the atria, interatrial septum, conduits, and prosthetic valves. Although it is a semi-invasive procedure, TEE has proven safe in critically ill patients once respiratory status is stabilized. Cardiac MRI and CT may be helpful as well, providing both a cardiac assessment and helping delineate extracardiac pulmonary anatomy; however, both procedures may be difficult in unstable patients.

When the clinical and noninvasive data are inconclusive, and specifically, to exclude superimposed disease, cardiac catheterization may be necessary. It is important that the goals of the study be predetermined and that the catheterization be performed by personnel familiar with congenital heart disease. Incomplete information can lead to inappropriate treatment.

Etiologies of Pump Failure

There are several causes of pump failure unique to the population of adults with congenital heart disease. The right ventricle functioning in the systemic circulation is encountered in two groups of patients: those with congenitally corrected transposition of the great arteries (L-transposition), and those with transposition of the great vessels palliated with an interatrial baffle operation (i.e., Mustard or Senning procedure). Although the right ventricle hypertrophies and is thus able to pump against the increased afterload for many years, late failure is a feature of the natural history of the patient population usually presenting in the fourth or fifth decade of life.²¹ The signs and symptoms are those of pulmonary congestion and occasionally low output. It is necessary to exclude obstruction of the pulmonary venous limb of the interatrial baffle, which may also lead to pulmonary venous congestion and be confused with failure of the systemic ventricle. Likewise, systemic venous congestion may occur in the presence of obstruction to the systemic venous limb of the baffle.

These structural lesions may require percutaneous intervention or surgery. Precipitants should be identified such as incessant atrial tachyarrhythmias, which can lead to ventricular dysfunction. Occasionally excessive alcohol use or superimposed viral myocarditis can impact ventricular function. Treatment with inotropic agents may be indicated acutely until adequate afterload reduction can be instituted. The use of β -blocker therapy in the failure of the systemic right ventricle may be of long-term benefit by analogy to left ventricular failure, but only limited studies have been performed in this patient group. Biventricular pacing has also been used to a limited extent in congenital heart disease and systemic right ventricles and may also be of benefit in advanced cases.²² Patients with intractable cases should be considered for heart transplantation.

Another group of patients who are likely to develop heart failure are those whose anatomy falls within the broad category of single ventricles. These include the rare patients with double outlet right ventricles, double-inlet left ventricles, tricuspid atresia, and pulmonary atresia with intact ventricular septum. By adulthood, these patients have been treated with a variety of palliative procedures, in most cases to increase pulmonary blood flow most frequently through a cavopulmonary connection (i.e., Fontan or Glenn procedure), although adults are still occasionally seen with a systemic-pulmonary arterial connection (i.e., Potts or Waterston procedure). Heart failure may be an inevitable feature of the natural history of the single ventricle, but patients may present at earlier stages with failure of palliative procedure. The latter is of particular concern in patients with one of the variants of the Fontan procedure. In the previous iteration of this procedure, direct connection, usually via a conduit, between the right atrium and the pulmonary artery was established. Sluggish flow within the right atrium can lead to thrombus formation, rising pressures within the Fontan circuit and increasing coronary sinus pressures with decreased coronary perfusion pressures. The left ventricle develops diastolic dysfunction. Additionally, the enlarging right atrium may cause atrial septal shift that obstructs the flow of the right pulmonary veins leading to increases in pulmonary pressure. Fontan conversion to an extracardiac conduit may be considered for these patients. When combined with a Maze procedure, this operation may help control atrial arrhythmias. The role of this procedure, which carries considerable morbidity and mortality, is still under debate. Whether younger patients with Fontan surgery who received extracardiac conduits fare better in terms of late heart failure remains to be seen.

Other potential causes of late systolic failure include lesions which lead to chronic volume overload of the systemic ventricle. Included in this group are congenital causes of aortic and atrioventricular valve regurgitation (mitral in the systemic left ventricle and tricuspid in the systemic right ventricle), ventricular septal defect, or patent ductus arteriosus with large left to right shunts.

Abnormalities of Diastolic Function

Diastolic dysfunction as the cause of right or left ventricular failure is less common in patients with congenital heart disease than in those with acquired heart disease, but its incidence will increase as congenital patients continue to age. Symptoms of pulmonary congestion may occur in the setting of left ventricular hypertrophy and fibrosis due to long-standing left ventricular outflow tract obstruction, congenital valvular aortic stenosis, or

aortic coarctation. Once obstruction is relieved, the hypertrophy regresses, but fibrosis may persist, producing late arrhythmias and even sudden death. A well-recognized consequence of impairment in left ventricular diastolic function that occurs with age is increased left-to-right shunting across an ASD. The increased shunting may contribute to the almost ubiquitous atrial arrhythmias in patients older than 60 years with ASD and ultimately right ventricular failure.

Right ventricular hypertrophy is most common in the setting of pulmonary valve stenosis. The overwhelming success of surgical and balloon valvuloplasty for this condition in childhood has generally insured normal survival in those treated. Patients with tetralogy of Fallot demonstrate left and right ventricular fibrosis by late gadolinium enhancement on MRI that correlates with ventricular dysfunction, exercise intolerance, and arrhythmia,¹⁶ and similarly increased fibrosis after atrial switch procedures correlates with aging, declining function, and clinical events.²³

Abnormalities of Valve Function

The sudden development of left-sided valvular regurgitation is most likely to present as acute heart failure. Acute aortic regurgitation associated with congenital heart disease is most likely from destruction of a bicuspid valve due to endocarditis or from dissection of the aorta in Marfan syndrome. Aortic valve endocarditis may also occur in the setting of discrete fibromuscular subaortic stenosis and may complicate a so-called supracristal (subarterial) VSD. An acute manifestation of the latter is rare.

Acute mitral regurgitation may also occur in the setting of endocarditis or as a result of chordal rupture in the presence of mitral valve prolapse. Prosthetic valve dysfunction is discussed later in this chapter.

Management

Initial management of the patient should be aimed at acute stabilization by reducing preload using diuretics and nitrates, reducing afterload using vasodilators, and providing inotropic support when necessary. However, therapies for heart failure must be tailored to the individual. For example, in patients with Eisenmenger syndrome or unrepaired tetralogy of Fallot, excessive diuresis can result in a severe fall in cardiac output, and afterload reduction with systemic vasodilators may result in worsening right-to-left shunt. Correction of inciting or aggravating conditions such as arrhythmias and fever may benefit the patient. Once the patient is acutely stabilized, further diagnostic procedures can be performed to determine definitive therapy.

Patients with outflow tract obstruction and secondary hypertrophy are highly dependent on adequate preload and, therefore, are subject to hypotension with diuresis. Thus, treatment of congestive heart failure due to diastolic dysfunction includes relief of obstruction when present, careful diuresis with avoidance of hypovolemia, and slowing of the heart rate when appropriate. For patients in atrial fibrillation, restoration of sinus rhythm may improve cardiac output.

Failed Palliative Procedures

Systemic-Pulmonary Arterial Shunts

Systemic-pulmonary shunts (Table 34-3) are employed in cyanotic patients with severely reduced pulmonary arterial blood flow, usually due to outflow obstruction. The three most commonly used shunts were the Waterston procedure, which connects the ascending aorta to the right pulmonary artery; the

Table 34–3. Palliative Shunts

	Anatomy	Comment
Systemic Arterial–Pulmonary Arterial		
Classic BT	Subclavian artery to PA	Absent ipsilateral radial pulse; continuous murmur
Modified BT	Subclavian to PA conduit	Preserved pulse; continuous murmur
Central shunt	Aorta to PA conduit	Continuous murmur
Waterston	Ascending aorta to RPA	Continuous murmur*
Potts	Descending aorta to LPA	Continuous murmur*
Systemic Venous–Pulmonary Arterial		
Glenn	Superior vena cava to PA	No murmur; arrhythmias uncommon
Fontan	Total cavopulmonary shunt	No murmur; atrial arrhythmias common
Other		
Rastelli	Right ventricle to PA	Valve degeneration may lead to pulmonary insufficiency murmur

*Continuous murmur may disappear in presence of pulmonary hypertension.

BT, Blalock-Taussig; LPA, left pulmonary artery; PA, pulmonary artery; RPA, right pulmonary artery.

Potts procedure, which connects the descending aorta to the left pulmonary artery; and the Blalock-Taussig shunt, which connects the subclavian artery directly (classic) or indirectly via a Gore-Tex graft (modified) to the pulmonary artery. The Waterston and Potts procedures are no longer performed because they are associated with a high incidence of congestive heart failure and pulmonary vascular disease; however, adults with tetralogy of Fallot and pulmonary atresia who have had palliative procedures are still occasionally encountered. Congestive heart failure, endocarditis, brain abscess, and severe cyanosis due to outgrowing of the shunt or development of pulmonary vascular disease are potential sequelae in these patients.

Patients with the classic Blalock-Taussig shunt have an absent pulse in the ipsilateral arm; in those with a modified Blalock-Taussig shunt, the pulse is preserved. A continuous murmur is a normal finding; its absence heralds obstruction of the shunt. Thus worsening cyanosis and a diminished murmur should prompt urgent catheterization and intervention. Endarteritis may also complicate this type of shunt.

Cavopulmonary Connections

Cavopulmonary connections (see Table 34-3) consist of a group of palliative procedures commonly performed in patients with tricuspid atresia and other single ventricle lesions, broadly categorized into the Glenn procedures and the Fontan procedure. In the Glenn procedure, the superior vena cava is anastomosed to the right pulmonary artery. However, in older children and adults, the blood supply from the head and neck is rarely adequate for relief of cyanosis; thus many patients proceed to a total cavopulmonary connection (i.e., Fontan procedure), which is accomplished through a variety of surgical techniques. Supplemental systemic-pulmonary arterial shunts are also used. Pulmonary blood flow is predominantly passive; thus systemic venous pressures are elevated.

The family of Fontan procedures is associated with frequent complications that include chylous pleural effusions, liver failure, protein-losing enteropathy, and pulmonary thromboembolic disease. Although they are more likely to present chronically,

these complications may occasionally result in an acute decompensation, especially in patients with limited cardiopulmonary reserve and may be triggered by arrhythmia or a pulmonary thromboembolic event. In addition, increasing pleural effusions compromise respiratory status through atelectasis, exacerbating cyanosis. Ascites are a result of liver failure, and hypoalbuminemia may also reduce lung volumes by elevating the diaphragm. Thrombi arising in the deep venous system and right atrium can result in pulmonary emboli, with a rise in pulmonary artery pressures and consequent reduction in pulmonary blood flow. Acutely, TEE and catheterization with angiography may be necessary to exclude conduit obstruction and thromboembolic disease. Acute management may include thoracentesis, paracentesis, and anticoagulation or thrombolytic therapy.

Prosthetic Valve and Prosthetic Material Failure

The presentation of prosthetic valve dysfunction in adults with congenital heart disease is generally similar to that in patients who have had valve replacement for acquired heart disease; however, there are several important differences in patients who had valve replacement during childhood. First, the size of the valve may be an important factor because growth of the patient produces increased requirements for higher stroke volumes. Thus the patient with prosthetic valve mismatch may have diminished exercise tolerance and heart failure. Second, the rate of degeneration of bioprostheses or homografts is faster in young patients; the leaflet thickening and tearing may occur as early as 5 years following implantation instead of the expected 10 to 15 years in adult patients.²⁴ Third, prosthetic valves are more frequently combined with a conduit that can also become obstructed through a process known as pseudointimal thickening.

Other complications of prosthetic valves common in those with acquired and congenital valve disease include endocarditis and thrombosis; the latter is confined primarily to mechanical prostheses. Primary failure is rare in the types of mechanical valves (most frequently, St. Jude bileaflet valves) usually encountered in this population.²⁵

The clinical presentation may be that of sudden heart failure, syncope, or a cerebral, cardiac, or peripheral embolic event. Acute valve thrombosis can result in cardiopulmonary arrest. Transthoracic echocardiography may detect stenosis by identifying an increased gradient across an obstructed valve or conduit and regurgitation of a prosthetic aortic valve, but it is rarely adequate for identifying the cause of obstruction or detecting prosthetic mitral regurgitation. In these cases TEE is usually required.²⁶ Moreover, when prosthetic valve endocarditis or thrombosis is suspected, TEE is virtually mandated because of the low sensitivity of surface imaging in these entities. Degeneration of bioprosthetic leaflets and perivalvular leaks are also accurately diagnosed with TEE. Conduit obstruction is more likely to present subacutely and may require catheterization and angiography for diagnosis. The preferred treatment of an acute thrombosis of a mechanical prosthesis is surgery; if surgery is not possible, thrombolytic therapy has met with some success, albeit with a high rate of hemorrhagic complications.²⁷ The management of anticoagulation during surgery and pregnancy in patients with prosthetic valves is similar to that for those with acquired disease.

Other prosthetic materials are used for patch closures of ASDs and VSDs. Operations performed before 1970 were more prone to patch leaks. Although these persistent defects are rarely hemodynamically significant, they represent an important nidus for endocarditis at the site of the jet lesion and are a potential cause of hemolysis.

The long-term sequelae of palliative procedures most often have slow chronic deterioration of functional capacity. The less common acute presentations are potentially life-threatening and require prompt diagnosis and, frequently, emergency intervention.

Other Catastrophic Emergencies

Cerebrovascular Disease

Among the neurologic complications of congenital heart disease is subarachnoid hemorrhage as a result of rupture of an aneurysm of the circle of Willis in association with aortic coarctation. Although rupture is more common in those with unrepaired coarctation, patients with repairs remain at risk, especially in the presence of persistent hypertension. Patients with coarctation of the aorta are also at increased risk of thrombotic strokes as a result of long-standing hypertension.

Additional neurologic complications of congenital heart disease include brain abscesses and embolic stroke in the presence of right-to-left shunt. Brain abscesses may have new onset of seizures, headache, or unexplained fever. The diagnosis can be made by computed tomography scanning or magnetic resonance imaging. In young patients with acute cerebral ischemia, an intracardiac communication responsible for right-to-left shunting should be suspected. Many patients have been shown to have a patent foramen ovale by transthoracic echocardiography or TEE. An ASD may also have a cerebral ischemic stroke.

Thrombotic strokes are rare in patients with cyanotic heart disease and secondary erythrocytosis.²⁸ Prophylactic phlebotomy is not indicated in the asymptomatic patient with an elevated hematocrit; however, the patient with decompensated erythrocytosis, defined as an increasing hematocrit or iron deficiency,²⁹ may have headaches, lethargy and, less frequently, seizures. These patients can benefit from iron replacement in the

event of iron-deficiency states and phlebotomy in the event of extreme polycythemia. A reasonable target for phlebotomy is a hematocrit of less than 60%, which should be achieved gradually by serial phlebotomy with volume replacement.

Pulmonary Hemorrhage

Pulmonary hemorrhage can occur in patients with Eisenmenger syndrome as a result of pulmonary infarction and pulmonary arteriolar rupture. These life-threatening events may complicate pregnancy and are potentially fatal; however, the differential diagnosis of hemoptysis includes pulmonary edema, which may respond to diuretic therapy, and pulmonary infections.³⁰ When chest radiography is nondiagnostic, bronchoscopy may be required.

Pulmonary artery hemorrhage more commonly complicates right heart catheterization with a flow-directed balloon-tipped catheter, in particular in the presence of severe pulmonary vascular disease. When it is necessary to perform invasive monitoring, care should be taken not to inflate the balloon in a small pulmonary branch artery but rather to inflate it in a larger branch, then float it out to a smaller branch to obtain the pulmonary capillary wedge pressure.

Control of hemoptysis may be thwarted by the bleeding diathesis that accompanies the polycythemia of cyanotic heart disease. These management issues are beyond the scope of this chapter.

Eisenmenger Syndrome

In Eisenmenger syndrome, irreversible pulmonary vascular disease develops in response to left-to-right shunt (e.g., VSD, ASD, PDA).³¹ There is consequent reversal of shunt flow to right-to-left and cyanosis. The oxygen saturation is markedly decreased, and polycythemia is present. There is ECG and radiographic evidence of right ventricular hypertrophy. These patients have tenuous hemodynamics and are susceptible to severe hypotension in the setting of dehydration or hypovolemia from many causes, including diuretic treatment. Because of the fixed pulmonary vascular resistance, there is limited ability to increase cardiac output. Systemic vasodilators are contraindicated because they may result in hypotension and worsening cyanosis with increased right-to-left shunting. Pregnancy is poorly tolerated; a high fetal and maternal mortality is associated with Eisenmenger syndrome.³² Pulmonary thrombosis, hemorrhage, or both may complicate pregnancy. Endocarditis and arrhythmias are common (discussed previously). Also as mentioned previously, brain abscess may occur in this setting.

Conclusion

The numbers of adult patients with congenital heart disease are increasing at a steady rate. These patients require ongoing surveillance for potential residual complications related both to the natural history of their primary lesion and to the palliative and reparative procedures performed. They are not likely to present frequently to emergency rooms and CICUs; however, appropriate treatment requires an understanding of how the physiology of the particular congenital heart lesion influences the clinical presentation and the response to conventional therapies. Awareness of the likely complications to expect with common lesions coupled with a consciousness of the unique anatomy of each individual will raise diagnostic accuracy and help institute the best treatment plan, often based on analogies to general cardiac care.

Overdose of Cardiotoxic Drugs

Megan DeMott, Michael Young, Saralyn R. Williams,
Richard F. Clark

CHAPTER 35

Calcium Channel Antagonists	Propoxyphene
β-Adrenergic Antagonists	Carbamazepine
Digoxin	Chloroquine
Sodium Channel Blocking Agents	Management of Sodium Channel Blocking
Cyclic Antidepressants	Drug Toxicity
Antipsychotics (Phenothiazines, Butyrophenones, and Atypical Agents)	Illicit Drugs
Antihistamines	Conclusion

CARDIAC DYSRHYTHMIAS, myocardial depression, and vasodilation are the major cardiovascular effects observed in poisonings. A large number of therapeutic and nontherapeutic agents possess toxicity directed toward the cardiovascular system, whether in the setting of actual overdose or merely therapeutic misadventure. In this chapter we address some of the most significant and most common cardiovascular toxins. We describe these toxicants briefly, review their relevant pharmacology, delineate their known pathophysiology, describe clinical manifestations of their poisonings, and discuss their current management recommendations. In all such cases, consultation with a medical toxicologist or a certified regional poison control center should be considered.

We begin with a review of poisoning due to calcium channel antagonists and β-adrenergic receptor antagonists (β-blockers). These two primary cardiovascular drug classes account for well more than half of the life-threatening events and deaths due to cardiovascular agents reported to the American Association of Poison Control Centers each year.¹ Digitalis poisoning is also discussed. Finally, agents that produce cardiotoxicity primarily through sodium channel blockade and those with prominent sympathomimetic toxicity are also reviewed.

Not included in this chapter are a number of other cardiotoxic agents that are less commonly encountered or that demonstrate unique mechanisms of toxicity that are beyond the scope of this general discussion. The reader is referred elsewhere for review of these agents, which include clonidine and other antihypertensive agents, antidysrhythmics not noted earlier, cyclosporine, colchicine, chemotherapeutic agents (doxorubicin; anthracyclines such as daunorubicin, and idarubicin), and certain metals (notably selenium, cobalt, copper, and arsenic).

Calcium Channel Antagonists

Pharmacology

The calcium channel blocking drugs are a heterogeneous class of drugs that block the inward movement of calcium into cells from extracellular sites through “slow channels.”² There are

three major classes of these agents: phenylalkylamines (e.g., verapamil), benzothiazepines (e.g., diltiazem), and dihydropyridines (e.g., nifedipine, amlodipine, nicardipine, nimodipine, felodipine). They are used in the treatment of coronary vasospasm, supraventricular dysrhythmias, hypertension, migraine headache, Raynaud phenomenon, subarachnoid hemorrhage, and many other disease states.³ In general, calcium channel antagonists are rapidly and completely absorbed from the gastrointestinal tract and, with the exception of nifedipine, undergo extensive first-pass hepatic metabolism yielding low systemic bioavailability. The volume of distribution is large for all but nifedipine, and protein binding is high (>90% for all but diltiazem). Elimination is almost entirely by the liver; impaired renal function does not affect clearance with the exception of a somewhat pharmacologically active metabolite of verapamil that is renally excreted.⁴ Terminal half-lives are generally from 3 to 10 hours, but all three classes of calcium channel antagonists are available in sustained-release preparations, which can result in greatly prolonged half-lives.

Pathophysiology

In susceptible individuals or in overdose, these agents can exert profound effects on the cardiovascular system. They work by antagonizing L-type voltage gated ion channels in the cardiac pacemaker cells, and through depression of calcium ion flux in smooth muscle cells of blood vessels. Sinus node depression, impaired atrioventricular (AV) conduction, depressed myocardial contractility, and peripheral vasodilation may result.

Electrophysiologic effects are most prominent for verapamil and diltiazem and are seen much less often with nifedipine and other dihydropyridines, which work primarily on the peripheral vasculature. Sinus node function may be significantly altered by verapamil and diltiazem in patients with underlying sinus node disease; in excess, these agents may prolong AV nodal conduction sufficient to produce advanced heart block. Depression of myocardial contractility by impeding phase 2 calcium influx is most pronounced in overdose or in patients who already have depressed myocardial function from underlying disease or

concomitant drugs. Contraction of vascular smooth muscle, particularly arterial smooth muscle, is also mediated by calcium influx that is inhibited by calcium antagonists. In overdose, the effect of vasodilation on systemic blood pressure may be profound. However, in some cases, especially those involving the dihydropyridines, vasodilation may be ameliorated by a reflex increase in sympathetic activity, with increased heart rate and cardiac output.

Clinical Manifestations

The most serious consequences of calcium antagonist toxicity result from their effects on the cardiovascular system. Generally, these effects are an extension of the pharmacodynamic effects of the specific agent, although unique features of the different agents' specificity profiles may be lost in overdose.⁵ Clinical features are summarized in Table 35-1. Bradycardia and conduction defects are among the most frequent findings in overdose of verapamil or diltiazem. Additionally, hypotension is present in most significant exposures to any calcium antagonist. These features generally develop within 1 to 2 hours of exposure, but the onset of moderate to severe cardiovascular manifestations may be delayed for more than 12 hours when a sustained release preparation has been ingested.⁶

Patients at particular risk for toxicity from calcium antagonists include those with sinus node dysfunction, AV nodal conduction disease, severe myocardial dysfunction, obstructive valvular disease, hypertrophic cardiomyopathy, hepatic failure (leading to impaired elimination), and combined treatment of a calcium antagonist with β -blockers or digoxin.⁷ In addition, verapamil may dangerously accelerate conduction through accessory pathways when administered intravenously

to patients with accessory or anomalous AV connections such as in Wolff-Parkinson-White syndrome.⁸ It should not be given to patients with atrial fibrillation and evidence of pre-excitation on electrocardiography.

Profound hypotension is the major manifestation of overdose with nifedipine and may produce reflex tachycardia, flushing, and palpitations. Conduction defects are rare unless there is an underlying conduction disease, a very large ingestion, or the presence of coingestants such as β -blockers.^{5,7}

Lethargy, confusion, dizziness, and slurred speech are common in calcium channel antagonist poisoning. Coma usually occurs in the setting of cardiovascular collapse with profound hypotension; seizures are rare. Nausea and vomiting may occur. Metabolic acidosis is common in severely poisoned patients and likely represents hypoperfusion. Hyperglycemia is also common in overdose with calcium antagonists, and can serve as an important diagnostic clue to differentiate poisoning with these medications from others with similar clinical effects.

Management

Initial management of poisoning due to calcium antagonists is similar to that for other toxic drug exposures with initial support of the airway, adequate ventilation, and attention to circulatory status, followed by gastrointestinal decontamination when appropriate. If accidental or intentional oral overdose has occurred, the administration of activated charcoal orally or through a nasogastric tube is indicated when the patient's airway is not at risk of compromise by potential aspiration. In general, gastric lavage is no longer routinely advocated in the management of overdose patients, except perhaps in recent massive ingestions that present within the first hour. Repeated doses of activated charcoal and the use of whole bowel irrigation with an iso-osmotic, isotonic lavage solution, such as polyethylene glycol (Go-Lytely) should be considered early in cases involving a slow-release preparation. Recommended rates of whole bowel irrigation are 2 L/hr in adults and 500 mL/hr in children, via nasogastric tube. Continuous cardiac monitoring should be instituted in anticipation of cardiovascular collapse.

Specific therapy for sinus node depression or AV nodal conduction abnormalities is only necessary when hemodynamic status is compromised. Calcium salts may be administered, but routine doses are often ineffective at improving conduction. Atropine may be given, but is often ineffective at reversal of conduction defects, and pacing may need to be employed. Because of the effects of calcium antagonists on the myocardium and on the peripheral vasculature, hypotension may persist despite correction of electrical activity and conduction.

Hypotension should be addressed based on the pathophysiology discussed earlier. Intravenous fluids and vasoconstriction with agents such as norepinephrine, epinephrine, phenylephrine, or dopamine may be successful in hypotension primarily due to peripheral vasodilation. Hypotension due to depressed myocardial contractility may be responsive to intravenous administration of calcium salts (calcium chloride 10% solution, 10 to 20 mL, or calcium gluconate 10% solution, 30 mL, followed by continuous infusion). The optimal dose of calcium is unclear from the available literature, and the danger of hypercalcemia-induced impairment of myocardial contractility and vascular tone must be kept in mind.¹⁰ However, calcium levels have been elevated to as high as 15 to 20 mg/dL in previous case reports without any adverse effects, and with an improvement in blood pressure.¹¹

Table 35-1. Clinical Features of Calcium Antagonist and β -Blocker Overdose

Cardiovascular
Hypotension, shock
Dysrhythmias
Sinus bradycardia
Second- and third-degree atrioventricular block with nodal or ventricular escape
Sinus arrest with atrioventricular nodal escape
Asystole
Prolonged QRS, ventricular ectopy/tachycardia (propranolol)
Hypertension, tachycardia (pindolol)
Central Nervous System
Lethargy, confusion, coma
Respiratory arrest
Seizures (especially from propranolol)
Gastrointestinal
Nausea, vomiting
Metabolic
Hyperglycemia (verapamil, diltiazem)
Hypoglycemia (β -blockers)
Lactic acidosis

Glucagon has had some anecdotal success in cases of calcium antagonist overdose, and several animal models have shown its efficacy in this setting.¹² Its use is discussed further in the section on treatment of β -blocker toxicity. Calcium antagonists are generally both highly protein bound and extensively distributed in tissue. Therefore, enhanced elimination techniques such as hemodialysis and hemoperfusion are unlikely to be of benefit, and clinical reports have failed to support a role in either therapeutic or overdose settings.^{13,14}

Finally, a newer treatment using a hyperinsulinemia/euglycemia protocol has shown impressive results in case reports of calcium antagonist poisoning.¹⁵ Laboratory research in this area has also been promising.¹⁶ Numerous reports of the success of this treatment, along with published reviews of the management of calcium channel blocker toxicity, support its use early in the management of these poisonings. Insulin is thought to improve ionotropy and increase peripheral vascular resistance. Although the mechanisms are not completely known, it is thought to have a direct ionotropic effect on cells and to improve calcium pumps in myocardial cells.^{16,17,19} The most common insulin dosing regimen is 0.5 to 1 unit/kg/hr, along with 0.5 g/kg/hr of glucose using D₅, D₁₀, D₂₅, or D₅₀ (the latter two typically require central venous access due to their vascular irritant effects). In general, however, these patients are often already hyperglycemic and may not require the glucose component of the regimen while they remain toxic from the poisoning. Serum glucose concentrations should be checked hourly while the patient is on this therapy.

In severe refractory cases, cardiovascular bypass remains a viable option. Implementation has revealed successful results in previous reports, as patients are supported through the toxic effects of their poisoning.^{20,21} If patients can survive through the metabolism of the medication, they can often demonstrate a full recovery, both cardiovascularly and neurologically.

β -Adrenergic Antagonists

Pharmacology

Many β -adrenergic antagonists (β -blockers) are available, with profiles varying to greater or lesser degrees in the pharmacodynamic properties of receptor selectivity, intrinsic sympathomimetic activity, membrane stabilization, bioavailability, lipid solubility, protein binding, elimination route, and half-life. β -blockers are generally rapidly absorbed from the gastrointestinal tract, with peak plasma concentrations achieved after 1 to 2 hours and with elimination half-lives of 2 to 12 hours for nonsustained release preparations. Reduced first-pass hepatic extraction and impaired hepatic metabolism in liver disease or in massive overdose may contribute to toxicity by prolonging the half-life of the primary agent or an active metabolite.

Pathophysiology

Poisoning from β -blockers primarily affects the cardiovascular system, disrupting normal coupling of excitation-contraction and impairing ion transport in myocardial and vascular tissue. The mechanism of toxicity from β -blocker poisoning is difficult to fully explain, but appears to be related to impaired response to catecholamine stimulation of β -receptors, to disturbances of sodium and calcium ion homeostasis, and to membrane stabilization. Receptor subtype (β_1 versus β_2) selectivity may suggest the predominant effect of toxicity due to a given agent, but

in large overdoses this selectivity is often lost. Quinidine-like (membrane-stabilizing) effects, especially seen in propranolol poisoning, and to a lesser extent with acebutolol, oxprenolol, and betaxolol, may result in impaired conduction, prolonged QRS duration, and ventricular ectopy or tachycardia. The lipophilicity of propranolol also facilitates CNS penetration, frequently leading to seizures.

Clinical Manifestations

β -blocker toxicity is most commonly due either to administration to patients with underlying cardiac disease or to acute massive overdose. In the setting of acute overdose with a nonsustained release product, the onset of symptoms can be expected to occur within 6 hours of ingestion.²²

Generally, poisoning due to β -blockers shares many features of clinical presentation with poisoning due to calcium channel antagonists (see Table 35-1), but the hallmark of β -blocker poisoning is hypotension, due predominantly to impaired contractility. Sinus node depression and conduction abnormalities are also common. As noted earlier, membrane-stabilizing properties seen most prominently with propranolol may lead to impaired conduction, QRS prolongation, and ventricular dysrhythmias.^{23,24} Highly β -selective agents (atenolol, nadolol) may produce hypotension with a normal heart rate, but selectivity is frequently lost in large overdose. Overdose of agents with intrinsic sympathomimetic activity, most notably pindolol, may actually manifest with hypertension and tachycardia due to a stimulation. Sotalol is a unique agent that possesses some class III antiarrhythmic properties and therefore may produce Q-T interval prolongation, ventricular tachycardia, and torsades de pointes.²⁵

Lethargy and coma may be present in patients with β -blocker poisoning. Seizures are rare manifestations of β -blocker poisoning, except for propranolol. This appears to correspond with CNS effects of the drug rather than to hypoperfusion of the CNS.^{23,24} Bronchospasm and respiratory depression may occur from overdose with β -blockers, but are infrequent. Hypoglycemia may also occur in contradistinction to calcium channel antagonists that result in hyperglycemia.²⁶

Management

The initial approach to managing a patient with β -blocker overdose is similar to that for calcium channel antagonist overdose. However, β -blockers are receptor antagonists as opposed to calcium channel antagonists, which block ion channels and movement of calcium into the cell. This may explain why β -blocker poisoning is more responsive than calcium channel antagonist poisoning to therapeutic approaches that either competitively overcome the agent at the blocked receptor (high-dose norepinephrine, epinephrine) or bypass the receptor to achieve a common physiologic end point (glucagon).

Glucagon is the mainstay of antidotal therapy for symptomatic β -blocker toxicity. Glucagon is a polypeptide hormone that appears to bypass the β -adrenergic receptor on a cardiac myocyte and increases intracellular levels of cyclic AMP by stimulating a distinct glucagon receptor on the membrane. The resultant promotion of transmembrane calcium flux and intracellular calcium release leads to restoration of chronotropy and inotropy.²⁷ Although not universally effective, glucagon is of benefit in the majority of β -blocker overdoses. The initial dose of glucagon for a symptomatic β -blocker poisoning in the average adult is 3 to

5 mg bolused intravenously. The bolus may be repeated, and a continuous infusion of 2 to 5 mg/hr or higher may be necessary to maintain conduction and contractility. Mild nausea and vomiting, along with mild hyperglycemia, may occur with these doses, but otherwise the use of glucagon is without significant side effects.

As with calcium channel antagonist toxicity, calcium salts have been reported to be useful in β -blocker toxicity. In studies, calcium infusion can increase blood pressure in hypotensive β -blocker poisonings without any concomitant effect on heart rate.²⁸ Thus calcium therapy may augment glucagon treatment in these cases. Recommended starting doses are 1 to 3 grams of calcium chloride 10% solution (10 to 30 mL) given intravenously. If central line access is not available, calcium gluconate should be used, as calcium chloride can be irritating to peripheral veins.

Some β -blocking agents, such as propranolol and acebutolol, can also act as membrane-stabilizing drugs, and can cause QRS prolongation in overdose. When the QRS duration is widened to greater than 120 milliseconds, treatment with sodium bicarbonate boluses may be required (see later). Some animal models and case reports have shown proven benefit with sodium bicarbonate in such circumstances.²⁹

Phosphodiesterase inhibitors such as amrinone have not been shown to be of any additional benefit when compared with glucagon for management of β -blocker overdose, but their use might be considered if other therapy is failing.^{30,31} These agents may vasodilate and should be discontinued if blood pressure does not immediately respond.

There is no clear advantage to a specific β -adrenergic agonist in the treatment of β -blocker poisoning, although many toxicologists prefer epinephrine, norepinephrine, or their combination. Isoproterenol was commonly used in the treatment of these poisonings in the past, but may not be available at some hospitals. Dose should be titrated to effect with restored perfusion or return of an appropriate heart rate.

Successful use of an intra-aortic balloon pump support in patients in whom other measures were unsuccessful has been reported.³² This may allow sufficient time for elimination of the toxicant and should be considered when the patient remains profoundly hypotensive despite glucagon and high-dose vasopressors.

Enhanced elimination measures such as hemodialysis are unlikely to be of benefit for most of these medications. Exceptions include those patients with impaired renal function or in the setting of toxicity by a renally excreted agent, such as atenolol, acebutolol, nadolol, or sotalol.

Digoxin

Pharmacology

Cardiac glycosides such as digoxin have been used for centuries in the treatment of a variety of heart diseases. Poisonings, both accidental and intentional, from these agents were once among the most difficult to manage, and fatalities were common. With recent advances in the management of congestive heart failure using newer classes of drugs, and the development of digoxin-specific Fab antibody fragments, the incidence of severe digoxin toxicity has declined.

Digoxin is well absorbed after ingestion, and although intravascular concentrations may rise rapidly and dramatically after oral overdose, tissue distribution may be delayed. The

estimated volume of distribution in adults is 7 to 8 L/kg. The kidney excretes over 60% of digoxin unchanged, while digitoxin is metabolized by hepatic enzymes.

Pathophysiology

Cardiac glycosides inhibit the sodium-potassium ATPase pump on cell membranes. As a result, in acute toxic exposures, extracellular and serum potassium concentrations rise, along with intracellular sodium and calcium concentrations. Both conduction and contractility are impaired by the drug's effect on cardiac myocytes, but enzyme inhibition occurs throughout the body. There is an increase in automaticity and a decrease in depolarization and conduction velocity, which is mediated by an increase in vagal tone.

Clinical Manifestations

There are no dysrhythmias diagnostic of digoxin toxicity. Several rare dysrhythmias, such as ventricular bigeminy and bidirectional ventricular tachycardia, are highly suggestive of poisoning by this agent. The classic early cardiac presentation of chronic toxicity is the appearance of premature ventricular contractions in a patient with atrial fibrillation whose ventricular response rate had been previously well controlled. Most patients with chronic, unintentional toxicity will complain first of anorexia and fatigue and will often have nausea and vomiting. Neurologic symptoms can begin subtly as visual changes, described as blurred vision, decreased visual acuity, or yellow halos, and progress on to confusion, hallucinations, seizures, or coma.^{33,34}

Fatalities from digoxin poisoning result most often from cardiovascular collapse. Ventricular dysrhythmias, severe AV block, and depression of myocardial contractility are seen in massive overdose and may be refractory to most conventional therapies. Hyperkalemia can also be significant, especially in acute poisonings, and may contribute to dysrhythmias.

Management

Before digoxin-specific Fab fragments, the treatment of severe digoxin poisoning consisted of the administration of large doses of atropine and vasopressors, along with the early use of external or transvenous cardiac pacemakers. These therapies are often of little benefit in significantly toxic victims. The development of digoxin-specific Fab antibody fragments has revolutionized the management of these poisonings.

Digoxin-specific Fab fragments (Fab) are ovine IgG antibodies to digoxin that have had the Fc portion removed by papain digestion to reduce immunogenicity. When administered intravenously into a victim with digoxin toxicity, Fab fragments reverse conduction disturbances, restore contractility, and re-establish sodium-potassium ATPase activity by removing digoxin off receptor sites.³⁵ Hyperkalemia is also reversed after Fab administration. Signs and symptoms of toxicity should resolve in less than an hour but are often gone within 10 minutes. Patients with severe hypotension or cardiac arrest may not be able to circulate the antibody fragments and may therefore be refractory to treatment.³⁶

The dose of Fab fragment recommended to reverse digoxin toxicity is an equimolar dose to that of the ingested cardiac glycoside. A dose of 50 to 100 mg will neutralize 1 mg of digoxin. One vial contains 40 mg, and the manufacturer recommends a starting dose of 10 vials when the amount ingested or the level is unknown. Tables are available in the Fab package insert or

through regional poison control centers to relate the dose of Fab to the measured serum digoxin concentration. Allergic reactions to Fab are extremely rare, and skin testing is unnecessary.³⁵ Fab has also been shown to be effective in the treatment of severe cardiac glycoside cardiotoxicity from plants such as oleander containing similar compounds, but larger doses of the Fab may be required.³⁷

Sodium Channel Blocking Agents

Of all categories of cardiotoxic drugs, perhaps the most heterogeneous contains those that impair sodium conduction through membrane channels (Table 35-2). These substances are commonly described as having “quinidine-like” or “membrane stabilizing” effects on the myocardial cell. Substances exhibiting these properties include analgesics, antihistamines, psychotropics, antidepressants, antidysrhythmics, anticonvulsants, and local anesthetics. Many of these medications have unique clinical effects at therapeutic doses, but in overdose, each can produce similar cardiotoxicity. The most common group of sodium channel blocking drugs, and the one to which all others are compared, is the class I antiarrhythmic agents.

Pathophysiology

All sodium channel blocking substances affect conduction of impulses throughout the myocardium by influencing the movement of ions through the cell membrane. Sodium, potassium, and calcium ion exchange through channels in the myocardial cell membrane is responsible for the various phases of the action potential. All class I antiarrhythmics block fast sodium channels, decreasing the slope of phase 0 of the action potential. In overdose, this effect leads to a gradual widening of the QRS complex, eventually culminating in heart block or ventricular dysrhythmias. Depression of myocardial contractility contributes to the hypotension produced by these agents.

The subclassification of class I agents is partly based on the effect of these agents on potassium channels during cell repolarization. Blockade of potassium channels, most commonly displayed by class Ia drugs, leads to prolongation of repolarization and a subsequent increase in Q–T interval duration.³⁹ As the duration of repolarization and therefore the Q–T interval

lengthens, the opportunity for early afterdepolarizations during this relative refractory period increases. Episodes of polymorphic ventricular tachycardia (torsades de pointes) can occur in this situation, especially in the presence of low potassium or magnesium concentrations.⁴⁰ Class Ib agents shorten repolarization and reduce the duration of the action potential, while leaving potassium channels open and the Q–T intervals unaffected.³⁹ Class Ic drugs are the most potent sodium channel blockers³⁸ but have little effect on the repolarization phase of the action potential.

Pharmacology and Clinical Manifestations

Class Ia Antiarrhythmics

As noted earlier, all drugs in this class inhibit fast sodium channels in a dose-dependent manner. Generally, class Ia drugs are high potency sodium channel blockers.³⁸ Depression of slow inward calcium and outward potassium movement may account for reduced action potential plateau and prolonged repolarization. The result is prolongation of the relative refractory period, decreased pacemaker automaticity, and a generalized slowing of conduction through the heart.

Quinidine

Quinidine, the prototype of class Ia antiarrhythmics, was released in the United States in the early 1900s. Orally ingested quinidine has good bioavailability. The sulfate reaches peak plasma concentrations within 90 minutes, while the absorption of gluconate and polygalacturonate salts may be delayed 3 to 6 hours.⁴¹ Quinidine is highly protein-bound, with a large volume of distribution throughout the body (3.0 L/kg).⁴¹ Up to 40% of an ingested dose of quinidine may be eliminated by the kidneys, but the remainder is metabolized to inactive products in the liver. High “therapeutic” plasma concentrations of quinidine were found in some individuals that developed both QRS and Q–T interval prolongation, and a sudden loss of consciousness associated with its use was soon described.⁴¹ These symptoms, referred to as “quinidine syncope,” were found to be caused by ventricular tachydysrhythmias.³⁸ The incidence of these attacks is estimated to be 2% to 4%, and they are usually associated with polymorphic ventricular tachycardia.³⁸ This dysrhythmia is often related to a prolonged Q–T interval, but some studies have determined that quinidine-associated ventricular tachycardia often does not present as torsades de pointes and may not be associated with a prolonged Q–T interval.⁴² Studies have also demonstrated little relationship between quinidine concentrations and the incidence of this dysrhythmia.^{44,48} Hypokalemia, however, is frequently found in patients with quinidine-associated syncope.^{40,45}

As quinidine serum concentrations increase, Q–T interval prolongation is the earliest and most predictable electrocardiographic effect,⁴⁶ followed closely by QRS widening. In overdose, QRS widening is almost always present, with bundle branch blocks, sinoatrial and AV blocks, sinus arrest, and junctional or ventricular escape rhythms noted at high concentrations.^{39,40}

Hypotension from quinidine, like many other of the drugs discussed in this section, is multifactorial. Unlike quinidine syncope, quinidine-induced generalized myocardial depression is dose-dependent.^{40,47} At low doses, especially when administered intravenously, quinidine exerts little negative inotropic effect but is an antagonist of peripheral α -receptors, leading to vasodilation.⁴⁰ This effect can result in orthostatic syncope in some

Table 35-2. Common Sodium Channel Blocking Drugs

Carbamazepine

patients. At toxic concentrations, quinidine causes circulatory collapse due to a profound negative inotropic effect.⁴⁷ In addition to shock, severely poisoned patients can have recurrent dysrhythmias, central nervous system depression, and renal failure.

The optical isomer of quinidine is quinine, and this compound has the capability to produce the same signs and symptoms in overdose.^{48,49} Toxic doses of either of these agents can also lead to cinchonism, a condition named after the tree from which these compounds are derived.⁴⁹ This syndrome results in tinnitus, blurred vision, photophobia, confusion, delirium, and abdominal pain.⁴⁹ Quinine amblyopia may result from large ingestions of these compounds, and the visual loss may be complete and sudden. Although vision returns in some patients as toxicity resolves, the loss may be permanent.⁵⁰ Coma and seizures can occur with toxic concentrations of these drugs, even in hemodynamically stable individuals.⁴⁰ Cinchonism is not reported with poisonings of the other class Ia agents.

Quinidine also has antimuscarinic effects and it may exacerbate the ventricular response to atrial flutter via enhanced conduction of the atrioventricular (AV) node. Furthermore, its potassium channel blockade may cause increased insulin release in the pancreatic islet cells, leading to hypoglycemia.⁵¹

Procainamide

A therapeutic oral dose of procainamide reaches peak plasma concentration within an hour, but massive ingestions can greatly delay absorption and prolong toxicity.⁴⁹ Like quinidine, up to 40% of a given dose of procainamide may be eliminated unchanged in the urine. Unlike quinidine, procainamide is metabolized to a compound with cardiac activity similar to that of the parent drug, *N*-acetylprocainamide (NAPA), which may complicate the correlation of plasma levels of the parent compound with clinical effects.⁴⁹ The therapeutic volume of distribution of procainamide is 2.0 L/kg, with a plasma half-life of 3 to 4 hours. The plasma half-life in overdose may increase significantly.⁴⁹

Cardiotoxicity from procainamide is mechanistically similar to that described from quinidine. Myocardial depression, polymorphic ventricular tachycardia, and other cardiac dysrhythmias are all expected at high serum concentrations of procainamide.⁴⁹ However, procainamide exerts a less negative inotropic effect, and a lower incidence of ventricular dysrhythmia than quinidine.^{52,53} Hypotension is mostly seen with intravenous use and usually only during infusions faster than 20 mg/min.⁴⁰ Procainamide overdose can result in severe hypotension and dysrhythmias identical to those described with quinidine. Inability to electrically pace the heart of a procainamide-intoxicated patient due to high pacing thresholds has been described.⁵⁴ Serious toxicity from procainamide includes lethargy, confusion, and depressed mentation along with the cardiotoxicity.³⁹⁻⁴¹ Other adverse events in acute overdoses include seizures and antimuscarinic effects.⁵⁵ Hematologic abnormalities such as agranulocytosis, thrombocytopenia, and hemolytic anemia have been reported in long-term use of procainamide.⁵⁶ Procainamide may also produce a lupus-like syndrome.

Disopyramide

Peak serum concentrations of disopyramide may be delayed up to several hours in toxic ingestions owing to its antimuscarinic effects on intestinal motility.⁴⁰ The protein binding (50% to 60%) and volume of distribution (<1 L/kg) of disopyramide

are less than those of quinidine or procainamide and suggest the possibility that hemodialysis could be effective in removing toxic concentrations.^{40,57} A therapeutic dose of disopyramide has a mean plasma half-life of 6 to 8 hours and is 40% to 60% eliminated by the kidneys.⁴⁹ The main hepatic metabolite, mono-*N*-dealkylated disopyramide, has little cardiac activity, but produces more antimuscarinic effects than the parent compound.

Disopyramide is the newest of the Class Ia antiarrhythmic agents and demonstrates electrophysiologic effects similar to quinidine and procainamide. Although Q-T interval prolongation does not usually occur with therapeutic concentrations of disopyramide, syncopal episodes have been reported.⁵⁸ Of all class Ia agents, the negative inotropic effects of disopyramide are most pronounced, and hypotension can be seen in disopyramide poisoning without concomitant electrocardiographic changes.^{40,59,60} This may in part be related to its ability to block myocardial calcium channels.⁶¹ Although mild antimuscarinic effects can be noted in poisonings of all class Ia agents, those following disopyramide toxicity are the most clinically significant⁴⁰ and can result in sinus tachycardia, blurred vision, altered mental status, seizures, urinary retention, and ileus, at times without accompanying serious cardiotoxicity.⁴⁰ Overdose experience with disopyramide is limited in the United States.

Class Ib Antiarrhythmics

Drugs in this class suppress automaticity similarly to the class Ia agents but shorten the action potential refractory phase and increase conduction through hypoxic myocardial tissue.⁶² Class Ib drugs have rapid "on-off" binding kinetics for myocardial sodium channels and possess the highest affinity for sodium channels that are in the inactivated state.⁴⁹ At therapeutic concentrations, these compounds moderately depress phase 0 of the myocyte action potential. The resultant effects on the electrocardiogram include a normal or shortened Q-T interval and an unchanged QRS duration.⁶³

Lidocaine

A large first-pass effect is seen with oral dosing of lidocaine, and only 30% to 35% of an ingested dose is bioavailable.⁶⁴ However, large ingestions have resulted in significant absorption, resulting in toxicity.⁶⁵ Lidocaine is well absorbed topically through abraded epithelium and from the trachea and bronchi after endotracheal administration.⁶⁶ The apparent volume of distribution of lidocaine is 1.3 L/kg, but it is significantly reduced in the presence of congestive heart failure.⁶⁷ The liver metabolizes virtually all of a lidocaine dose, with an elimination half-life in therapeutic concentrations of about 2 hours.⁴⁹ The most significantly active metabolite is monoethylglycinexylidide (MEGX), with a half-life also of 2 hours.⁶⁸

Lidocaine is the prototype of class Ib antiarrhythmics, and in poisoning it causes cardiovascular and CNS toxicity. Lidocaine is primarily metabolized in the liver to MEGX. Both compounds are neurotoxic at high concentrations and can cause seizures and apnea.⁶³ Some individuals experience mild neurologic symptoms at therapeutic plasma concentrations.⁶³ Since lidocaine rapidly passes through the blood-brain barrier, patients with toxicity usually manifest CNS dysfunction as initial symptoms.⁶⁹ Early signs of CNS toxicity from lidocaine include lightheadedness, agitation, confusion, hallucinations, and dysarthria. Some individuals initially complain of tongue or

perior numbness. Progression to convulsions or coma can be rapid. Cardiovascular toxicity occurs primarily in massive overdose. Following central nervous system dysfunctions, intrinsic cardiac pacemakers are depressed, conduction is delayed, and myocardial contractility is impaired.^{70,71} Large intravenous lidocaine doses greater than 1 g have resulted in asystole, complete heart block, and refractory hypotension.^{63,70,72}

Phenytoin

Phenytoin absorption from the gastrointestinal tract can be erratic, and peak levels after an oral overdose can be delayed up to 24 hours or more.⁷³ Phenytoin is 90% protein bound, and the volume of distribution of the free drug is 0.5 L/kg.^{49,73} Signs of toxicity correlate better with free phenytoin levels, but most laboratories still assay for both bound and unbound fractions. Phenytoin is metabolized to nontoxic metabolites by the liver. At high concentrations, these enzymes become saturated, and the half-life may increase to several days as elimination kinetics change from first order to zero order.⁷⁴ Patients with low serum albumin concentrations may be particularly prone to chronic phenytoin toxicity, owing to the higher relative fraction of free drug.⁴⁹

Like lidocaine, phenytoin is classified as a class Ib agent. Poisoning with phenytoin occurs most often during long-term therapy for epilepsy when a medication inhibiting phenytoin metabolism is added, or when the patient develops a disease state impairing hepatic mixed function oxidase activity. Acute overdoses occur less frequently, but the resulting clinical presentation is similar.

Phenytoin poisoning primarily causes neurotoxicity, manifested as drowsiness, ataxia, dysarthria, and nystagmus. In massive poisonings, coma and seizures can be seen, but respiratory depression is infrequent. Cardiac dysrhythmias and hypotension are rarely reported with toxic phenytoin ingestions but are often encountered during rapid intravenous infusions.⁷⁵ Although phenytoin does have sodium channel blocking effects on myocardial tissue, the diluent of the intravenous solution, propylene glycol, has been implicated as the source of myocardial depression and dysrhythmias associated with intravenous infusion.⁷⁶ Slowing the rate of infusion prevents the majority of these complications.

Tocainide, Mexilitine

Overdose experience with other class Ib drugs has been limited. Tocainide toxicity has resulted in gastrointestinal symptoms, seizures, and cardiac dysrhythmias similar to other class I agents.⁷⁷ Therapeutic use of tocainide resulting in blood dyscrasias⁷⁸ and pulmonary fibrosis⁷⁹ has also been reported. Mexilitine poisoning has caused seizures, ventricular dysrhythmias, and impaired myocardial conduction.⁸⁰ Other adverse effects of mexilitine are primarily neurologic and comparable to symptoms that occurred with lidocaine.

Class Ic Antiarrhythmics

Class Ic drugs (encainide, flecainide, propafenone) bind to sodium channels in the activated state and have the most potent sodium channel blocking effects of all class I antiarrhythmics.⁴⁹ Therapeutic concentrations of class Ic agents produce little effect on myocyte repolarization compared to other class I antiarrhythmics.⁸¹ At higher concentrations, these agents exert a significant negative inotropic effect.⁸² Overdose experience with these

drugs is limited, but they would be expected to produce similar cardiovascular effects as other class I compounds, with no antimuscarinic features. Seizures, hypotension, and dysrhythmias have been reported after a 3- to 4-g overdose of encainide.⁸²

Class III Antiarrhythmics

Class III agents (amiodarone, ibutilide, dofetilide) block the rapidly activating component of the delayed rectifier potassium channels.⁴⁹ These potassium channels are responsible for phase 3 repolarization in cardiac action potentials. Therefore Class III drugs delay repolarization and cause an increase in duration of the action potential and an increase in the effective refractory period. On the electrocardiogram, this results in prolonged Q-T intervals. By increasing the refractory period, these drugs are very useful in terminating re-entrant dysrhythmias.

Amiodarone

Amiodarone is an antidysrhythmic with a multitude of pharmacologic effects. It undergoes hepatic metabolism through cytochrome oxidase systems to produce another pharmacologically active but less potent metabolite, desethylamiodarone.⁸³ The main mechanism of action of amiodarone is prolongation of cardiac myocyte repolarization through blockade of the rapidly activating delayed rectifier potassium channel. Collectively this represents a class III antidysrhythmic effect. However, amiodarone is also a weak α - and β -adrenergic receptor antagonist and may block inactivated sodium channels and L-type calcium channels.⁸⁴ Expected electrocardiographic outcomes are prolonged Q-T intervals, ventricular dysrhythmias, and conduction blocks. Amiodarone is used to terminate re-entrant atrial or ventricular dysrhythmias and it has recently been added to the Advanced Cardiac Life Support (ACLS) tachydysrhythmia guidelines.⁸⁵ Despite its more frequent use today, there are few reported cases of oral amiodarone overdose resulting in significant cardiac toxicity. The low toxicity is likely due to its low and unpredictable oral bioavailability (22% to 86%) and large volume of distribution (>6.0 L/kg).⁸⁶ Intravenous overdose of amiodarone has not been reported although hypotension, bronchospasms, and hepatitis from therapeutic doses have been described. Most of the toxic effects reported from amiodarone in the literature are from long-term treatment and appear to be dose-related. Chronic use of amiodarone has been associated with pneumonitis, hypothyroidism, thyrotoxicosis, hepatitis, skin discoloration, and corneal damage.⁸⁷ Although not well studied, cholestyramine has been suggested as treatment for both acute and chronic amiodarone toxicity by its gastrointestinal binding of unabsorbed amiodarone and blockade of enterohepatic circulation of the drug.⁸⁸

Ibutilide, Dofetilide

Both ibutilide and dofetilide are newer class III antiarrhythmics used for chemical cardioversion of atrial fibrillation or flutter. Because of their effect on the rapidly activating delayed rectifier potassium channels, both drugs can delay action potentials and prolong Q-T intervals.⁴⁹ Experiences with overdoses of either drug are limited but expected toxicity would be induction of ventricular dysrhythmias. Toxic effect of either drug occurs within 60 minutes of administration and therapeutic use has resulted in torsades de pointes.^{84,89} Therefore a reasonable observational period of 4 to 6 hours is recommended in all patients who received ibutilide or dofetilide.

Cyclic Antidepressants

Toxicity from cyclic antidepressants is perhaps the most well-described of all fast sodium channel blocking compounds. These substances are responsible for more fatalities each year than any of the other drugs in this group.⁹⁰ After being originally studied for their antihistaminic properties in the 1940s, cyclic antidepressants were introduced into the pharmaceutical market in the United States in the 1960s, rapidly replacing electroshock therapy as a more “humane” treatment for severe depression.

Pharmacology

The “first generation” of cyclic antidepressant compounds, known as the tertiary amines, includes amitriptyline, imipramine, doxepine, and trimipramine. All are potent inhibitors of myocyte sodium channels. Each undergoes metabolism in the liver. Amitriptyline and imipramine are hepatically converted to the active secondary amines nortriptyline and desipramine, respectively, and these latter compounds were soon marketed as second-generation therapies for depression.⁴⁹ The membrane-stabilizing effects of these second-generation agents were soon appreciated as being similar to that of their parent compounds.⁴⁹

Newer marketed antidepressants, categorized as serotonin or norepinephrine reuptake inhibitors (i.e., trazodone, fluoxetine, sertraline, bupropion, paroxetine, and others) have so far demonstrated far less sodium and potassium channel impedance. Although each of these drugs may cause adverse reactions in overdose, their cardiotoxicity appears to be minimal in comparison to the first- and second-generation cyclic drugs.

In therapeutic doses, cyclic antidepressant drugs are rapidly absorbed. Although one might expect delayed gastric emptying as a result of an antimuscarinic effect in large ingestions, clinical signs of cyclic antidepressant toxicity usually appear within 6 hours.⁹¹ Asymptomatic patients without concomitant ingestions should not develop toxicity after 6 hours. Antimuscarinic effects on the central and peripheral nervous systems usually precede cardiotoxicity, but large ingestions of agents with less muscarinic receptor activity, such as imipramine, may present initially with hypotension and dysrhythmias. Cardiotoxicity, mental status depression, and seizures resulting from these agents can proceed rapidly, necessitating continuous monitoring.

Cyclic antidepressants are significantly protein bound in circulation and widely distributed in the body (40 L/kg).⁴⁹ Hepatic metabolism is the major route of elimination for these compounds, with some, such as amitriptyline and imipramine, producing active metabolites. Elimination half-life can be prolonged in overdose due to enzyme saturation.

Pathophysiology

The pathophysiology of cyclic antidepressant cardiotoxicity results from four main properties: (1) fast sodium channel or membrane-stabilizing effects, (2) muscarinic receptor blockade, (3) α -receptor blockade, and (4) norepinephrine reuptake blockade. Animal data also suggest blockade of delayed rectifier potassium channel and the γ -aminobutyric acid (GABA) receptor complex in the brain.^{92,93}

Cyclic antidepressants block fast sodium channels in a manner similar to quinidine and other class Ia antiarrhythmics, markedly decreasing the slope of phase 0 of the action potential.⁴⁹ Prolongation of both the QRS and Q–T interval durations have been demonstrated clinically in overdose, but in vitro

experiments show that cyclic antidepressants block primarily fast depolarizing sodium currents and actually shorten repolarization.^{94,95} The Q–T prolongation resulting from cyclic antidepressant toxicity is mainly attributed to the result of progressive QRS widening with globally impaired myocardial conduction.⁹⁵ However, the potential blockade of the delayed rectifier potassium channels may also contribute to the Q–T prolongation.⁹³ The cardiotoxic effects include ventricular dysrhythmias and depressed myocardial contractility.⁹⁵

Cyclic antidepressants block several receptor sites in both the central and peripheral nervous system, including H₁ and H₂ receptors, dopamine receptors, and muscarinic receptors.⁹⁶ This effect on the autonomic nervous system produces a clinical syndrome of dry mouth, blurred vision, sinus tachycardia, altered mental status (ranging from confusion and hallucination to seizures and coma), ileus, urinary retention, and anhidrosis. These signs and symptoms frequently precede the sodium channel blocking effects and are more common with doxepin and amitriptyline than imipramine.^{49,96}

Cyclic antidepressants are potent α -receptor antagonists. This effect is responsible for the orthostatic hypotension often experienced by patients at the initiation of therapy with these compounds.⁴⁹ The resulting vasodilation can be severe in overdose and combined with the impaired cardiac output from myocardial depression can lead to refractory hypotension and cardiovascular collapse.⁹⁷ α -Receptor blockade of the pupil in patients with cyclic antidepressant toxicity can prevent the anticipated antimuscarinic mydriasis, resulting in an unanticipated miotic pupillary effect.

The hypothesized mechanism of antidepressant action of cyclic antidepressants lies in their ability to block the catecholamine reuptake pump on the presynaptic terminal of neurons.⁹⁶ In overdose, this effect can deplete presynaptic catecholamine concentrations, thought to contribute to dysrhythmias and hypotension.⁴⁹

Hypotension can be present in cyclic antidepressant poisoning without significant dysrhythmias. Sinus tachycardia is usually present before the development of ventricular dysrhythmias or heart block.⁹⁸ Several studies have evaluated the electrocardiographic abnormalities predictive of toxicity from these agents. One review found that 33% of patients with QRS intervals greater than 100 ms developed seizures and 14% developed ventricular dysrhythmias.⁹⁹ There was also a 50% incidence of ventricular dysrhythmias in patients with QRS duration exceeding 160 ms.⁹⁹ Unfortunately, up to 25% of normal individuals may have a QRS duration greater than 0.10 second.⁴⁹ Another study suggested that a rightward terminal vector, best seen in the R wave of lead aVR, may correlate with the degree of cyclic antidepressant toxicity.^{100,101} In this study, an R wave of lead aVR greater than 3 mm notably predicted toxicity. Although having electrocardiographic abnormalities can be useful in assessing potential toxicity, none of the findings is 100% sensitive. Absence of these concerning findings is more indicative that cardiac toxicity is not developing.

Antipsychotics (Phenothiazines, Butyrophenones, and Atypical Agents)

Phenothiazine derivative compounds such as Thorazine, thioridazine, and prochlorperazine may have clinical effects similar to the cyclic antidepressants. Antimuscarinic toxicity is frequently

more pronounced in poisonings from these drugs, rather than their membrane-stabilizing cardiac effects. However, heart block and wide complex tachycardias and refractory hypotension are occasionally reported in overdoses of these agents.^{102,103} Fatalities are rare, even in massive ingestions of these drugs. The most common clinical presentation of phenothiazine overdose is neurotoxicity, manifesting as delirium, agitation, coma, seizures, and other antimuscarinic effects.

Haloperidol and droperidol are butyrophenone antipsychotic and antiemetic compounds available in the United States. Although these drugs share the potent dopamine receptor blocking properties of the phenothiazines, overdoses of these agents lack the prolonged sedation and antimuscarinic effects most often seen with phenothiazines. Torsades de pointes has been reported with the butyrophenones but usually follows large parenteral dosing.¹⁰⁴

Newer, atypical antipsychotics, such as quetiapine, olanzapine, risperidone, and ziprasidone, seem to have fewer effects on cardiac conduction. Most atypical antipsychotics have inhibitory functions at serotonin receptors, in addition to antimuscarinic and dopamine receptor blocking properties. Retrospective data and case reports have demonstrated the ability of some of these drugs to block fast sodium channels and potassium channels, resulting in QRS and Q-Tc prolongation, respectively. In general, these effects are much less common than with the older “typical” antipsychotic agents.

Antihistamines

Many H₁ receptor antagonists have been found to exert similar effects on the myocardial action potential as the class Ia antidysrhythmic compounds. The most commonly used medication in this class, diphenhydramine, has been shown to effectively block fast sodium channels at high concentrations.¹⁰⁵

In mild to moderate poisonings with these agents, patients most often exhibit a classic antimuscarinic syndrome, with sinus tachycardia, dry mouth, and confusion, often marked by hallucinations and psychotic behavior. The toxic syndrome may also include seizures, urinary retention, decreased gastric motility, and coma. Respiratory depression can occur in some severe cases, necessitating ventilator support.

In massive poisonings, antihistamines can impair fast sodium channel conduction, resulting in dysrhythmias and hypotension similar to that seen with other sodium channel blocking agents.^{105, 106} Dysrhythmias and cardiovascular collapse from these drugs are exacerbated by acidosis and, therefore, often occur after seizures, which frequently cause a sudden decline in the serum pH.^{105, 106}

Propoxyphene

Propoxyphene is an opioid analgesic found in combination with acetaminophen in Darvocet, and with salicylates in Darvon. Hepatic metabolism of propoxyphene produces an active metabolite known as norpropoxyphene. Both agents block fast sodium channels, causing QRS prolongation in toxic serum concentrations.¹⁰⁷ Overdoses of propoxyphene can result in hypotension and widening of the QRS complex, which can lead to ventricular dysrhythmias.¹⁰⁸ It is this membrane-stabilizing effect that is also thought to be responsible for the greater incidence of seizures from propoxyphene poisonings than from

other opioids. As with other sodium channel blocking agents, widening of the QRS complex with propoxyphene poisoning has been shown to respond to therapy with sodium bicarbonate (see later discussion).¹⁰⁹ Propoxyphene-induced seizures can be refractory to conventional anticonvulsants, such as phenytoin, necessitating use of benzodiazepines and phenobarbital for control.

Carbamazepine

Carbamazepine is an anticonvulsant with structural similarity to the cyclic antidepressants. In vitro, carbamazepine cardiotoxicity resembles that of the class Ia antiarrhythmics. However, carbamazepine rarely causes significant quinidine-like effects in poisoning, even with massive ingestions.^{110,111} Carbamazepine toxicity often results in mental status changes and occasionally respiratory depression.^{110,111} In addition, toxic carbamazepine concentrations may produce blockade of muscarinic receptors, resulting in the classic antimuscarinic syndrome with effects such as sinus tachycardia, dry mouth, and mydriasis.

Chloroquine

Chloroquine is a common antimalarial agent that often results in severe toxicity when taken in overdose. Chloroquine is structurally related to quinine and quinidine, and cardiotoxicity resulting from any of these agents can be indistinguishable.¹¹¹ The toxic to therapeutic ratio of chloroquine is low, and ingestions of as little as 300 mg by children have been fatal.¹¹² Seizures commonly and rapidly accompany the cardiotoxicity of this drug and appear to be unrelated to hypoxia.¹¹¹ A combination of intensive supportive care, intravenous boluses of benzodiazepines for convulsions, and vasopressor use for cardiovascular support has been shown to decrease mortality in animal models and human case reports of chloroquine poisoning.¹¹³

Management of Sodium Channel Blocking Drug Toxicity

As in the treatment of other cardiotoxic drug overdoses discussed in this chapter, the initial management of poisonings involving sodium channel blocking medications should begin with airway and circulatory support (Table 35-3). Any patient who is not breathing or in whom a patent airway is of question should receive endotracheal intubation and mechanical ventilation. Combative patients may require sedation and paralysis before an endotracheal tube can be placed.

Resuscitating the patient poisoned with sodium channel blocking drugs can be challenging. The hypotension resulting from massive ingestions of these agents is multifactorial and often refractory to intravenous fluid boluses. Vasopressors may be necessary in some situations, and vasopressor choice may be important. Although dopamine is employed with success in many cases of poisoning-related hypotension, it may be ineffective or even exacerbate the hypotension associated with cyclic antidepressants, phenothiazines, and other α -receptor blocking agents.¹¹⁴ Dopamine is the precursor of norepinephrine and requires uptake into the presynaptic terminals for activation; thus it may be ineffective with these agents, which block the catecholamine reuptake pump. At higher doses, the vasoconstrictive

Table 35–3. Outline of General Management of Sodium Channel Blocking Agent Toxicity

1. Stabilize airway.
2. Control breathing and hyperventilate patient if head injury is possible, or if cardiotoxicity is present and intravenous access is not established.
3. Resuscitate blood pressure and treat dysrhythmias.
 - a. Start intravenous normal saline or Ringer's lactate.
 - b. Normalize serum pH.
 - (1) Intravenous sodium bicarbonate
 - (2) Hyperventilation
 - c. Vasopressors
 - (1) Norepinephrine
 - (2) Phenylephrine
 - (3) Dopamine
 - d. Administer lidocaine for refractory ventricular dysrhythmias in cyclic antidepressant or class Ia antiarrhythmic poisoning.
4. Decontamination
 - a. Consider gastric lavage if less than 1 hour after massive poisoning.
 - b. Administer 1 g/kg oral activated charcoal

effects of dopamine are antagonized by the α -blocking effects of some of these drugs, leading to unopposed β -receptor stimulation of blood vessels and worsening of hypotension. For these reasons, vasopressors with more direct α -receptor stimulation, such as norepinephrine or phenylephrine, may be required for consistent blood pressure support.

The most helpful adjunct in the management of sodium channel blockade from drug poisoning has proved to be sodium bicarbonate. Sodium bicarbonate has been shown to be effective in raising the blood pressure and treating dysrhythmias associated with cyclic antidepressants, cocaine, flecainide, quinidine, chloroquine, and diphenhydramine.¹¹⁵⁻¹²¹ Sodium bicarbonate has been shown in both animal models and human cases of toxicity from these agents to increase blood pressure and improve conduction through the heart. Studies suggest that this is the result of the concomitant effects of both the bicarbonate and sodium components because they offer a synergistic benefit together when compared to each alone. Thus the beneficial effects are likely secondary to both an increase in the blood pH and an increase in the extracellular sodium concentration.

Although controlled studies do not exist to support the use of sodium bicarbonate for every drug in this category, its empirical administration to patients with evidence of toxicity from impaired sodium conduction seems prudent. The degree of alkalinization that one must achieve to be of benefit has not been well defined. Maintaining serum pH in normal ranges has been sufficient in our practice, but many authors recommend bolus injections of sodium bicarbonate to keep serum pH between 7.45 and 7.50. One common practice is the addition of 50 to 100 mmol sodium bicarbonate (1 to 2 ampules) to 1000 mL of 5% dextrose and water, titrating the infusion to an alkaline pH. This exercise may require frequent analyses of serum pH and sodium, and may lead to hyponatremia if not monitored closely. Intermittent boluses of sodium bicarbonate, at 1-2 meq/kg are equally effective. The bolus method is preferred by many toxicologists for the ability to more precisely titrate sodium bicarbonate doses to the effect of a narrowed QRS.

In some severe cases of sodium channel blocking drug toxicity, ventricular dysrhythmias may be refractory to the aforementioned management. Oxygenation should be maintained and resuscitative efforts continued as long as cardiac activity is present. Patients have survived neurologically intact after over an hour of advanced cardiac life support following massive cyclic antidepressant poisoning.¹²² Prolonged resuscitation may allow enough drug redistribution from cardiac receptors to restore conduction. The use of lidocaine has been effective in improving cardiac performance after overdose of membrane-stabilizing drugs,¹¹⁶ and can be administered in cases refractory to sodium bicarbonate.

Several therapeutic considerations should be addressed with regard to the antimuscarinic toxicity resulting from agents such as cyclic antidepressants, antihistamines, and phenothiazines. The antimuscarinic signs and symptoms that usually predominate are seldom life-threatening. Seizures from these agents, in the absence of severe hypotension or hypoxia, are most likely related to blockade of muscarinic receptors in the brain. They are usually self-limited and easily controlled with benzodiazepines or barbiturates. Sinus tachycardia produced by reduced vagal tone does not require specific treatment. Physostigmine, a short-acting carbamate cholinesterase inhibitor, can reverse the CNS toxicity and the sinus tachycardia associated with these agents, but may exacerbate impaired conduction throughout the heart, occasionally resulting in asystole.¹²³ For this reason, physostigmine is best reserved for cases with altered mental status in whom no cardiac conduction delays are present.

All patients with severe antimuscarinic signs and symptoms will need a urinary catheter if urinary retention occurs. Multiple doses of activated charcoal, and food and beverages, should be avoided in those individuals with evidence of impaired gastric motility. Soft restraints may be necessary and are usually adequate in individuals with agitation due to the CNS effects of these drugs. They are also usually preferred over pharmacologic restraints so as not to further impair the neurologic examination.

Gut decontamination may prevent absorption after ingestions of any of the agents discussed earlier. If benefit is to be derived from gastric decontamination, it should be undertaken soon after ingestion. The longer the delay, the more the drug escapes into the small intestine where most absorption occurs. Gastric decontamination more than 1 hour after ingestion may be of little benefit unless drugs that delay gastric emptying are involved in the poisoning. Large studies have found no effect on outcome when gastric decontamination is avoided altogether.¹²⁴ Syrup of ipecac is no longer recommended as a method of decontamination. Furthermore, gastric lavage is no longer routinely advocated, with the exception of life-threatening poisonings that present within 1 hour of ingestion.

Activated charcoal has been found to bind most cardiotoxic drugs and may be of benefit in limiting absorption. The timing of activated charcoal administration is also important, but charcoal administration may still be effective in binding a drug that has entered the duodenum. It is therefore rational to administer a dose of activated charcoal to most patients with a history or clinical evidence of ingesting a cardiotoxic substance. The recommended dose of activated charcoal is 1 g/kg, and patients may either drink the aqueous charcoal suspension (which has no taste) or have the dose administered through a nasogastric tube when intubated or uncooperative. Caution should be used

when using activated charcoal in obtunded patients or in those who are unable to protect their airway because this poses a risk of aspiration. Multiple doses of activated charcoal have been found to be of benefit in poisonings with agents such as theophylline and phenobarbital, but this therapy is not likely to benefit humans poisoned with any of the cardiotoxic agents listed in this chapter. In addition, those drugs that slow gastrointestinal motility may predispose the patient to charcoal bezoar formation when multiple doses are administered.¹²⁵

Extracorporeal removal of drugs using techniques such as hemodialysis or hemoperfusion has proved beneficial in overdoses of compounds such as theophylline, salicylates, and phenobarbital. Most other drugs, including those listed in this chapter, have not been found to be well removed by these modalities.

Illicit Drugs

Psychostimulant toxicity is a common cause of emergency department visits. Deaths have been described as a result of the multiorgan effects of these drugs. Although only cocaine and amphetamine derivatives are discussed here in detail, other agents such as ephedrine, pseudoephedrine, and phenylpropanolamine may cause similar clinical effects in toxic concentrations.

Cocaine

Cocaine is an alkaloid derived from the leaves of *Erythroxylon coca* and other trees indigenous to Peru and Bolivia. The alkaloid is dissolved in hydrochloric acid to form a water-soluble salt termed *cocaine hydrochloride* (chemical name, benzoyl-methylecgonine). Cocaine hydrochloride is sold as crystals, granules, or white powder. "Crack" (cocaine freebase) is the basic, nonsalt form that is created by the organic esterification of cocaine hydrochloride from a basic solution with ether. When crack is heated, it melts and forms a fat-soluble vapor that can be smoked and rapidly absorbed through the lungs. The name *crack* is derived from the popping sound made by the drug when it is heated. Therapeutically, cocaine is classified as an ester type of local anesthetic and currently limited to use as a mucosal anesthetic.

Pharmacology

Cocaine is well absorbed from the mucous membranes of the nose, lung, genitourinary, and gastrointestinal tract. Administration can occur through the intravenous, respiratory, intramuscular, and rectal routes. The method and dose of administration determine the onset of action. The "high" from intravenous administration of cocaine peaks within a few minutes after injection. Inhalation of the drug will produce effects within 1 to 3 minutes, but oral ingestion may delay symptoms up to 60 to 90 minutes. Plasma concentrations after intranasal use peak within 20 to 30 minutes and gradually decline over the next 60 minutes.¹²⁶

Cocaine is metabolized by nonenzymatic hydrolysis and liver esterases, including plasma cholinesterase. The two major metabolites include benzoylecgonine and ecgonine methyl ester, neither of which crosses the blood-brain barrier. Both of these compounds are water-soluble and are excreted in urine. Cocaine metabolites may be detected in urine up to 72 hours after an exposure, although heavy users may have positive urine screens

for up to 3 weeks.¹²⁷ When a user of cocaine also coingests ethanol, hepatic transesterification will create another pharmacologically active metabolite, cocaethylene. Cocaethylene is not on routine urine screens for cocaine metabolites.

Pathophysiology

The pharmacologic effects of cocaine in humans include the ability to stabilize membranes and block nerve conduction. The resulting effects on myocardial tissue cause blockade of fast sodium channels, leading to widening of the QRS complex with subsequent dysrhythmias. The sympathomimetic effects of cocaine are caused by impaired catecholamine reuptake and enhanced catecholamine release at nerve terminals.¹²⁶ The increased synaptic concentrations of neurotransmitters stimulate α - and β -receptors throughout the autonomic nervous system resulting in a cascade of clinical effects. Cocaine may also enhance the release of norepinephrine and dopamine in the CNS.¹²⁸ The unique ability of cocaine to inhibit nerve conduction while enhancing vasoconstriction is primarily responsible for its cardiovascular toxicity.¹²⁶

Cocaethylene is also a potent sodium channel blocking agent and appears to prolong the recovery time for the channel compared with cocaine.¹²⁹ In animal models, cocaine plus ethanol depressed myocardial contractility more than either agent given alone.^{130,131} Once formed, cocaethylene has a longer half-life than cocaine.

The mechanism of cocaine-induced myocardial ischemia is thought to be multifactorial. Cocaine increases myocardial oxygen demand while increasing heart rate and blood pressure. Usually, myocardial oxygen demand results in coronary vasodilation; however, cocaine taken by some routes can induce coronary vasospasm.¹³² Coronary artery thrombus formation has also been implicated as a cause of cocaine-induced myocardial ischemia. Thrombus formation leading to myocardial infarction has been associated with coronary artery vasospasm.¹³³ The vasospasm may damage the endothelium and cause release of vasoactive substances precipitating platelet aggregation. Cocaine may enhance this effect because in vitro studies have demonstrated that cocaine alone may directly stimulate platelet aggregation and platelet thromboxane production.¹³⁴ Cocaine activates platelets in whole blood by inducing the release of platelet granule contents and by promoting the binding of fibrinogen to the surface of the platelet.¹³⁴

Clinical Manifestations

The clinical effects of cocaine result from diffuse hyperadrenergic stimulation both centrally and peripherally. The peripheral sympathomimetic effects include tremor, mydriasis, urinary retention, and ileus. Adrenergic stimulation of the CNS leads to agitation, hallucinations, seizures, and coma.¹³⁵ Patients may experience psychosis, paranoia, and anxiety due to increased dopaminergic transmission.¹³⁶ Cerebrovascular complications from cocaine-induced vasospasm and a hyperadrenergic state include cerebral infarctions, transient ischemic attacks, and subarachnoid and intracranial hemorrhages.^{135,136}

Myocardial ischemia and infarction are well-documented complications of cocaine use. Ischemia of the myocardium does not require a massive exposure to cocaine and occurs commonly in the young adult with no history of cardiac risk factors. Symptoms of chest pain may be typical, atypical, or absent. A delay of several hours in the onset of chest discomfort may

occur after exposure to the drug.¹³⁷⁻¹³⁹ Electrocardiograms from patients with cocaine-associated chest pain may demonstrate a variety of abnormalities, including classic findings of myocardial injury such as ST segment elevation but may also be normal or have only nonspecific findings. A study of 42 cocaine users with chest pain and normal or nondiagnostic electrocardiograms documented 8 of these patients as having acute myocardial infarctions, defined by total creatinine kinase and myocardial isoenzyme levels.¹⁴⁰ Thus single or even serial electrocardiograms may not be useful in ruling out cocaine-induced ischemia.

Cocaine has been associated with a variety of dysrhythmias. Sinus tachycardia is common owing to the sympathomimetic effects. Atrial fibrillation, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation have all been described.¹⁴¹ Dysrhythmias may occur with or without underlying ischemia. Since cocaine can cause sodium channel blockade, this can lead to widening of the QRS complex and can precipitate associated dysrhythmias. Sodium channel blockade should be treated with sodium bicarbonate, as previously discussed.

Hypertension is also common with cocaine poisoning. The elevation in blood pressure combined with tachycardia may increase shear forces on the great vessels, resulting in aortic dissection,¹⁴² and coronary artery dissection.¹⁴³ The intestinal vasculature is susceptible to α -stimulating effects of catecholamines, and ischemic colitis has been described in adults¹⁴⁴ and in neonates after in utero exposure to cocaine.¹⁴⁵ The uteroplacental vasculature may also respond to cocaine exposure with diminished uterine blood flow after maternal cocaine use.¹⁴⁶

Extreme hyperthermia is often documented in cocaine overdose. Temperatures are frequently reported in excess of 106° F and are thought to result from a disturbance in thermoregulation due to excess dopaminergic stimulation, combined with excessive musculoskeletal activity and agitation.^{147,148} Although cocaine-induced hyperthermia may occur independent of seizure activity, it can be exacerbated by concomitant convulsions.¹⁴⁹ An acute rise in the central body temperature has also occurred after rupture of bags of cocaine ingested by body packers.¹⁵⁰

Rhabdomyolysis also contributes to the morbidity and mortality of cocaine poisoning. All routes of cocaine exposure have been associated with a rise in serum creatinine phosphokinase level from direct myotoxicity.¹⁵⁰⁻¹⁵² An association has been made between drug-induced hyperthermia and rhabdomyolysis, but observations suggest that cocaine can also induce rhabdomyolysis independently of hyperthermia.¹⁵⁰ Cocaine-induced rhabdomyolysis is associated with myoglobinuric renal failure.¹⁵² Cocaine is not known to be directly toxic to the renal tubules; however, the effects of cocaine on renal blood flow may exacerbate the effects of myoglobinuria.

Amphetamine Derivatives

Amphetamine derivatives, such as methamphetamine, are popular agents of abuse available as many different “designer” drugs in the phenylethylamine family (Table 35-4). Substitutions of the phenylethylene ring can result in many compounds with similar effects. The only approved uses of phenylethylamines in the United States at this time are for treatment of narcolepsy, attention deficit disorder, and short-term use for weight loss.

Amphetamines have been recognized for their stimulant properties for centuries and continue to be abused by various

Table 35-4. Designer Amphetamines

Chemical Name	Nickname
3,4-Methylenedioxymethamphetamine	MDMA, Adam, Ecstasy, XTC
3,4-Methylenedioxyethamphetamine	MDEA, Eve
3,4-Methylenedioxyamphetamine	MDA, Love Drug
4-Methyl-2,5-dimethoxyamphetamine	DOM/STP, Serenity, Tranquility

routes including intravenous and oral administration. “Ice” is a pure preparation of methamphetamine and is marketed in a solid form, hence its nickname. This preparation is volatile and can be smoked, resulting in rapid absorption and effect. This form of methamphetamine rapidly became one of the leading drugs of abuse in Hawaii and California in the 1980s.^{153,154} Illicit laboratories are able to produce large quantities of methamphetamines because of easy availability of most reagents.

Abuse of the phenylethylamines results in euphoria with increased self-confidence and well-being. Persistent use with repetitive doses over several days is common. During this “speed run,” the user may not sleep or eat owing to the stimulant and anorectic effects of the drug. Chronic use of amphetamines leads to tachyphylaxis, and increasing doses are usually required to maintain euphoria.

Pharmacology

The volume of distribution of amphetamines tends to be large, and the half-life ranges from 8 to 30 hours.¹⁵⁵ Elimination is primarily through hepatic transformation, but renal excretion results in significant elimination of certain members of the amphetamine family, such as methamphetamine.¹⁵⁶ Although acidification of the urine may enhance the excretion of some amphetamine derivatives, it may also exacerbate renal toxicity in the presence of rhabdomyolysis and is therefore not recommended.¹⁵⁷

Pathophysiology

The pharmacologic mechanisms of action of amphetamines are diverse but are thought to rely on indirect effects on catecholamine receptors. These compounds act by entering presynaptic neurons and stimulating the release of endogenous catecholamines such as norepinephrine and dopamine. Amphetamines also inhibit the reuptake of catecholamines and their breakdown by the monoamine oxidase enzyme system. These effects may last for hours, whereas those of cocaine may resolve within several minutes.¹⁵⁵

Increased catecholamine release results in stimulation of α - and β -receptors, both peripherally and centrally. Dopaminergic and serotonergic receptor stimulation may contribute to the behavioral disturbances and hyperthermic effects that are common with these poisonings.¹⁵⁸ The release of dopamine may be responsible for the pleasurable effects reported with these drugs. Although all members of the amphetamine family may produce a generalized hyperadrenergic state, the pattern of effects with these compounds differs with modification of the parent phenylethylamine molecule, resulting in different anorectic, cardiovascular, and hallucinogenic properties.¹⁵⁹

Clinical Manifestations

Physical findings in amphetamine poisoning are similar to those seen with other sympathomimetic drugs. The cardiovascular toxicity of amphetamines manifests most commonly as tachycardia and hypertension. Dysrhythmias are a common cause of death and can include ventricular tachycardia and ventricular fibrillation.¹⁶⁰ Hypertensive emergencies with intracranial hemorrhages and cerebrovascular accidents may be more common with amphetamine and methamphetamine than cocaine abuse.¹⁶¹ Acute myocardial ischemia, infarction, aortic dissection, and dilated cardiomyopathy are also known to occur in the setting of amphetamine use.¹⁶² Diffuse vascular spasm has also been reported with amphetamine poisoning, and may result in death.^{163,164}

CNS toxicity is the most common reason for amphetamine-poisoned patients to present to a hospital. Most victims are agitated, anxious, and can become volatile and violent. Tactile and visual hallucinations may contribute to patient agitation, and psychoses similar to paranoid schizophrenia are frequently observed in these patients. Mydriasis and diaphoresis are common. Seizures often complicate amphetamine poisoning.¹⁶⁴

As in acute cocaine intoxication, hyperthermia is well documented in amphetamine poisoning and is associated with increased morbidity and mortality. Hyperthermia may occur independent of seizures and has been associated with rhabdomyolysis, coagulopathy, renal failure, and death.¹⁶⁴⁻¹⁶⁶

Management

Successful treatment of sympathomimetic poisoning begins with aggressive supportive care. Management of airway, breathing, and circulation are initial priorities. Placement of the patient in a quiet setting may reduce the amount of stimulation and reduce patient agitation; however, the victim must be continuously monitored for potential complications. Vital signs should be obtained frequently and body temperature verified by rectal thermometer if hyperthermia is suspected. Rapid cooling measures should be instituted as soon as hyperthermia is discovered, and neuromuscular paralysis may be required in severe cases of hyperthermia.

Decontamination of the patient who ingested sympathomimetics or bags containing these drugs begins with the administration of activated charcoal as described earlier. Whole-bowel irrigation with an iso-osmotic, isoelectric lavage solution (e.g., Go-Lytely) may enhance the removal of bags from the gastrointestinal tract.¹⁶⁷ Due to the large volume of distribution of these agents, hemodialysis and hemoperfusion are not effective in their removal; however, hemodialysis may be required if acute renal failure develops as a complication of rhabdomyolysis.

Rapid and effective control of hypertension from sympathomimetic poisoning is imperative. The use of β -blockers to control the hypertension associated with sympathomimetics is controversial because these compounds may potentiate both coronary and peripheral vasoconstriction due to unopposed α -agonist activity.^{168,169} Case reports have suggested the use of labetalol as an alternative to nonselective β -blocking agents,¹⁷⁰ but labetalol is a more potent β than α antagonist. One study of patients given intranasal cocaine while undergoing angiography demonstrated that labetalol reduced the mean arterial pressure but had no effect on coronary artery vasoconstriction.¹⁷¹ Use of direct vasodilators such as nitroglycerin, nitroprusside, or phenolamine is optimal.^{172,173}

Cocaine or amphetamine-related chest pain must be considered to represent active myocardial ischemia. Therapy should initially include the application of oxygen and the reduction of central sympathomimetic effects with the liberal use of benzodiazepines. Nitroglycerin has been demonstrated to be effective in alleviating cocaine-induced vasoconstriction in diseased and nondiseased coronary arteries.¹⁷³ An antiplatelet drug such as aspirin may be administered because platelets are activated by cocaine. Heparin or thrombolytics may be considered when ischemia is refractory to more conservative management.

Treatment of sympathomimetic-induced dysrhythmias begins with the administration of benzodiazepines to sedate the patient and reduce catecholamine release.¹⁷⁴ Wide complex tachydysrhythmias from cocaine have been effectively treated by administering intravenous sodium bicarbonate.¹⁷⁵ Lidocaine may be considered for treatment of dysrhythmias secondary to ischemia or refractory to sodium bicarbonate but should be used with caution because it has potentiated cocaine-induced seizures and death in rats.¹⁷⁶

Benzodiazepines are the mainstay of treatment for CNS effects of sympathomimetic poisonings. These sedative-hypnotics have been demonstrated to reduce the lethality of both cocaine and amphetamines.^{174,177} Butyrophenones have also been effective in reducing the dopaminergic-based delirium associated with amphetamine use.¹⁷⁸ Butyrophenones must be administered cautiously to patients with either cocaine or amphetamine toxicity because most antipsychotic medications may lower seizure thresholds, alter temperature regulation, and cause acute dystonias.

Conclusion

Many drugs possess the ability to cause life-threatening cardiotoxicity in overdose. In this chapter we have outlined some of the most significant and most common agents in this regard, with emphasis on clinical presentation and management. Although primary resuscitative efforts in all disease states should focus on airway and circulation, the varied mechanisms of action of cardiotoxic compounds may require specific therapeutic interventions. Early consultation with a certified regional poison control center or a medical toxicologist may assist in the care of these patients.

Hemostasis and the Coagulation Cascade
Antithrombins—Mechanism of Action
Unfractionated Heparin (UFH)
Low Molecular Weight Heparins (LMWH)

Synthetic Pentasaccharides (Fondaparinux and Idraparinux)
Direct Thrombin Inhibitors
Conclusions

DRUGS INTERFERING with blood coagulation are a mainstay of cardiovascular therapy. This therapeutic area is undergoing unprecedented change with the clinical introduction of newer drugs and intensive research into their role in the management of acute coronary syndromes (ACS) and percutaneous coronary intervention (PCI). These recent advances in antithrombin and antiplatelet therapy have led to significant improvement in patient outcomes. Although unfractionated heparin (UFH) alone has been the mainstay of antithrombin therapy for many years, studies with low molecular weight heparins (LMWHs), pentasaccharides, direct thrombin inhibitors (DTIs), and parenteral antiplatelet agents (glycoprotein IIb/IIIa inhibitors) have altered the landscape of therapy for patients having ACS and undergoing PCI.

Although improvements have been made in efficacy, this must be balanced with the need for safety. Both indirect and direct thrombin inhibitors have found an expanded role in PCI as recent trials have demonstrated their efficacy and safety.

Population-based surveys conducted in Europe during 1999–2001 demonstrated that more than 90% of patients with ACS receive aspirin upon hospital admission and that most (80%) also receive either UFH or LMWHs, with the proportions receiving these two forms of heparin approximately equal.^{1–3}

The Seventh American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy and the American College of Cardiology/American Heart Association/ Society for Cardiovascular Angiography and Interventions (ACC/AHA/SCAI) updated their recommendations for anticoagulation therapy in patients undergoing PCI in recent years and the European Society of Cardiology has also recently published its position paper on anticoagulants in heart disease.^{4–6}

The development of anticoagulant therapy in heart disease has added to the complexity of patient management for clinicians. The explosion of research has meant that both clinical

application of each drug and combination therapy has become increasingly intricate. The management of patients in the acute setting will continue to evolve.

Hemostasis and the Coagulation Cascade

When a blood vessel is damaged, the site of disruption is rapidly sealed to prevent blood loss. Hemostasis refers to the formation of a platelet and fibrin plug at the site of injury. This requires activation of platelets and coagulation at the site of injury. The clot is later dissolved by another protease reaction, fibrinolysis, which also prevents the vessel from being occluded by the clot during its formation. In order for the blood to stay fluid within the circulation, a delicate balance between the carefully regulated systems of coagulation and fibrinolysis is needed. Disturbances in either system will cause a tendency toward thrombosis or bleeding.⁷ Coagulation, as shown in [Figure 36-1](#), has often been represented as two independent pathways that converge to a common pathway, with thrombin generation as the end point of the cascade. This model gives a good representation of the processes observed in clinical coagulation laboratory tests. The prothrombin time measures the factors of the so-called extrinsic pathway, and activated partial thromboplastin time measures factors in the intrinsic pathway. However, this model has inadequacies relating to the *in vivo* hemostatic processes. For example, deficiencies of factor XII, high molecular weight kininogen (HK), or prekallikrein do not cause clinical bleeding, and others have shown that under normal circumstances, hemostasis is initiated by tissue factor (TF), a transmembrane glycoprotein.^{8,9} TF is a member of the class II cytokine receptor superfamily and functions both as the receptor and as the essential cofactor for factors (F) VII and VIIa. Assembly of the

Figure 36-1. Coagulation cascade. Simplified schematic shows coagulation by activation of factor XII (intrinsic pathway) and factor VII/tissue factor (TF) (extrinsic pathway). F, factor; PLTS, platelets. Act, activated; PL, phospholipids

TF/FVIIa complex on cellular surfaces leads to the activation of FX and initiates coagulation. TF is constitutively expressed in cells surrounding blood vessels and large organs to form a hemostatic barrier. In addition to its role in hemostasis, the TF/FVIIa complex has been shown to elicit intracellular signaling resulting in the induction of various genes, thus explaining its role in various biologic functions, such as embryonic development, cell migration, inflammation, apoptosis, and angiogenesis.¹⁰⁻¹²

Cell-based Model of Coagulation

In this model, coagulation occurs in three overlapping phases: initiation, priming, and propagation.^{9,13,14} During the process of hemostasis, a break in the vessel wall brings plasma into contact with TF-bearing cells. FVII binds to TF and is rapidly activated by coagulation proteases and by noncoagulation proteases, depending on the cellular location of the TF.¹⁵⁻¹⁷ The FVIIa/TF complex then activates FX and FIX. The activated forms of these two proteins (IXa and Xa) play very different roles in subsequent coagulation reactions. FXa can activate plasma FV on the TF cell. If FXa diffuses from the protected environment of the cell surface from which it was activated, it can be rapidly inhibited by the TF pathway inhibitor (TFPI) or antithrombin (AT). However, the FXa that remains on the TF cell surface can combine with FVa to produce small amounts of thrombin (the enzyme responsible for clot formation). This thrombin, although not sufficient to cleave fibrinogen throughout a wound, nonetheless plays a critical role in amplifying the initial thrombin signal. The initial FVIIa/TF complex is subsequently inhibited by the action of the TFPI in complex with FXa.^{18,19} In contrast to FXa, FIXa is not inhibited by TFPI, and only slowly inhibited by AT. FIXa moves in the fluid phase from TF-bearing cells to nearby platelets at the injury site.

In the amplification phase (priming phase), low concentrations of thrombin activate platelets adhering to the injury site to release FV from their α -granules. Thrombin cleaves the partially activated FV to a fully active form. Thrombin also cleaves FVIII, releasing it from the von Willebrand factor. Such activated

Figure 36-2. Mechanism of action of heparin derivatives.

A, Unfractionated heparin (UFH) possesses the pentasaccharide unit necessary for its interaction with antithrombin (AT). The UFH/AT complex is able to block the thrombin active site. **B**, Low-molecular-weight heparins (LMWHs) (short chains) do not bind to exosite 2 of thrombin, in contrast to the longer UFH chains. All LMWH/AT complexes can still bind to factor Xa (FXa). **C**, Synthetic pentasaccharides (fondaparinux and idraparinux), similar to LMWHs, bind and activate AT and allow AT to inhibit FXa efficiently. Hirudin and bivalirudin bind to thrombin via the active site and exosite 1, displacing thrombin from fibrin.

factors bind to platelet surfaces, which provide the backbone for thrombin generation that occurs during the propagation phase.²⁰

In the propagation phase, the phospholipid surface of activated platelets acts as a cofactor for the activation of the FVIIIa/FIXa complex and of the FVa/FXa complex, which accelerate the generation of FXa and thrombin, respectively. The burst of thrombin leads to the bulk cleavage of fibrinogen to fibrin. Soluble fibrin is finally stabilized by FXIIIa, also activated by thrombin, to form a fibrin network (i.e., a thrombus).

Arterial Thrombosis

Arterial thrombosis can occur from at least two main different mechanisms, endothelial erosion or plaque rupture.^{21,22} Plaque rupture results in the exposure of thrombogenic material (e.g., collagen and TF) to the circulation and subsequent activation of platelets and coagulation cascade. This, coupled with the simultaneous release of vasoactive substances, induces thrombus formation and vasoconstriction, which result in myocardial ischemia and ACS.

Antithrombins—Mechanism of Action

Thrombin has an active site and two exosites, one of which, exosite 1, binds to its fibrin substrate, orienting it toward the active site. Figure 36-2 displays the mechanisms of action of

the different thrombin inhibitors described below. The heparin derivatives in current use include UFH, LMWHs, and the synthetic pentasaccharide derivatives fondaparinux and idraparinux. These are all parenteral drugs that must be administered by intravenous (IV) or subcutaneous (SC) injection, and they are classified as indirect anticoagulants because they require a plasma cofactor (essentially AT) to exert their anticoagulant activity, while the DTIs (hirulog and hirudin) bind thrombin, essentially displacing it from fibrin.

Unfractionated Heparin

UFH was discovered almost 90 years ago and is the prototype of its derivatives. It is a natural product that can be isolated from beef lung or porcine intestinal mucosa. It consists of highly sulfated polysaccharide chains, with a mean of about 45 saccharide units. Only one third of the heparin chains possess a unique pentasaccharide sequence that exhibits high affinity for antithrombin (AT), and it is this fraction that is responsible for most of the anticoagulant activity of heparin.⁵

Pharmacokinetics, Metabolism, and Administration

UFH must be given parenterally either by continuous IV infusion or by SC injection. When given SC for treatment of thrombosis, higher doses of heparin than those administered by IV infusion are needed to overcome the fact that the bioavailability of heparin after SC injection is only about 30%.²¹ This is, however, highly variable among individuals.⁵ A number of plasma proteins compete with AT for heparin binding, thereby reducing its anticoagulant activity. The levels of these proteins vary among patients. This phenomenon contributes to the variable anticoagulant response to heparin and to the phenomenon of heparin resistance.²¹ Heparin is cleared through a combination of a rapid saturable phase and a slower first-order mechanism. Heparin binds to endothelial cells, platelets, and macrophage during the saturable phase. Once the cellular binding sites are saturated, heparin enters the circulation, from where it is cleared more slowly via the kidneys. The complex kinetics of heparin clearance render the anticoagulant response to UFH nonlinear at therapeutic doses, with both the peak activity and duration of effect increasing disproportionately with increasing doses.²¹

Dosing and Monitoring

Heparin can be given in fixed or weight-adjusted doses, and nomograms have been developed to aid with dosing.²² The doses of UFH recommended for the treatment of ACS are lower than those typically used to treat venous thromboembolism due to the lower thrombus burden in arterial thromboses. Due to the varying anticoagulant response of UFH among patients, UFH therapy is monitored and the dose is adjusted based on these results. The test most often used to monitor heparin is the activated partial thromboplastin time (aPTT). The activated clotting time (ACT) is used to monitor the higher doses of UFH given to patients undergoing PCI or cardiopulmonary bypass surgery.

An aPTT ratio between 1.5 and 2.5 (calculated by dividing the reported therapeutic aPTT range by the control value for the reagent) was associated with a reduced risk for recurrent VTE in a previous large retrospective registry.²³ Based on this study, an aPTT ratio of 1.5 to 2.5 was adopted as the therapeutic

range for UFH. Both the ACCP and the European Society of Cardiology agree that aPTT ratios should be adapted to the reagents used and that the use of a fixed aPTT target in seconds for any therapeutic indications of UFH should not be strictly applied. Despite these shortcomings, the aPTT is the most common method used for monitoring its anticoagulant response. The aPTT should be measured approximately 6 hours after the bolus dose of heparin, and the continuous IV dose should be adjusted according to the result. Various heparin dose-adjustment nomograms have been developed, but none is applicable to all aPTT reagents, and, for the reasons discussed above, the therapeutic range should be adapted to the responsiveness of the reagent used.

Side Effects

Bleeding is the major complication of heparin therapy. Other complications of heparin include heparin-induced thrombocytopenia (HIT) and osteoporosis. HIT is caused following the formation of heparin/platelet factor 4 (PF4) complexes. Antibodies are produced against the neoepitope on PF4 that binds to Fc receptors on the platelet, causing its activation.²⁴ Activated platelets are then removed from the circulation, which causes thrombocytopenia. Osteoporosis is a complication of long-term treatment with therapeutic doses of heparin and appears to be the result of heparin binding to osteoblasts with subsequent osteoclast activation.

Clinical Evidence

UFH has mainly been used in the management of patients with non-ST-segment elevation-ACS (NSTEMI-ACS), adjuvant therapy during PCI, and in the STEMI population (with or without fibrinolytic agents). In trials comparing the association of heparin plus aspirin versus aspirin alone in NSTEMI-ACS, a trend toward benefit was observed in favor of the heparin-aspirin combination, but at the cost of an increase in bleeding. Recurrence of events after interruption of UFH explains why this benefit is not maintained over time, unless the patient was revascularized before the interruption of UFH.²⁵ Adjunctive UFH use in the setting of STEMI, together with the use of fibrinolytic agents, has a narrow therapeutic window. The ISIS-3 and GISSI-2 trials examined its use with streptokinase and found no reduction in mortality at 35 days or 6 months with an increase in major bleeding. The evidence for the use of UFH with tissue plasminogen activator (tPA) was more favorable and it became standard therapy after the superiority of front-loaded tPA with UFH was demonstrated in the GUSTO-1 trial.²⁶ Intravenous UFH using a bolus of 60 U/kg (maximum 4000 U) followed by a maintenance infusion of 12 U/hr (maximum 1000 U) for 48 hours is recommended with tPA and other fibrin-specific fibrinolytic agents.⁵

UFH is the most commonly used anticoagulant during PCI. ACT monitoring is used in this case because the required level of anticoagulation is beyond the range that can be measured using aPTT. Randomized trials have shown UFH to reduce ischemic complications.^{27,28} UFH in a dose of 60 to 100 IU/kg and a target ACT between 250 and 350 seconds are recommended. A target of 200 seconds is advocated for UFH dosing in conjunction with glycoprotein (Gp) IIb/IIIa inhibitors.²⁹⁻³² After completion of PCI, UFH is not indicated because continued treatment does not reduce ischemic complications and is associated with a higher risk of bleeding.³³

Low Molecular Weight Heparin

In the early 1980s, LMWH was introduced as an alternative to UFH, first for the prevention of deep vein thrombosis (DVT) among postoperative patients.^{34,35} Four LMWHs have been studied in the setting of acute coronary syndromes, enoxaparin, reviparin, tinzaparin, and dalteparin. Enoxaparin and dalteparin have been approved by the FDA for use in cardiovascular disease, and enoxaparin is the most widely studied of the LMWHs.

The high bioavailability and minimal plasma protein binding of LMWH leads to a predictable dose-response, which obviates the need for plasma monitoring.³⁶ In addition, LMWH has been reported to have a lesser effect on platelet aggregation than UFH.³⁷ Other benefits of LMWH include a higher antifactor Xa:IIa ratio, less inhibition by platelet factor 4, and an inhibition in the early rise in von Willebrand factor.³⁸

Pharmacokinetics, Metabolism, and Administration

The LMWHs are most commonly administered SC, although an IV bolus has also been evaluated, most commonly in studies in the STEMI population. Enoxaparin is dosed according to body weight, with the most common dose used in ACS being 1 mg/kg every 12 hours. Following a single SC injection, enoxaparin has a peak plasma antifactor Xa activity within 3 to 6 hours.³⁹ One study demonstrated that 97.6% of patients had antifactor Xa activity above therapeutic range at the time of catheterization if enoxaparin was administered with 8 hours of planned PCI.⁴⁰ Enoxaparin is weakly metabolized in the liver. Renal clearance of active fragments represents about 10% of the administered dose, whereas about 40% of active and inactive fragments combined are excreted renally. Based on antifactor Xa activity, elimination half-life is 4.5 to 5 hours after a single dose and approximately 7 hours after repeated dosing.⁴¹

Clinical Evidence

Based on early experience with LMWHs,⁴²⁻⁴⁴ two pivotal trials examined the efficacy and safety of enoxaparin in patients with ACS. The ESSENCE trial evaluated enoxaparin in the setting of ACS.⁴⁵ They randomized more than 3000 patients to enoxaparin or UFH for at least 48 hours. At 14 days, the incidence of death, MI, or recurrent angina was significantly lower in patients randomized to enoxaparin than those receiving UFH (16.6% versus 19.8%, $p = 0.019$), and the outcomes remained significantly different at 30 days (19.8% versus 23.3%, $p = 0.016$). Although there was no significant difference in major bleeding (6.5% versus 7.0%, $p = \text{NS}$), the incidence of any bleeding event was significantly higher in the enoxaparin group (18.4% versus 14.2%, $p = 0.001$), primarily driven by an increase in injection-site ecchymosis. The TIMI 11B trial, which randomized nearly 4000 patients to either UFH or enoxaparin, again showed a statistically significant difference in ischemic outcomes favoring enoxaparin (12.4% versus 14.5%, $p = 0.048$) with no difference in major bleeding.⁴⁶

The SYNERGY trial randomized more than 10,000 patients having NSTEMI-ACS and high risk features undergoing an early invasive strategy to enoxaparin versus UFH.⁴⁷ More than half received a Gp IIb/IIIa inhibitor and two thirds received clopidogrel or ticlopidine. There was no significant difference in the incidence of death or nonfatal MI by 30 days between patients who received enoxaparin or UFH (14.0% versus 14.5%, $p = \text{NS}$).

In addition, the rates of acute complications, including abrupt closure, threatened abrupt closure, unsuccessful PCI, and emergency CABG surgery were not significantly different between the groups. There was, however, a significantly higher incidence of major bleeding (9.1% versus 7.6%, $p = 0.008$) in the enoxaparin group.

There have also been two large meta-analyses reported evaluating the role of enoxaparin in NSTEMI-ACS.^{48,49} Eikelboom and colleagues analyzed five trials involving more than 12,000 patients comparing UFH with LMWH. They reported no significant difference between LMWH and UFH in terms of 7-day incidence of a composite of death or recurrent MI (2.2% versus 2.3%, $p = 0.34$).⁴⁸ Petersen and colleagues evaluated six studies, including almost 22,000 patients randomized to either enoxaparin or UFH, and reported their results in 2004.⁴⁹ There was a significant difference favoring enoxaparin in terms of the 30-day incidence of a composite of death or recurrent MI (10.1% versus 11.0%, $p = 0.05$) with no difference in major bleeding (4.7% versus 4.5%, $p = \text{NS}$) at 7 days.

The ACC/AHA guidelines for the treatment of patients with NSTEMI, last updated in 2002, suggest that LMWHs are preferred over UFH in the absence of renal failure.⁶

Although enoxaparin gained a firm footing in the treatment of NSTEMI-ACS, it was not until 2001 that the first randomized trial evaluating its use as an adjunct to fibrinolytic administration for STEMI was reported. In the HART II trial, 400 consecutive patients with STEMI received aspirin and tissue tPA and were randomized to enoxaparin or UFH for at least 3 days in a non-inferiority design.⁵⁰ At 90 minutes, there was no significant difference in artery patency (80.1% versus 75.1%), and at 1 week, there was a trend toward a significant difference in reocclusion rates favoring enoxaparin (5.9% versus 9.8%, $p = 0.12$). There were no significant differences in in-hospital major bleeding (3.6% versus 3.0%) or death at 30 days (4.5% versus 5.0%).

The ASSENT-3 trial randomized more than 6000 patients with STEMI who were to undergo fibrinolytic therapy with tenecteplase to 1 of 3 regimens: full-dose tenecteplase plus enoxaparin, full-dose tenecteplase plus UFH, or half-dose tenecteplase plus low-dose UFH and a 12-hour infusion of abciximab. The composite incidence of 30-day mortality, in-hospital reinfarction, and refractory ischemia was significantly reduced with enoxaparin compared with UFH (11.4% versus 15.4%, $p = 0.0002$).⁵¹ When in-hospital major bleeding was added to the composite end point, the results still favored enoxaparin (13.7% versus 17.0%, $p = 0.0037$).

The EXTRACT-TIMI 25 study randomized more than 20,000 patients to enoxaparin or UFH following fibrinolytic therapy.⁵² The study reported a significant difference favoring enoxaparin in terms of a composite of death or nonfatal recurrent MI within 30 days (9.9% versus 12.0%, $p < 0.001$) and nonfatal reinfarction alone (3.0% versus 4.5%, $p < 0.001$), with a trend toward decreased mortality (6.9% versus 7.5%, $p = 0.11$). However, major bleeding at 30 days was significantly higher (2.1% versus 1.4%, $p < 0.001$).

Guidelines published in 2004 for the management of patients with STEMI, before the publication of the results of the EXTRACT-TIMI 25 study, suggest LMWH might be considered as an ancillary therapy among patients undergoing fibrinolytic therapy provided they are less than 75 years old and do not have underlying renal dysfunction.⁵³

Synthetic Pentasaccharides (Fondaparinux and Idraparinux)

A synthetic analogue of the antithrombin-binding pentasaccharide sequence found in UFH and LMWH, fondaparinux binds antithrombin and enhances its reactivity with factor Xa.⁵⁴

Pharmacokinetics, Metabolism, and Administration

Fondaparinux shares all the pharmacologic and biologic advantages of LMWHs over UFH, but in comparison with LMWHs, fondaparinux selectively inhibits FXa, without specific inhibition of thrombin (it is too short to bridge antithrombin to thrombin). As a synthetic molecule, fondaparinux is highly standardized and has no antigenic properties. A derivative of fondaparinux, termed idraparinux, is a synthetic, long-acting, highly sulfated analogue of fondaparinux, with prolonged a half-life.

In plasma, fondaparinux binds to antithrombin, and there is no detectable binding to other plasma proteins (a finding that explains why it produces a more predictable anticoagulant response than heparin). With excellent bioavailability after SC injection and a plasma half-life of about 17 hours, fondaparinux can be administered SC once daily and produces a predictable anticoagulant response and exhibits linear pharmacokinetics when given in doses ranging from 2 to 8 mg.⁵⁵ The drug is excreted unchanged in the urine. Consequently, dose adjustments are necessary in patients with renal insufficiency, and fondaparinux should not be used in those with renal failure.

The specific anti-Xa activity of fondaparinux is about sevenfold higher than that of LMWHs. Fondaparinux does not bind to platelets or PF4. Because it does not induce the formation of heparin/PF4, complexes that serve as the antigenic target for the antibodies that cause HIT, HIT is unlikely to occur with fondaparinux. However, fondaparinux also fails to interact with protamine sulfate, the antidote for heparin. If uncontrolled bleeding occurs with fondaparinux, a procoagulant such as recombinant factor VIIa may be effective.⁵⁶ However, recombinant factor VIIa is not available in all hospitals, and the drug is expensive and can cause thrombotic complications.

Like fondaparinux, idraparinux is a selective indirect FXa inhibitor.⁵⁷ Idraparinux binds antithrombin with such high affinity (more than tenfold higher than that of fondaparinux) that its plasma half-life of 130 hours is similar to that of antithrombin. The anti-FXa activity and inhibition of thrombin generation of idraparinux are dose-dependent.

Fondaparinux is given SC once daily in fixed doses. A dose of 2.5 mg is used in patients with NSTEMI and STEMI and for thromboprophylaxis in medical and orthopedic surgery patients. A dose of 7.5 mg is used for treatment of VTE. Because of the long half-life, idraparinux can be given SC once a week.⁵⁷

Fondaparinux and idraparinux have little or no effect on routine tests of coagulation, such as the aPTT or ACT.⁵⁸ These tests are therefore unsuitable to monitor the clinical use of these drugs. If monitoring is required, their anticoagulant effect can be measured with anti-Xa assays.

Besides bleeding, side effects of fondaparinux and idraparinux are largely unknown. In contrast to UFH or LMWHs, fondaparinux does not cause HIT and has actually been used successfully to treat HIT. Although data are lacking, in vitro and in vivo studies suggest that fondaparinux may have less effect on bone than UFH or LMWHs.^{59,60}

Clinical Evidence

Fondaparinux has been studied for venous thromboprophylaxis, treatment of venous thromboembolism and in the treatment of acute coronary syndromes. For thromboprophylaxis, four large phase 3 trials comparing fondaparinux with enoxaparin in patients undergoing major orthopedic surgery, and in general medical and surgical patients, have been performed.⁶¹⁻⁶⁴ In these trials, fondaparinux was found to reduce the risk of venous thromboembolism by approximately 55% compared with enoxaparin. Major bleeding occurred more frequently in the fondaparinux-treated group ($p = 0.008$), but the incidence of bleeding leading to death or reoperation, or occurring in a critical organ, was not significantly different between the two groups. It is possible that the increase in major bleeding with fondaparinux relative to enoxaparin reflects the timing of therapy following surgery (6 hours with fondaparinux versus 12 to 24 hours with enoxaparin).

Fondaparinux also has been evaluated for the initial treatment of established venous thromboembolism in two phase III clinical trials. In the MATISSE DVT trial,⁶⁵ 2205 patients with DVT were randomized, in a blinded fashion, to receive either fondaparinux or enoxaparin for 5 days followed by a minimum 3-month course of treatment with an oral vitamin K antagonist. At 3 months, the rates of recurrent symptomatic venous thromboembolism with fondaparinux or enoxaparin were 3.9% and 4.1%, respectively, whereas major bleeding rates were 1.1% and 1.2%, respectively. None of these differences was statistically significant.

In the open-label MATISSE PE trial,⁶⁶ 2213 patients with PE were randomized to receive either fondaparinux or unfractionated heparin (by continuous infusion) for 5 days followed by a minimum 3-month course of therapy with an oral vitamin K antagonist. At 3 months, the rates of recurrent symptomatic venous thromboembolism occurring after therapy with fondaparinux or unfractionated heparin were 3.8% and 5.0%, respectively, whereas major bleeding rates were 1.3% and 1.1%, respectively. Based on these two trials, fondaparinux appears to be at least as effective and safe as LMWH or UFH for the initial treatment of venous thromboembolism.

In ACS, fondaparinux was first evaluated in two dose-finding phase 2 trials in NSTEMI-ACS and two phase 2 elective PCI studies.⁶⁷⁻⁷⁰ These studies identified the lowest dose of 2.5 mg SC once daily to be the safest, with at least similar efficacy as higher dosages.

The OASIS-5 trial randomized 20,078 patients with NSTEMI-ACS to SC fondaparinux 2.5 mg daily versus SC enoxaparin 1 mg/kg body weight twice daily for a mean of 6 days.⁷¹ The prespecified primary end point was death, MI, or refractory ischemia at 9 days. This end point was reached in 5.8% with fondaparinux compared with 5.7% with enoxaparin, which satisfied the prespecified criterion for noninferiority ($p = 0.007$). Major bleeds were halved with fondaparinux compared with enoxaparin (2.2% vs 4.1%, $p < 0.001$), with lower rates of bleeding complications at the access site (3.3 versus 8.1%, $p < 0.001$). Major bleeding was an independent predictor of long-term mortality, which was lower with fondaparinux (5.8% versus 6.5% at 6 months, $p = 0.05$). At 6 months, the composite outcome of death, MI, or strokes was also significantly reduced (11.3% versus 12.5%, $p = 0.007$). Overall, the trial demonstrated that fondaparinux was equivalent to enoxaparin in terms of efficacy but with a substantially lower rate of major bleeding, which

translated into a significantly lower long-term mortality and morbidity.

The OASIS-6 trial evaluated the effect of fondaparinux, given for up to 8 days, compared with standard adjuvant anticoagulant treatment in 12,092 patients with STEMI.⁷² The trial had a complicated design with two strata: 5658 patients were randomized to fondaparinux versus the placebo and 6434 patients were randomized to fondaparinux versus UFH. Both strata contained subgroups with and without reperfusion treatments and also with the use of different types of reperfusion (i.e., streptokinase [73% of thrombolysis], urokinase, tPA agents, and primary PCI). In the overall population, the end point of death or reinfarction at 30 days was significantly reduced from 11.2% in the control group to 9.7% in the fondaparinux group ($p = 0.008$). The benefit was, however, only seen in stratum I with 11.2% versus 14.0% ($p < 0.001$) in the fondaparinux versus placebo groups, respectively. In contrast, there were no significant differences in stratum II (8.3% versus 8.7% in the fondaparinux and UFH groups, respectively). In the 3768 patients treated with primary PCI, who all were in stratum II, there was no benefit and actually a trend toward harm of fondaparinux, with a 30-day rate of death or MI of 6.1% with fondaparinux versus 5.1% in the UFH group ($p = 0.19$). There was a higher rate of guiding catheter thrombosis (22 versus 0, $p < 0.001$) and more coronary complications (270 versus 225, $p = 0.04$) with fondaparinux. There was a trend toward fewer severe bleeds with fondaparinux combining both strata, and, interestingly, severe bleeds were even less common with fondaparinux than with placebo in stratum I patients. It appears from these results that in acute STEMI without indication for UFH, fondaparinux is more effective and as safe as no anticoagulant treatment regardless of whether any reperfusion treatment is used or not. Secondly, in STEMI patients treated with thrombolysis, fondaparinux is at least as effective and as safe as UFH, although at present a claim of superiority is doubtful. In STEMI patients treated with primary PCI, fondaparinux used as the only anticoagulant seems associated with a risk of harm, based on an increased rate of coronary complications. This risk seems avoidable by pretreatment with UFH before PCI.

Idraparinux

This drug has been developed for long-term anticoagulation. The AMADEUS trial enrolled patients with AF at high risk of stroke with an indication for vitamin K antagonists. Patients were randomized to receive idraparinux 2.5 mg once weekly SC or VKAs (goal INR 2-3) for 6 to 24 months. This trial has been prematurely interrupted for safety reasons (unpublished results).

Direct Thrombin Inhibitors

Direct thrombin inhibitors (DTIs) are derivatives of hirudin, a polypeptide first isolated from the salivary glands of the medicinal leech, *Hirudo medicinalis*.⁷³ They are bivalent molecules that are capable of binding the active site and fibrin-binding site of thrombin. Rather than catalyzing the production of endogenous thrombin inhibitors, DTIs bind directly to thrombin and inhibit its interaction with substrate, thereby preventing fibrin formation, thrombin-mediated activation of the coagulation cascade and thrombin-induced platelet aggregation.⁷⁴ Although indirect thrombin inhibitors such as heparin and LMWH lead to the inactivation of only circulating thrombin, because of their

mechanism of action, DTIs are capable of inactivating clot-bound heparin as well. Importantly, in comparison to heparin derivatives, HIT has not been reported in patients receiving bivalirudin.

Two hirudin preparations are available, desirudin and lepirudin (65 amino acids), each of which is approved for use in thrombosis associated with HIT.⁷⁴ Bivalirudin is a synthetic derivative of hirudin (20 amino acids) and is approved for use as an alternative to heparin in patients undergoing PCI. Lepirudin and desirudin are irreversible inhibitors of thrombin. Antidesirudin and antilepirudin antibodies have been described among patients receiving these agents, leading to decreased clearance and a lower dose requirement.⁷⁵ There are three consequences of the smaller size and synthetic nature of bivalirudin: (1) immunogenicity has not been reported; (2) it can be cleaved by thrombin, thus restoring thrombin activity; and (3) it binds reversibly.

Although some early clinical studies evaluated the use of hirudin among patients with ACS, a narrow therapeutic index has limited its use.⁷⁶ The following discussion, therefore, will be limited to bivalirudin because it is the only DTI approved by the FDA for use in percutaneous coronary intervention and in the setting of acute coronary syndromes.

Pharmacokinetics, Metabolism, and Administration

Bivalirudin is administered parenterally. It is most frequently administered as a weight-based bolus (usually 0.75 mg/kg) followed by an infusion (usually 1.75 mg/kg/hr) through the completion of PCI. Its peak plasma concentration after a 15-minute bolus infusion occurs within 5 minutes of the completion of the infusion, and its half-life is approximately 25 minutes. Elimination of bivalirudin is via a combination of renal excretion and proteolytic cleavage, both by endogenous proteases and thrombin itself. Therefore, in patients with renal impairment, bivalirudin has a lower renal clearance and a longer half-life. The aPTT should be monitored more carefully among patients with kidney disease.

Clinical Evidence

Despite the use of heparin, the rate of ischemic and hemorrhagic complications during the early balloon angioplasty era coupled with a need for an antithrombotic strategy among patients with a history of HIT led to the introduction of bivalirudin.

The viability of bivalirudin as an alternative to heparin in patients undergoing balloon angioplasty was first reported by Topol and colleagues in a dose-escalation study that evaluated the efficacy of bivalirudin in patients undergoing elective coronary balloon angioplasty.⁷⁷ In a nonrandomized trial, patients receiving the bivalirudin had rates of abrupt vessel closure (6.2% among all patients, 3.9% among patients receiving the two highest doses of bivalirudin) similar to that previously reported with heparin (6% to 8%).⁷⁸⁻⁸⁰

Among patients with STEMI undergoing fibrinolysis, the HERO-2 trial randomized more than 17,000 patients to bivalirudin or heparin. Mortality at 30 days was not statistically different (10.8% versus 10.9%, $p = \text{NS}$), but bivalirudin was associated with a lower incidence of reinfarction within 96 hours (1.6% versus 2.3%, $p = 0.001$) that was countered by a small but significant increase in moderate (1.4% versus 1.1%, $p = 0.05$) and severe (0.7% versus 0.5%, $p = 0.07$) hemorrhagic outcomes.⁸¹

The REPLACE-2 trial randomized more than 6000 patients undergoing urgent or elective PCI to unfractionated heparin plus planned Gp IIb/IIIa blockade or bivalirudin plus provisional

Gp IIb/IIIa blockade.⁸² Bivalirudin was not inferior in terms of the composite primary outcome of the 30-day incidence of death, MI, urgent repeat revascularization or in-hospital major bleeding (9.2% versus 10.0%, $p = \text{NS}$); however, in-hospital major bleeding was significantly less common (2.4% versus 4.1%, $p < 0.001$). At 1 year, there was no significant difference in mortality (1.9% versus 2.5%, $p = \text{NS}$) between the groups.⁸³

The aforementioned studies evaluated patients undergoing urgent or elective PCI, but most excluded patients with ACS scheduled to undergo coronary angiography and subsequent PCI.

The ACUITY trial randomized almost 14,000 patients with NSTEMI-ACS and planned early invasive strategy to three arms: UFH or enoxaparin plus Gp IIb/IIIa blockade, bivalirudin plus Gp IIb/IIIa blockade, or bivalirudin monotherapy with provisional Gp IIb/IIIa blockade at the discretion of the treating physician.⁸⁴ There were three primary 30-day end points: (1) a composite ischemia end point (death from any cause, MI, or unplanned revascularization), (2) major bleeding, and (3) a composite of the ischemia end point plus major bleeding. There was no significant difference in any of the three primary end points among patients who received a heparin product plus Gp IIb/IIIa blockade compared with those who received bivalirudin plus Gp IIb/IIIa blockade (7.7%, 5.3%, and 11.8%, respectively, among patients receiving bivalirudin plus Gp IIb/IIIa blockade versus 7.3%, 5.7%, and 11.7%, respectively, among patients receiving heparin plus Gp IIb/IIIa blockade, all $p = \text{NS}$). Compared with those who received a heparin product plus Gp IIb/IIIa blockade, bivalirudin alone was associated with a noninferior rate of ischemic outcomes (7.8% versus 7.3%, $p = \text{NS}$) but was associated with significantly reduced major bleeding (3.0% versus 5.7%, $p < 0.001$) and the composite ischemic and hemorrhagic outcome (10.1% versus 11.7%, $p = 0.02$). A subsequent subgroup analysis of patients who underwent PCI in the ACUITY trial (nearly 8000 patients) reported similar findings.⁸⁵

The joint American College of Cardiology/American Heart Association/Society for Cardiovascular Angiography and Interventions guidelines for patients undergoing PCI, last updated in 2005 before the publication of the ACUITY trial, gives bivalirudin a Class I recommendation among patients with a history of HIT and a Class IIa recommendation among low-risk patients. Guidelines for patients with STEMI give bivalirudin a Class IIa recommendation among patients undergoing fibrinolytic therapy with streptokinase.⁸⁶

Conclusions

Antithrombin therapy in the treatment of cardiovascular disease has rapidly evolved over the past decade. This evolution has arisen from extensive randomized controlled trials that have explored the numerous clinical applications of therapy in terms of both efficacy and safety. The largest body of evidence has been obtained with LMWH and, more specifically, enoxaparin, showing superiority or at least equivalence to UFH in ACS patients undergoing currently recommended early invasive strategy. Enoxaparin use has been shown to be simple and safe without the need for monitoring or dose adjustment when combined with Gp IIb/IIIa receptor inhibitors. However, biologic monitoring (anti-Xa measurement) may be needed in special situations such as prolonged treatments in obese patients (BMI >30)

or those with renal insufficiency (creatinine clearance <60 mL/min) when accumulation of the drug is likely to occur.

From the results of the recent OASIS-5 and OASIS-6 trials, fondaparinux has demonstrated positive effects on both efficacy and safety. However, despite these encouraging results, many cardiologists have voiced uncertainty about using the drug routinely instead of UFH or enoxaparin in ACS patients because of concerns about catheter thrombosis in patients undergoing PCI. The need for combining UFH with fondaparinux to overcome this potential detrimental side effect is a limitation that needs further investigation.

Bivalirudin has been shown to be as effective and safe as heparin plus a Gp IIb/IIIa inhibitor for ACS patients rapidly managed in the catheterization laboratory. However, it remains to be seen whether bivalirudin can replace selective procedural abciximab use in the catheterization laboratory in high-risk ACS patients with positive troponin undergoing PCI. The practicality and benefit of bivalirudin in ACS patients may be more for the low-risk patients having rapid access to the catheterization laboratory. Patients who require a prolonged upstream treatment (>24 hours) may not be ideal candidates given the cost of bivalirudin and the lack of data.

There is no doubt that safety has become a critical issue as outlined by recent randomized studies providing evidence that severe bleeding and transfusion are associated with poorer prognosis, increase in mortality, and cost. Fondaparinux and bivalirudin represent an opportunity to improve safety. The three new anticoagulants, enoxaparin, fondaparinux, and bivalirudin, have demonstrated improvements in comparison to UFH that will certainly lead to changes in recommendations of anticoagulation in ACS.

At present, therapy is targeted in patients having ACS either with or without PCI. The reduction in morbidity and mortality in this population over recent years has stemmed from not only the advances of antithrombin therapy but also from the combination of improved primary and secondary prevention. This spectrum of care ranges from health care promotion and lifestyle changes to advancements in antiplatelet therapy, techniques in PCI, and risk factor modification. For continued improvements in patient care, all these areas need to be addressed along with an ongoing interest in the development of newer agent and therapies. These advancements should not only concentrate on efficacy but equal importance should be placed on improving safety.

Antiplatelet Therapy

John Hammock, Steven R. Steinhubl, Khaled M. Ziada

CHAPTER

37

The Platelet and Acute Coronary Syndromes
Antiplatelet Therapy for Unstable Angina and Non-STEMI
Antiplatelets in ST segment elevation Myocardial Infarction

Antiplatelet Therapy and Bleeding Complications
Conclusions and Future Directions

OVER THE last 2 decades, clinical management and outcomes of patients having acute coronary syndromes (ACS) have progressed dramatically. The better understanding of the role of the platelet in the pathophysiology of the acute coronary syndrome has been the fundamental pillar for that progress. The development and availability of effective pharmacologic agents and the advance of coronary revascularization procedures have been the tools by which the basic science paradigm shift was translated into reductions in morbidity and mortality of patients having unstable angina (UA), non-ST segment (NSTEMI) and ST-segment myocardial infarction (STEMI).

The Platelet and Acute Coronary Syndromes

Plaque rupture and luminal thrombus formation are the sentinel events that convert the atherosclerotic disease process from a slowly progressive condition causing insidious luminal obstruction to an acute coronary event that may lead to clinical deterioration and possible death. Plaque rupture is a term that describes the development of a gap in the fibrous cap exposing its collagen and the underlying lipid-rich core to flowing blood.¹ This event results in activation of the circulating platelets, which in turn initiates a sequence of events involving the activated platelet: adhesion, aggregation, and secretion (Fig. 37-1).

Platelet activation occurs via multiple stimuli including adenosine diphosphate (ADP) and thromboxane A₂, but collagen and thrombin are the two most potent platelet activators. Once collagen is available for binding, platelet adhesion and activation depend on two major collagen receptors located on the platelet membrane: the integrin glycoprotein Ia/IIa ($\alpha_2\beta_1$) and glycoprotein VI. Both of these receptors generate activation signals that enhance platelet thrombus formation. Thrombin is also a potent stimulus for platelet activation by binding and cleaving platelet protease activated receptors (PAR), PAR₁, and PAR₄. This process forms a tethered-ligand that acts to initiate transmembrane signaling, also leading to platelet activation.²⁻⁴

Once activated, platelet adhesion occurs when platelet glycoprotein Ib-IX-V binds to tissue von Willebrand factor (vWF).⁵ At least one other receptor that participates in platelet adhesion includes the platelet receptor Ia/IIa, which binds to collagen

fibrils.⁶ Platelet aggregation soon follows and is primarily mediated by the glycoprotein IIb/IIIa complex ($\alpha_{IIb}\beta_3$). Glycoprotein IIb/IIIa adhesion proteins are found on platelets and megakaryocytes. They are the most abundant glycoprotein found on the platelet surface with approximately 80,000 copies. The glycoprotein IIb/IIIa complex requires platelet activation, which causes a conformational change in the receptor thereby becoming a high-affinity fibrinogen binding receptor. Fibrinogen bridges activated platelets forming a platelet plug. The cytosolic portion of the glycoprotein IIb/IIIa complex stimulates actin rearrangement resulting in platelet spreading, aggregation, and clot retraction. Glycoprotein IIb/IIIa receptor antagonists are powerful antiplatelet drugs and will be discussed in detail later in this chapter.²⁻⁴

Activated platelets secrete substances from their granules, which stimulate further activation and aggregation. These mediators include, but are not limited to, adenosine diphosphate (ADP), thromboxane A₂, fibrinogen, fibronectin, and thrombospondin. There are at least two receptors that bind ADP: P2Y₁₂ and P2Y₁. The thienopyridine drugs prasugrel, clopidogrel, and ticlopidine block the P2Y₁₂ receptor. Thromboxane A₂ is an arachidonic-acid metabolite and a strong platelet stimulator. The production of thromboxane A₂ depends on the cyclo-oxygenase pathway, which is irreversibly inhibited by acetyl salicylic acid or aspirin (see Fig. 37-1).²⁻⁴ It should be noted that the aforementioned steps of adhesion, aggregation, and secretion do not occur in a stepwise fashion, but are presented that way for simplicity. In reality, these processes occur simultaneously and much work is still needed to better define targets for future antiplatelet drugs.

Antiplatelet Therapy for Unstable Angina and Non-STEMI

As previously described, the first step in the process of coronary thrombus formation involves platelet activation and aggregation. Therefore antiplatelet therapy is the cornerstone of treatment in UA and NSTEMI. Numerous clinical trials have established that appropriate antiplatelet therapy in UA and NSTEMI reduces mortality and other ischemic events. When antiplatelet therapy is used in the coronary care unit (CCU), it is imperative that physicians ensure their patients are receiving these agents at

Figure 37-1. In the inactive state, the platelet is rich with membrane receptors and contains dense granules (*top panel*). When the membrane receptors are stimulated, the platelet is activated (*middle panel*), leading to morphologic changes and a cascade of events, which result in deformational change and activation of the final common pathway of platelet activation: the glycoprotein (GP) IIb/IIIa receptor complex. Activation of that receptor leads to binding of fibrinogen, aggregation of platelets, and formation of a platelet-rich thrombus. The *bottom panel* shows the sites of action of the most commonly used platelet inhibitors in clinical practice. Aspirin inhibits the cyclooxygenase enzyme and reduces formation of thromboxane A₂ (TXA₂), thienopyridines irreversibly inhibit the P2Y₁₂ receptor, and GP IIb/IIIa inhibitors inhibit the activated IIb/IIIa receptor. ADP, adenosine diphosphate; PGH₂, prostaglandin H₂.

the appropriate dosages and cautiously watch for side effects, namely bleeding and hematologic abnormalities.

Acetyl Salicylic Acid (ASA or Aspirin)

The importance of effective and early use of aspirin in acute coronary syndromes has been a well-established management strategy for decades. Fortunately, the awareness of this fact among the public and health care professionals encountering these patients is very high. In many instances, patients reach for aspirin as they are calling emergency medical services for acute onset chest pain. The dispatchers receiving the calls instruct the patient to use aspirin if they have it available and the paramedics immediately provide it upon arrival to the scene. For those who

did not receive it, almost all patients with chest pain are given aspirin in the emergency department.

When aspirin is given acutely as a tablet, it should be chewed to achieve rapid platelet inhibition within approximately 20 minutes. Aspirin blocks the production of thromboxane A₂ by irreversibly acetylating a serine residue on cyclo-oxygenase 1. This prevents the conversion of arachidonic acid to prostaglandin-H₂, a precursor of thromboxane A₂. Thromboxane A₂ causes vasoconstriction and platelet aggregation.⁷ Unless there is a well-documented severe allergic reaction, all patients with acute coronary syndrome should be treated with aspirin.

The benefit of aspirin in unstable angina has been demonstrated in several trials. In the Veterans Administration Cooperative

Trial, 1266 men with unstable angina were randomized to receive either aspirin or placebo. The primary end points were death and myocardial infarction (MI). The incidence of death or acute MI was reduced by 51% in the aspirin group (5.0% versus 10.1%, $p = 0.0005$). Examined individually, both nonfatal acute MI and death were dramatically reduced by more than 50% in the aspirin group, although the reduction in death did not quite reach the level of statistical significance (3.4% versus 6.9%, $p = 0.005$ for acute MI and 1.6% versus 3.3%, $p = 0.054$).⁸ Further conformation for the benefit of aspirin was provided in the Canadian multicenter trial where 555 unstable angina patients were randomized to aspirin, sulfinpyrazone, both, or neither. In those randomized to aspirin, there was a significant risk reduction of 51% in combined end points of death and nonfatal MI ($p = 0.008$).⁹ Individual end points of both death and nonfatal myocardial infarction reached statistical significance. Sulfinpyrazone showed no clinical benefit in this trial. Further trials in patients with unstable angina continued to demonstrate a significant reduction in event rates in those receiving aspirin therapy.¹⁰

Despite the extensive body of literature describing the benefits of aspirin, little is known about the most effective dose. As little as 30 mg/day chronically can completely inhibit serum TXB₂ production,¹¹ and many studies suggest equal benefit with doses less than 150 mg daily compared to higher doses when taken long-term (Fig. 37-2).¹² For instance, in 3131 patients with minor stroke or CVA, 30 mg of aspirin daily was just as effective as 283 mg daily in preventing death from vascular causes, nonfatal stroke, or nonfatal myocardial infarction.¹³ Many large, blinded, controlled trials in addition to several meta-analyses of placebo-controlled trials have evaluated the optimal aspirin dose in treating patients with nearly every clinical manifestation of atherosclerosis including stroke, transient ischemic attack (TIA), percutaneous coronary and peripheral interventions, carotid endarterectomy, and myocardial infarctions. In all of these trials, there is no relationship between increasing aspirin dosage and improved clinical efficacy¹² (Table 37-1, see Fig. 37-2).

Although only 30 mg/day of aspirin is needed to inactivate thromboxane production, the rapidity of platelet inactivation should also be considered in the context of ACS. In a small study involving 18 healthy volunteers, chewing 162 mg and 324 mg of aspirin resulted in maximal inhibition of TXA₂ within 15 minutes. This was not seen with the 81 mg dose.²⁴ When comparing 162 mg aspirin with 325 mg aspirin, both doses seem equally effective in lowering mortality in patients with an STEMI, however, recent data suggests that the 162 mg dose is associated with fewer episodes of bleeding. This was noted in a recent study where acute mortality and bleeding risk was evaluated in fibrinolytic-treated STEMI patients. Data was obtained from the GUSTO I and GUSTO III trials. After adjustment, aspirin dose (162 mg versus 325 mg) was not associated with 24-hour, 7-day, or 30-day mortality rates. There was also no noted difference in MI between the two groups. However, in-hospital moderate/severe bleeding occurred in 9.3% of those treated with 325 mg versus 12.2% among those receiving 162 mg ($p < 0.001$). After adjustment, 325 mg was associated with a significant increase in moderate/severe bleeding (OR, 1.14; 95% CI, 1.05 to 1.24; $p = 0.003$).²⁵

To assess the effect of aspirin dosage on number and severity of bleeding episodes, data from 31 trials including

Figure 37-2. Efficacy and safety of various aspirin doses in acute coronary syndrome. In the control arms of three large randomized trials examining the role of various antiplatelet agents in which aspirin was the sole antiplatelet agent, there was no evidence of any reduction in major ischemic events with increasing doses of aspirin (top graph). There is a clear trend, however, toward increasing bleeding complications with increasing aspirin dose (bottom graph). The definitions of the composite efficacy end points and the definitions of major or serious bleeding varied among the trials. MI, myocardial infarction. (Data from Campbell CL, Smyth S, Montalescot G, et al: Aspirin dose for the prevention of cardiovascular disease: a systematic review. *JAMA* 2007;297:2018-2024; figure courtesy of Charles Campbell, MD, University of Kentucky.)

192,036 patients was analyzed. The dosage of aspirin was compared with bleeding complications and these data were divided into several categories, including major bleeding, minor bleeding, gastrointestinal, stroke, fatal/life-threatening, and total bleeding episodes. In all of the aforementioned categories, aspirin doses higher than 100 mg/day were associated with significantly more events.²⁶

The ACC/AHA guidelines for treatment of UA/NSTEMI give aspirin a class IA recommendation for immediate and indefinite use in this patient population.²⁷ According to these recommendations, 162 to 325 mg should be administered once ACS is suspected. In patients who do not receive a stent, the first dose should be followed by 75 to 162 mg/day indefinitely. The same daily aspirin dose is recommended in patients who receive stents except during months following stent placement where the aspirin dose should be higher. In patients receiving a bare metal stent, 162 to 325 mg/day is recommended

Table 37–1. The Effect of Different Doses of Aspirin on Clinical Outcomes

Source	Study Population	Clinical End Point	Mean Follow-Up	Aspirin Dosages (Number of Patients)	Event Rate
1. UK-TIA Trial ¹⁴	TIA or minor stroke	Vascular death, MI or major stroke	4 yr	Placebo (N = 814) 300 mg daily (N = 806) 600 mg q12h (N = 815)	22.9% 20.1% 19.9%

for the first month after stenting. In patients who receive a drug eluting stent, 162 to 325 mg/day for 3 to 6 months is recommended.

Adenosine Diphosphate Receptor Antagonists

The adenosine diphosphate (ADP) receptor antagonists include ticlopidine, clopidogrel, and prasugrel. Both ticlopidine and clopidogrel are effective adjuvants to aspirin therapy in acute coronary syndrome. Prasugrel has just been approved for use in the US and clopidogrel is used more commonly than ticlopidine because of a more favorable side-effect profile and a shorter time to onset of platelet inhibition.

Clopidogrel

The introduction of clopidogrel to the field of ACS management has had a dramatic effect on the algorithms of therapy used all over the world. Clopidogrel has been found to be as effective, if not more effective, than aspirin when used in secondary

prevention of vascular events. This was demonstrated in the CAPRIE trial where 19,185 patients with recent ischemic stroke, recent MI, or symptomatic peripheral arterial disease were randomized to aspirin (325 mg) or clopidogrel (75 mg) and followed for 1 to 3 years. Patients assigned to receive clopidogrel had a statistically significant relative-risk reduction in the composite outcome of ischemic stroke, MI, or vascular death when compared with aspirin.²⁸ There was no significant difference in side effects between the two treatment groups.

The typical daily dose of clopidogrel is 75 mg daily. In circumstances when rapid platelet inhibition is desired such as ACS, a loading dose of clopidogrel at 300 or 600 mg can be given and has demonstrated additional antiplatelet aggregation properties when compared with aspirin alone.^{29,30}

When added to aspirin in patients with UA/NSTEMI, clopidogrel offers additional reduction in vascular events and death, as established in the CURE study.³¹ The study randomized 12,562 patients having an NSTEMI (defined by clinical symptoms plus

Figure 37-3. Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial. Compared with placebo, the addition of clopidogrel to aspirin and other standard therapeutics used to treat patients with acute coronary syndrome resulted in a statistically significant reduction in major adverse cardiovascular events over a 9 months follow up period (upper graph). The differences between the groups were evident within the first 30 days (bottom graph). (Data from Yusuf S, Zhao F, Mehta SR, et al: Effects of clopidogrel in addition to aspirin in patients with acute coronary syndromes without ST-segment elevation. *N Engl J Med* 2001;345:494-502.)

elevated cardiac enzymes or electrocardiographic changes) to receive aspirin plus clopidogrel versus aspirin plus a placebo. The study was designed to examine two primary outcomes: the first was a composite of cardiovascular death, MI, or stroke and the second consisted of the first primary outcome plus refractory ischemia. At 9 months, patients receiving aspirin plus clopidogrel had a statistically significant reduction in the first primary outcome (9.3% versus 11.4%, $p < 0.001$) (Fig. 37-3). Similarly, clopidogrel was associated with a statistically significant reduction in the second primary outcome (16.5% versus 18.8%, $p < 0.001$).³¹

Several observations solidified the role of clopidogrel in management of this patient population. The benefit appeared within 24 hours of presentation and was seen irrespective of the baseline risk stratification.³² Additionally, the continuation of clopidogrel after hospitalization in this group of patients further reduced subsequent ischemic vascular events (cardiovascular death, MI, or stroke). Moreover, the reduction in vascular events was independent of concomitant use of antiplatelet and antithrombotic medication, antihypertensives, lipid lowering

therapy, or coronary intervention.³³ However, a statistically significant increase in bleeding (based on the CURE definition) was seen in patients on dual antiplatelet therapy.³¹

With most patients with NSTEMI or severe UA being referred to coronary angiography and revascularization early in the course of their admission to the CCU, it is important to clearly define the value of clopidogrel therapy in patients undergoing PCI. The PCI CURE substudy tested the hypothesis that treatment with clopidogrel plus aspirin, before PCI would reduce post-procedure ischemic complications. Additionally, this trial evaluated the efficacy of long-term clopidogrel use along with aspirin in further reducing vascular complications after PCI. Patients were pretreated with aspirin and either clopidogrel or placebo for a median of 6 days before PCI. After stenting, more than 80% of patients were started on open label ticlopidine or clopidogrel for 4 weeks, and then resumed taking placebo or clopidogrel for an additional 8 months. In the clopidogrel arm, the primary outcome of death, MI, or urgent target vessel revascularization within 30 days was significantly reduced (4.5% versus 6.4% in the aspirin alone arm, $p = 0.03$). In patients receiving clopidogrel for at least 8 months, there were fewer events of cardiovascular death, MI, or revascularization from any cause ($p = 0.03$).³⁴

A limitation of PCI CURE was that patients were treated with clopidogrel for an average of 6 days before PCI. With the more rapid and early invasive strategies for managing NSTEMI and UA patients in the United States, this pretreatment duration is logistically unrealistic. The CREDO trial assessed the utility of clopidogrel loading less than 24 hours before PCI. In this trial, 2116 patients undergoing elective PCI for symptomatic coronary artery disease were randomized to receive clopidogrel 300 mg loading dose or placebo 3 to 24 hours before PCI. Subsequent to PCI, all patients received clopidogrel for an additional 28 days. From day 29 to 12 months, those individuals in the control group received a placebo while those loaded on clopidogrel received an additional 75 mg/day of clopidogrel for 12 months. At 28 days only a nonsignificant trend toward benefit was found with pretreatment with a loading dose compared with no pretreatment and no loading dose. However, in a post hoc analysis, patients who received the clopidogrel loading dose between 6 to 24 hours before PCI had a nearly significant 38.6% relative risk reduction in the composite of death, MI, or urgent target vessel revascularization ($p = 0.051$).³⁵ Further examination of this data revealed that a statistically significant reduction in death, MI, or urgent target vessel revascularization does not actually occur with the 300 mg loading dose unless it is given at least 15 hours before PCI.³⁶

The 600 mg dose has recently been found to inhibit platelets more rapidly and effectively than the 300 mg dose.³⁷⁻³⁹ Clinically, this may translate into fewer short-term ischemic events after PCI. Recently, Cuisset and colleagues demonstrated that patients who received the 600 mg loading dose of clopidogrel before PCI for an NSTEMI had fewer subsequent ischemic events (defined as cardiovascular death, acute or subacute stent thrombosis, recurrent ACS, and stroke) within 1 month, when compared to those receiving a 300 mg loading dose (5% versus 12%; $P = 0.02$).³⁸ These findings were subsequently confirmed in another trial: the ARMYDA-2. In that study, 255 patients scheduled for PCI were randomized to either a 300 mg or 600 mg loading dose of clopidogrel 4 to 8 hours before the procedure. The primary end point was 30-day death, MI, or target

vessel revascularization. Levels of troponin, CK, and CK-MB were measured at baseline, 8 and 24 hours after the intervention. The primary end point was reached in 4% of patients receiving 600 mg and 12% in patients receiving 300 mg clopidogrel ($p = 0.041$). The benefit of the higher loading dose was due to a reduction in periprocedural MI. There was also a significant reduction in peak values of troponin, CK, and CK-MB ($P = 0.038$).⁴⁰

The AHA/ACC guidelines for management of ACS give clopidogrel a class IA indication in patients who cannot take aspirin. If an early invasive strategy is taken, a preprocedural load and maintenance dose of clopidogrel should be given (IA). If an early noninvasive approach is taken, clopidogrel is recommended for at least 1 month (IA) and for up to 1 year if possible (IB). If no intervention is performed and the patient has recurrent symptoms, heart failure, or rhythm disturbances, clopidogrel load and daily maintenance dose can be added to current therapy (IA).²⁷

Ticlopidine

Ticlopidine is given at 250 mg twice daily with platelet inhibition starting within 24 to 48 hours. Ticlopidine is an effective antiplatelet agent in ACS patients and clearly demonstrated a reduction compared with placebo in nonfatal MI and combined end point of vascular death and nonfatal MI.⁴¹ The reduction in nonfatal MI and death was confirmed in a follow-up substudy in patients with angina at rest and with electrocardiographic changes who received the same dose of ticlopidine for 6 months.⁴²

Ticlopidine is prescribed less frequently than clopidogrel because of side effects, including nausea, vomiting, and diarrhea, but the most serious side effects are hematologic. Neutropenia was reported in 2.4% of patients with severe neutropenia in 0.8%. Even more concerning are the rare reported incidences of thrombotic thrombocytopenia purpura (TTP) associated with ticlopidine use.⁴³

The superior safety profile of clopidogrel over ticlopidine was demonstrated in three comparative studies between ticlopidine and clopidogrel in the post-PCI population. The reduced bleeding complications were achieved with no compromise in efficacy of reducing ischemic complications. In the larger randomized trial, 1020 patients were randomized after coronary stenting to a 28-day regimen of either (1) 300-mg clopidogrel loading dose followed by 75 mg daily; (2) 75 mg daily of clopidogrel; or (3) 250 mg twice daily ticlopidine. All patients received 325 mg of aspirin daily. The primary end point included any of the following: major peripheral or bleeding complications, neutropenia, thrombocytopenia, or early discontinuation of study drug. This occurred in 9.1% of the ticlopidine group compared with 4.6% in the combined clopidogrel group (relative risk 0.50; 95% CI 0.31 to 0.81; $p = 0.005$). Ischemic complications (cardiac death, MI, and target lesion revascularization) were low and comparable between treatment groups (0.9% with ticlopidine, 1.5% with 75 mg/day clopidogrel, 1.2% with the clopidogrel loading dose; $p = \text{NS}$ for all comparisons).⁴⁴

These results were supported in two separate studies. In the first, clopidogrel 75 mg daily or ticlopidine 500 mg daily was initiated just after stent placement in 700 patients. All patients were taking aspirin 100 mg. Therapy was continued for 4 weeks. A primary composite end point of ischemic events within 30 days of stent placement (cardiac death, urgent target vessel revascularization, angiographically documented thrombotic stent occlusion or nonfatal MI) was rare and not significantly different between both groups. Primary noncardiac end points

defined as noncardiac death, stroke, severe peripheral vascular or hemorrhagic events, or any events causing discontinuation of the study drug occurred in 16 patients taking clopidogrel and 33 patients taking ticlopidine ($p = 0.01$).⁴⁵ Further confirmation that clopidogrel was as effective as ticlopidine in patients receiving intracoronary stents occurred when 30-day event rates were measured in 500 patients receiving coronary stents that were treated with aspirin and clopidogrel (300 mg loading then 75 mg/day for 14 days) to 827 patients with coronary stents treated with aspirin and ticlopidine (500 mg loading dose and 250 mg twice daily for 14 days). Mortality was 0.4% in clopidogrel patients versus 1.1% in ticlopidine patients; nonfatal MI occurred in 0% versus 0.5%, stent thrombosis in 0.2% versus 0.7%, bypass surgery or repeat angioplasty in 0.4% versus 0.5%, and any event occurred in 0.8% versus 1.6% of patients, respectively ($p = \text{NS}$).⁴⁶

Prasugrel

The newest of the ADP receptor antagonists, prasugrel has recently been approved by the FDA for use in the US. Phase 3 clinical trials suggest it is a more potent platelet inhibitor that may add a new weapon for the treatment of ACS. The loading dose of prasugrel (60 mg) appears more potent than the commonly used 600 mg of clopidogrel. Similarly, the maintenance dose of prasugrel (10 mg) maintains a higher degree of platelet inhibition than a daily dose of 150 mg of clopidogrel.⁴⁷

The largest clinical investigation to date to examine prasugrel was the TIMI-38 or the TRITON trial.⁴⁸ In that study, 13,608 patients with moderate to high risk ACS scheduled for PCI were randomized to receive prasugrel (a 60-mg loading dose and a 10-mg daily maintenance dose) or clopidogrel (a 300-mg loading dose and a 75-mg daily maintenance dose) for 6 to 15 months. All patients received aspirin in addition to thienopyridine therapy. The primary efficacy end point was a composite of cardiovascular death, nonfatal MI, or nonfatal stroke, whereas the key safety end point was major bleeding. There was a statistically significant 19% reduction in the primary end point in the prasugrel group (9.9% versus 12.1%, hazard ratio for prasugrel versus clopidogrel, 0.81; 95% confidence interval [CI], 0.73 to 0.90; $p < 0.001$). The use of prasugrel was also associated with significant reduction in other ischemic complications, such as MI and urgent target-vessel revascularization. Interestingly, there was a significant reduction in stent thrombosis as well (1.1% versus 2.4%, $p < 0.001$).⁴⁸ However, there was a significant concern about the bleeding complications encountered in the TIMI-38 trial. Among patients receiving prasugrel and aspirin, there was a significant increase in the rate of major bleeding complications compared with those receiving clopidogrel (2.4% versus 1.8%, hazard ratio 1.32; 95% CI, 1.03 to 1.68, $p = 0.03$). Even more concerning, a similar statistically significant increase was noted in fatal bleeding (0.4% versus 0.1%; $p = 0.002$).⁴⁸ These findings represent a dilemma for prescribing physicians seeking a balance between improved efficacy, but without an increase in the risk of serious complications.

Glycoprotein IIb/IIIa Receptor Antagonists

Platelet aggregation depends on the glycoprotein IIb/IIIa receptor located on the surface of platelets. Often called the final common pathway, the IIb/IIIa receptor on the activated platelet undergoes a conformational change that allows binding of fibrinogen and vWF, which in turn cross-links with IIb/IIIa receptors on other activated platelets promoting platelet aggregation.

Figure 37-4. Benefit of glycoprotein IIb/IIIa inhibitors and value of troponin in identifying high-risk acute coronary syndrome. In the c7E3 Fab Antiplatelet Therapy in Unstable Refractory Angina (CAPTURE) trial, high-risk acute coronary syndrome patients received abciximab for 18 to 24 hours before percutaneous coronary intervention and only for 1 hour after the procedure. Major adverse cardiac events at 30 days were significantly reduced in the abciximab arm, primarily owing to a reduction in myocardial infarction. The reduction in events conferred by abciximab therapy was significantly more apparent in patients with troponin elevation on presentation (*red line graph*). Although there was a reduction in events with abciximab in the troponin-negative patients (*blue line graph*), that difference was not statistically significant. Differences between abciximab and placebo were noticed within the first 24 hours (i.e., before percutaneous coronary intervention), indicating that the reduction in ischemic events was driven by the intense platelet inhibition. (Data from *Randomised placebo-controlled trial of abciximab before and during coronary intervention in refractory unstable angina: the CAPTURE Study*. *Lancet* 1997;349:1429-1435.)

The glycoprotein IIb/IIIa receptor antagonists were initially approved as adjunctive pharmacologic agents that reduce the ischemic complications of PCI, particularly in patients at high risk of abrupt closure in the present era. The significant success of these agents in reducing abrupt closure and periprocedural myonecrosis established the importance of aggressive platelet inhibition in reducing ischemic complications. It was only natural that these agents be tested in other clinical situations in which the activated platelets play the fundamental role, namely in acute coronary syndromes. The intravenous IIb/IIIa receptor antagonists available for use in the United States include abciximab, eptifibatide, and tirofiban.

Abciximab

Abciximab was the prototype of all intravenous IIb/IIIa receptor antagonists. It is a chimeric human-murine monoclonal antibody that irreversibly binds to the IIb/IIIa receptor. Abciximab also cross reacts with the $\alpha_v\beta_3$ (vitronectin) receptor.⁴⁹ It has a plasma half-life of approximately 30 minutes and is cleared through the reticulo-endothelial system, but once bound to the platelet it remains nearly irreversibly bound and maintains some IIb/IIIa blockade for up to 10 to 14 days. The dose of abciximab approved for use in conjunction with other antithrombotics in the setting of PCI is a bolus of 0.25 mg/kg 10 to 60 minutes before intervention, and then given as an infusion of 0.125 μ g/kg/min (10 μ g/min maximum) for 12 hours.

Numerous landmark trials have established the value of abciximab as an adjunct to heparin for anticoagulation during PCI. Those trials included both stable and unstable patients.⁵⁰⁻⁵³ In those trials, the benefit of abciximab in reducing major adverse ischemic end points at 30 days (primarily periprocedural MI and urgent revascularization) was achieved with the use of the bolus and a 12-hour infusion regimen. However, in the earlier randomized trial, CAPTURE, abciximab was used in a different regimen, which resulted in some interesting observations.⁵⁴ In

this trial, 1266 patients with high risk ACS (refractory UA and/or NSTEMI) were randomized to a placebo or abciximab given for 18 to 24 hours before intervention and continuing for 1 hour after the procedure. The primary end point (death, MI, or urgent intervention within 30 days of enrollment) was significantly reduced in the abciximab group (11.3% versus 15.9%, $p = 0.012$). The observed difference was mainly because of the reduction in MI (4.1% versus 8.2% in favor of the abciximab group, $p = 0.002$). Interestingly, the benefit of intense antiplatelet therapy was observed within 24 hours, even before revascularization was attempted (Fig. 37-4). Further analysis of the CAPTURE study demonstrated the benefit of intense and early platelet inhibition by abciximab was mostly observed in patients having elevated serum troponin levels (see Fig. 37-3).⁵⁵

In contrast to the aforementioned studies, the GUSTO IV-ACS study evaluated the efficacy of abciximab therapy in patients with chest pain who were troponin positive or had 0.5 mm of ST depression and were not undergoing early revascularization. Somewhat surprisingly, there was no reduction in death or MI at 30 days in patients with ACS receiving abciximab as a bolus plus 24 to 48 hour infusion after presentation. In fact, at 48 hours, a higher rate of mortality was seen in patients receiving abciximab.⁵⁶ This observation (excess mortality with abciximab therapy) remained true after 1 year follow-up in patients having a low troponin or elevated c-reactive protein.⁵⁷ The reason for this excess mortality is unclear. One possibility is that subtherapeutic dosing or insufficient platelet inhibition by IIb/IIIa inhibitors may actually be harmful in patients with higher levels of inflammation.⁵⁸ The antiplatelet effects of abciximab become unpredictable and tend to diminish with time. This was found in a small pharmacodynamic study in 100 patients where platelet function was tested using a rapid platelet function assay (VerifyNow) immediately after an abciximab bolus, 8 hours into a 12-hour abciximab infusion, and 13 to 26 hours after the bolus. After the bolus, abciximab achieved 95% platelet inhibition.

At 8 hours platelet inhibition had decreased to $88 \pm 9\%$ with 13 patients achieving less than 80% inhibition. Between 13 and 26 hours (mean 19), platelet inhibition had dropped to a mean of $71 \pm 14\%$.⁵⁹ This failure to sustain an adequate degree of platelet inhibition may explain the excess mortality in patients receiving 24 to 48 hours of abciximab infusion in the GUSTO IV-ACS study.

In the current era of routine use of thienopyridines and aspirin to treat ACS patients, the question has been raised as to the role of IIb/IIIa antagonists in patients already receiving dual antiplatelet therapy. This question was examined in two clinical trials addressing the role of abciximab with PCI in low- and high-risk patients: ISAR REACT and ISAR REACT II. In ISAR REACT, 2159 patients undergoing elective PCI were randomized to receive abciximab or placebo. All patients received clopidogrel 600 mg 2 hours before the procedure and the composite end point was death, MI, or target vessel revascularization within 30 days. The primary end point was achieved in 4% of patients in both groups, suggesting that abciximab provided no additional benefit in low- to intermediate-risk patients undergoing elective PCI who are pretreated with clopidogrel.⁶⁰ Maximum antiplatelet therapy is desired in patients with ACS undergoing PCI because platelet aggregates can cause microemboli, leading to periprocedural MI and sudden cardiac death. Therefore the benefit of abciximab, when added to clopidogrel, may only be demonstrated in patients having an unstable plaque, as opposed to more stable atherosclerotic disease as seen in the patients studied in ISAR REACT. This hypothesis was tested in the ISAR REACT II trial, which randomized 2022 patients having acute coronary syndromes to receive abciximab or a placebo—after all patients were pretreated with heparin, aspirin, and 600 mg of clopidogrel. Again, the composite end point was death, myocardial infarction, or target vessel revascularization. The target end point was reached in 8.9% of the abciximab group and 11.9% of the placebo group (relative risk 0.75, 95% CI, 0.58 to 0.97; $p = 0.03$). The patients who benefited from abciximab had an elevated troponin, suggesting that abciximab is beneficial only in high-risk patients who already demonstrate evidence of active atherothrombotic disease with distal embolization.

Eptifibatide

Eptifibatide is a cyclic heptapeptide competitive inhibitor of platelet glycoprotein IIb/IIIa. Eptifibatide binding to the IIb/IIIa receptor is reversible and the drug's efficacy is dependent on maintaining a high serum concentration, which allows a steady state of IIb/IIIa receptor blockade. In patients with acute coronary syndrome, eptifibatide is given as a bolus of 180 $\mu\text{g}/\text{kg}$ followed by a continuous infusion of 2 $\mu\text{g}/\text{kg}/\text{min}$. In patients with a creatinine clearance less than 50 mL/minute, the continuous infusion is given as 1 $\mu\text{g}/\text{kg}/\text{min}$. High levels of platelet inhibition occurs within 1 hour, with platelet function normalizing 4 to 8 hours after discontinuation. It is secreted primarily in urine.

The benefit of eptifibatide in patients with acute coronary syndrome was established in the PURSUIT trial. This randomized placebo-controlled trial included 10,948 ACS patients without STEMI. Most patients received aspirin and heparin, and were then randomized to receive a placebo or eptifibatide (intravenous bolus of 180 $\mu\text{g}/\text{kg}$ followed by an infusion at 1.3 or 2.0 $\mu\text{g}/\text{kg}/\text{min}$). The duration of therapy extended to 72 hours (or 96 if intervention occurred later in the hospitalization) or until the

patient left the hospital. The primary end point was a composite of death and nonfatal MI at 30 days. In the eptifibatide group, there was a 1.5% absolute reduction in the incidence of the primary end point (14.2% versus 15.7%, $p = 0.04$), with this effect occurring in most major subgroups.^{43,61} Further investigation of the PURSUIT cohort reveals that eptifibatide reduced the rates of death and MI in patients before and after PCI, in stented and nonstented patients and those who did not undergo PCI, though the reduction in primary events appears greater in patients who had an early PCI.⁶²

Tirofiban

Tirofiban is a small, nonpeptide mimetic of the RGD (Arg-Gly-Asp) sequence of fibrinogen and is another reversible antagonist of the platelet glycoprotein IIb/IIIa receptor. Tirofiban is cleared renally and platelet function returns to normal 4 to 8 hours after discontinuation. In acute coronary syndrome patients, the initial infusion rate is 0.4 $\mu\text{g}/\text{kg}/\text{min}$ for 30 minutes and then continued at 0.1 $\mu\text{g}/\text{kg}/\text{min}$ for 12 to 24 hours after angioplasty.

The RESTORE trial was one of the first randomized, double-blind, placebo-controlled trials examining the role of tirofiban in 2139 patients undergoing PCI within 72 hours of presentation with ACS. Patients were randomized to receive tirofiban or placebo, while both groups were treated with heparin and aspirin. Tirofiban was administered as a bolus of 10 $\mu\text{g}/\text{kg}$ over 30 minutes followed by a 36-hour infusion of 0.15 $\mu\text{g}/\text{kg}/\text{min}$. At 30 days, the primary composite end point (all-cause death, MI, actual or threatened abrupt closure of the target vessel, and surgical or percutaneous revascularization for recurrent ischemia) was reduced from 12.2% in the placebo group to 10.3% in the tirofiban group (16% relative risk reduction, $p = 0.16$). There was a significant relative risk reduction in ischemic events at the 2- and 7-day mark after PCI (38% and 27%, $p = 0.005$ and $p = 0.02$, respectively) because of a reduction in nonfatal MI and the need for repeat angioplasty. However, based on the fact that the study did not meet the 30-day primary end point, tirofiban was not approved for use as an adjunctive agent for PCI.

The role of tirofiban in management of ACS was established in two subsequent studies: a comparison of aspirin plus tirofiban with aspirin plus heparin for unstable angina (PRISM) and inhibition of the platelet glycoprotein IIb/IIIa receptor with tirofiban in unstable angina and non-Q-wave myocardial infarction (PRISM-Plus).^{63,64} In PRISM, 3232 patients with UA or NSTEMI already receiving aspirin received either heparin or tirofiban for 48 hours. In PRISM-Plus, 1915 patients with UA or NSTEMI were randomized to receive tirofiban, heparin, or tirofiban plus heparin for a mean of 71.3 ± 20 hours. The primary composite end point in both studies included death, MI, or refractory ischemia. In PRISM, patients were randomized to either tirofiban alone or heparin alone with patients assigned to tirofiban receiving a loading dose of 0.6 $\mu\text{g}/\text{kg}/\text{min}$ for 30 minutes, followed by 0.15 $\mu\text{g}/\text{kg}/\text{min}$ for 47.5 hours. Angiography and revascularization were typically performed after 48 hours in both studies. In PRISM, the composite end point was 32% lower with tirofiban at 48 hours (3.8% versus 5.6% with heparin; risk ratio 0.67; $p = 0.01$). However, at 30 days the composite end point was the similar in both groups (15.9% in the tirofiban group versus 17.1% in the heparin group, $P = 0.34$). In PRISM-Plus, the frequency of the composite end point at 7 days was lower among patients receiving tirofiban plus heparin than those receiving heparin alone (12.9% versus 17.9%; risk ratio 0.68; $p = 0.004$). The

significantly improved outcomes in the tirofiban plus heparin arm were preserved at 30 days (18.5% versus 22.3%, $p = 0.03$) and at 6 months (27.7% versus 32.1%, $p = 0.02$). Importantly, the third arm of randomization in the study (those receiving tirofiban without heparin) was stopped prematurely because of an excess mortality at 7 days (4.6% compared with 1.1% for patients treated with heparin alone).

Although effective as a class, data suggests that clinical outcomes from the glycoprotein IIb/IIIa receptor blockade may differ between drugs. This was demonstrated in the comparison of two glycoprotein IIb/IIIa inhibitors, tirofiban and abciximab, for the prevention of ischemic events with PCI (TARGET) study.⁶⁵ In TARGET patients received either tirofiban or abciximab before undergoing PCI with stenting. The end point was a composite of death, nonfatal MI, or urgent target vessel revascularization at 30 days. The primary end point occurred more frequently in the tirofiban group than the abciximab group (7.6% versus 6.0%; $p = 0.04$). Each component of the composite end point had similar results (hazard ratio for death, 1.21; hazard ratio for MI, 1.27; and hazard ratio for urgent target vessel revascularization, 1.26), and the difference in the incidence of MI between the tirofiban group and the abciximab group was significant (6.9% versus 5.4%, $p = 0.04$).

The ACC/AHA guidelines for management of patients with UA or NSTEMI who are allocated to an early invasive strategy endorse the use of glycoprotein IIb/IIIa inhibitors, which can be given in addition to aspirin before diagnostic angiography (IA). However, abciximab should be used only if there will be no appreciable delay in angiography and PCI will likely be performed. Otherwise, eptifibatide or tirofiban should be used. If an initial conservative approach is chosen and the patient develops chest pain, heart failure, or arrhythmias, then tirofiban or eptifibatide should be used in addition to aspirin before angiography (IA). Furthermore, if patients are already receiving aspirin, clopidogrel, and an anticoagulant and have a return of ischemic discomfort, it is reasonable to add a glycoprotein IIb/IIIa antagonist before angiography (IIa). For patients undergoing an early invasive strategy, patients can be started on both clopidogrel and glycoprotein IIb/IIIa inhibitors before angiography (IIa). Again, abciximab should be used only if there is no appreciable delay in angiography and PCI is likely to be performed. Additionally, if there is an early conservative approach, it is reasonable to add tirofiban or eptifibatide to oral antiplatelet therapy (IIb).⁷⁷

Antiplatelets in ST Segment Elevation Myocardial Infarction

The paramount importance of early reperfusion in acute ST segment elevation MI as the primary goal of therapy has been well established.⁶⁶ The preferred mechanism by which such reperfusion is achieved has shifted over the years from thrombolytic therapy to primary angioplasty.^{1,67} In either case, patients having acute STEMI usually arrive at the coronary care unit with therapy already administered, either in the emergency room or in the catheterization laboratory.

Although the purpose of antiplatelet therapy in and of itself is not to achieve initial reperfusion in patients with STEMI, there is ample evidence that various antiplatelet agents can play a significant role as adjunctive therapies to improve outcome of the reperfusion therapy.

Although effective in dissolving arterial thrombi, fibrinolytic agents can activate thrombin and promote platelet aggregation, potentially leading to rethrombosis. This procoagulant activity has been demonstrated in several studies. Fibrinopeptide A levels, when used as a measure of thrombin activity, significantly increased after the infusion of both streptokinase and tissue plasminogen activator (tPA) in patients having acute STEMI.⁶⁸ The increased thrombin is thought to be due to upstream activation of coagulation factors because prothrombin levels are also elevated in patients receiving tPA.⁶⁹ More direct evidence of platelet activation with thrombolysis is demonstrated by assessing thromboxane biosynthesis in patients receiving streptokinase after having a STEMI. Major enzymatic metabolites of thromboxane A₂, urinary 2, 3-dinor-thromboxane B₂ and plasma 11-dehydro-thromboxane B₂, were markedly increased in patients that received intravenous streptokinase when compared with patients not receiving thrombolytic therapy. Platelets are the main source of thromboxane A₂, suggesting marked platelet activation after the infusion.⁷⁰ Thus the addition of effective antiplatelet therapy may not lead to patency, but can have a role in preserving the patency of the infarct-related artery that is prone to platelet activation and reocclusion.

Similarly, there is ample evidence for the benefits of antiplatelet agents in the context of PCI. The benefits of adjunctive antiplatelets have been seen in the form of improved flow, reduced embolization, reduced infarct size, and/or improve clinical outcomes.

Aspirin

The benefit of aspirin in the treatment of STEMI was clearly demonstrated in the ISIS-2 trial, in which more than 17,000 patients were randomized to receive an intravenous infusion of streptokinase, 1 month of 160 mg aspirin, both, or neither within 24 hours of a suspected acute MI. Vascular death was significantly reduced in patients receiving aspirin compared with a placebo (9.4% versus 11.8%, $2p < 0.0001$). The reduction in mortality in those receiving aspirin was very similar to patients receiving streptokinase compared with a placebo infusion (9.2% versus 12%, $2p < 0.0001$) (see Fig. 37-5). However, the greatest reduction in mortality occurred when aspirin and streptokinase were used in combination.⁷¹

Aspirin therapy is also proven to prevent reocclusion and recurrent ischemia after thrombolysis. In a meta-analysis of 32 studies that included angiographic assessment after receiving thrombolytic therapy (heparin plus streptokinase or heparin plus recombinant tissue type of plasminogen activator), patients receiving aspirin had a significantly lower rate of reocclusion compared with those who did not receive it (11% versus 25% $p < 0.001$).⁷²

A large meta-analysis of 287 studies including 135,000 patients (approximately 10% with acute STEMI), found antiplatelet therapy (mainly aspirin) resulted in a significant protective value in patients with acute STEMI. After a loading dose of 150 mg during the acute phase, lower doses of 75 to 150 mg daily were found to be effective maintenance therapy. The absolute risk reduction of having a major vascular event (MI, stroke, or vascular death) among patients with acute MI was 38 per 1000 patients treated (or 10.4% in the aspirin-treated group versus 14.2% in the control group; $p < 0.0001$). The absolute risk reduction in patients on antiplatelet therapy (mostly aspirin) compared with the control groups was 13 events per 1000 patients.⁷³

Figure 37-5. In the Second International Study of Infarct Survival (ISIS-2) trial, patients with suspected acute myocardial infarction were randomly assigned in a 2×2 factorial design to receive aspirin versus placebo and streptokinase (SK) versus placebo. A 23% relative reduction in mortality was achieved with aspirin therapy alone, which was almost identical to that achieved with thrombolytic therapy. Patients randomly assigned to aspirin and SK (data not shown) had the best outcomes in this trial. (Data from *Randomised trial of intravenous streptokinase, oral aspirin, both, or neither among 17,187 cases of suspected acute myocardial infarction: ISIS-2. ISIS-2 (Second International Study of Infarct Survival) Collaborative Group. Lancet 1988;2:349-360.*)

Given the significant mortality benefit demonstrated with aspirin administration, all patients having an STEMI should receive 162 to 325 mg of aspirin, preferably nonenteric coated and in chewable form for faster onset of action. Subsequently, they should continue taking a daily aspirin indefinitely. These recommendations are designated as class IA recommendations by the ACC/AHA guidelines for treatment of STEMI.¹

ADP Receptor Antagonists

Ticlopidine and clopidogrel are considered reasonable alternatives to aspirin in the minority of patients with STEMI who are unable to tolerate aspirin.¹ More importantly, these agents offer additional benefits when used in addition to aspirin in STEMI patients. The benefits of these thienopyridines can be seen in the early phase as adjuvants to the reperfusion strategy (primary angioplasty or thrombolytic therapy) and also as long-term maintenance therapy for more effective prevention of recurrent infarction and other ischemic vascular events.

Two trials have evaluated the role of clopidogrel in addition to aspirin compared with aspirin alone in medically treated STEMI patients: CLARITY-TIMI 28 and COMMIT trials. In CLARITY-TIMI 28, 3491 patients under 75 years of age, with a recent (12 hours) STEMI received a loading dose of clopidogrel (300 mg), then 75 mg daily or a matching placebo after receiving fibrinolytic therapy. All patients received aspirin, and heparin was given when for fibrin-specific thrombolytic agents were used. The composite end point included an occluded infarct-related artery on angiography, death, or recurrent MI before angiography. At the time of angiography, there was a 41% reduction in the incidence of an occluded infarct-related artery in the clopidogrel-treated patients (11.7% versus 18.4% in the aspirin only group, $p < 0.001$). Addition of clopidogrel also resulted in a 30% reduction in recurrent MI (from 3.6% to 2.5%; $p = 0.08$). Similar trends were seen at 30 days.⁷⁴

The COMMIT study included greater than 45,000 patients with an acute MI (87% with ST segment elevation and 6% with

left bundle branch block) not undergoing PCI, who received clopidogrel (75 mg) daily ($n = 22,961$) or a placebo ($n = 22,891$) in addition to aspirin (162 mg) daily until discharge or for up to 28 days (mean therapy of 14.9 days). No loading dose of clopidogrel was given and approximately half of the patients received fibrinolytic therapy before or shortly after enrollment. The primary end point of death alone was significantly reduced in all patients receiving clopidogrel compared with the placebo (1726 events in the clopidogrel group versus 1845 in the placebo group, corresponding to a significant 7% proportional reduction) (Fig. 37-6). Those receiving clopidogrel also had a significant 14% proportional reduction in the risk of reinfarction. There was a nonsignificant 14% proportional reduction in the risk of stroke. Furthermore, when specifically examining those receiving fibrinolytic therapy, there was a significant 11% proportional reduction in events in the fibrinolytic group that received clopidogrel compared with those receiving a placebo.⁷⁵

The combination of clopidogrel and aspirin has been prescribed by clinicians for STEMI patients undergoing primary and rescue PCI for several years. Initially, the rationale was based on extrapolation of the data from the NSTEMI trials demonstrating a reduction in the composite of death, MI, and target vessel revascularization.^{31,35} In addition, the widespread use of stents eventually leads to the near-immediate beginning of dual antiplatelet therapy in those patients. More recently, direct evidence of benefit of clopidogrel in the treatment of STEMI patients emerged from two clinical trials: the PCI-CLARITY trial and the TRITON or TIMI-38 trial.^{48,76}

In PCI-CLARITY, 863 patients undergoing PCI received aspirin and either a clopidogrel 300-mg loading dose, then 75 mg once daily or a placebo initiated with fibrinolysis and given until coronary angiography was performed (2 to 8 days after initiation of the study drug). Open-label clopidogrel with the 300-mg loading dose was recommended for those undergoing coronary stenting. The primary end point was the composite of cardiovascular death, recurrent MI, or stroke from PCI to

Figure 37-6. The Clopidogrel and Metoprolol in Myocardial Infarction (COMMIT) trial showed that addition of clopidogrel to standard, mostly noninterventional therapy for acute ST segment elevation myocardial infarction results in a significant reduction in the primary end point, all-cause mortality before hospital discharge (*right graph*), and in the composite end point of proportional death, reinfarction, and stroke during the same time period (*left graph*). (Data from Chen ZM, Jiang LX, Chen YP, et al: Addition of clopidogrel to aspirin in 45,852 patients with acute myocardial infarction: randomised placebo-controlled trial. *Lancet* 2005;366:1607-1621.)

30 days after randomization. Secondary outcomes included MI or stroke before PCI and the aforementioned composite from randomization to 30 days. Pretreatment with clopidogrel significantly reduced the incidence of cardiovascular death, MI, or stroke following PCI (3.6% versus 6.2%; $p = 0.008$). Pretreatment with clopidogrel also reduced the incidence of MI or stroke before PCI (4.0% versus 6.2%; $p = 0.03$), and there was a highly significant reduction in cardiovascular death, MI, or stroke from randomization through 30 days (7.5% versus 12.0%; $p = 0.001$).

In TRITON, patients having STEMI were not excluded and eventually represented 3534 of 13,608 patients included in the study. Patients scheduled for PCI received prasugrel (a 60-mg loading dose and a 10-mg daily maintenance dose) or clopidogrel (a 300-mg loading dose and a 75-mg daily maintenance dose) for 6 to 15 months. As previously discussed, the study as a whole achieved its primary efficacy end point: a statistically significant reduction in the composite of cardiovascular death, nonfatal MI, or stroke. In the STEMI subgroup, the results were similar with a significant reduction in the primary end point in the prasugrel arm (hazard ratio 0.79; 95% CI, 0.65 to 0.97; $p = 0.02$).

When used as the only antiplatelet agent, ADP receptor antagonists have demonstrated reduction in future vascular events in patients after myocardial infarction. A cumulative review of three studies compared the rate of vascular events (nonfatal MI, nonfatal stroke, and vascular death) in patients receiving at least 1 month of aspirin or ticlopidine, and demonstrated an odds reduction of 10% favoring ticlopidine.⁷⁷

The benefit of ticlopidine in secondary prevention after acute MI was also demonstrated in the STAMI trial, which compared ticlopidine 500 mg/day to aspirin 160 mg/day in 1470 patients after thrombolytic therapy for acute MI. The primary end points

evaluated in STAMI were the first occurrence of fatal and nonfatal MI, fatal and nonfatal stroke, angina with evidence of myocardial ischemia, vascular death, and all cause death within 6 months. There was no significant difference in the number of primary end points between the two groups, and patients taking ticlopidine had fewer nonfatal MI (2.4% versus 1.1%; $p = 0.049$).⁷⁸ Because of safety concerns associated with ticlopidine, clopidogrel is a more attractive option.

Early and sustained use of thienopyridine inhibitors can also have a major role in secondary prevention (i.e., reducing death, reinfarction, and other ischemic vascular events). The CAPRIE trial compared aspirin to clopidogrel in more than 19,000 patients with atherosclerotic vascular disease, including nearly 6,000 patients with recent myocardial infarction (35 days before randomization). After a mean follow-up of 1.9 years, there was no significant difference in stroke, MI, or other vascular death between patients treated with aspirin and those receiving clopidogrel. When other subgroups including patients with recent stroke and peripheral arterial disease were included in the evaluation, patients treated with clopidogrel had a statistically significant greater than 8% relative risk reduction in annual risk of ischemic stroke, MI, or vascular death compared with aspirin.²⁸

Patients with prior MI, ischemic stroke, or peripheral vascular disease were found to have further reduction in recurrent events when clopidogrel was administered in addition (not as a substitute) to aspirin. This was recently demonstrated in a subgroup of 9478 patients from the CHARISMA trial. With a median follow-up of 27.6 months, the rate of cardiovascular death, MI, or stroke was significantly lower when clopidogrel was added to aspirin compared with a placebo plus aspirin: 7.3% versus 8.8% (hazard ratio 0.83, 95% CI 0.72 to 0.96, $p = 0.01$). Hospitalizations for ischemia were also significantly decreased,

11.4% versus 13.2% (hazard ratio 0.86, 95% CI 0.76 to 0.96, $p = 0.008$).⁷⁹

Thienopyridines, specifically clopidogrel, currently has both Class I and Class II recommendations based on the ACC/AHA 2004 guidelines for treatment of STEMI and the 2007 update. A thienopyridine, preferably clopidogrel, should be taken in all patients who cannot take aspirin (Class I). Clopidogrel should be continued for at least 1 month after bare metal stent implantation, several months after drug-eluting stent implantation, and for at least 12 months in patients who are not at high risk for bleeding (Class I). Clopidogrel 75 mg should be added to aspirin therapy in patients with an STEMI regardless of whether they undergo reperfusion therapy with thrombolytics or receive no reperfusion therapy (Class IB). If CABG is planned, clopidogrel should be withheld for at least 5 days (Class IB). In patients less than 75 years of age who receive fibrinolytic therapy or who do not receive reperfusion therapy, it is reasonable to administer an oral loading dose of clopidogrel—300 mg (Class IIA). Long-term maintenance therapy (e.g., 1 year) of clopidogrel, 75 mg daily, is reasonable in STEMI patients regardless of whether they undergo reperfusion therapy with fibrinolytic therapy or do not receive reperfusion therapy.^{1,80}

Glycoprotein IIb/IIIa Inhibitors

Glycoprotein IIb/IIIa inhibitors can be used as adjunctive agents for the primary reperfusion therapy selected to manage an acute STEMI; be that thrombolysis or primary PCI. Most clinical investigations assessing the benefit of IIb/IIIa inhibitors in these situations examined the prototype agent abciximab, with few studies using eptifibatide and tirofiban.

IIb/IIIa Inhibitors and Thrombolytic Therapy

A significant body of literature addresses the role of glycoprotein IIb/IIIa inhibitors when used as adjuvants to thrombolytic therapy. One of the earliest studies was the TIMI 14 trial whereby 888 patients with an STEMI presenting less than 12 hours from symptom onset were treated with full dose (100 mg) of accelerated-dose alteplase (control), full dose abciximab (bolus plus infusion), abciximab in combination with reduced dose alteplase (20 to 65 mg), or abciximab in combination with reduced dose streptokinase (500,000 U to 1.5 MU). The most impressive TIMI 3 flow results were observed in the abciximab plus reduced-dose (50 mg) alteplase: 77% versus 62%; for the full-dose alteplase control group, $p = 0.02$.⁸¹

The initially encouraging results led a series of trials investigating the use of abciximab in conjunction with fibrinolytic therapy: SPEED, ENTIRE-TIMI 23, ASSENT-3, and GUSTO V trials.⁸²⁻⁸⁵ In the ENTIRE-TIMI 23 trial, 483 STEMI patients received full-dose tenecteplase or half-dose tenecteplase plus abciximab. A second randomization to unfractionated heparin or enoxaparin was performed, although doses of both heparin and enoxaparin were lower in the abciximab arm. Compared with those receiving full-dose tenecteplase, patients receiving tenecteplase-abciximab combination therapy had comparable TIMI 3 flow rates at 60 minutes and more complete ST segment resolution at 180 minutes regardless of the type of heparin used. Furthermore, there was a reduction in the rate of recurrent MI, but there were more episodes of increased bleeding. More importantly, the 30-day results demonstrated a significant reduction in combined death and MI in patients receiving full-dose tenecteplase and enoxaparin compared with

unfractionated heparin, and that became the most significant finding of the trial.⁸³

In the ASSENT-3 trial, 6095 patients with an acute STEMI were randomized to one of three regimens: full-dose tenecteplase + enoxaparin for 7 days, full-dose tenecteplase + unfractionated heparin for 48 hours, or half-dose tenecteplase + unfractionated heparin + 12-hour infusion of abciximab. The end points were 30-day mortality, in-hospital reinfarction, or in-hospital refractory ischemia. Safety end points included intracranial hemorrhage or in-hospital major bleeding. There was a significant reduction in the primary end point with enoxaparin and abciximab therapy when compared with conventional full-dose tenecteplase + heparin (11.4% with enoxaparin, 11.1% with abciximab, and 15.4% with full-dose tenecteplase, $p = 0.0002$). The benefits of enoxaparin and abciximab were primarily driven by the reduction in reinfarctions and in refractory ischemia. There was a higher rate of bleeding complications in the abciximab group and a nonsignificant increase in major bleeding complications in the enoxaparin group. There was no statistically significant reduction mortality at the 30-day and the 1-year time points.^{78,84}

The largest trial assessing the efficacy of abciximab with fibrinolytic therapy was the GUSTO V trial, in which 16,588 patients having STEMI within 6 hours were randomized to standard-dose reteplase or half-dose reteplase plus full-dose abciximab. The primary end point was 30-day mortality. The secondary end point was development of MI complications including, but not limited to, reinfarction and recurrent ischemia. At 30 days, there was no difference between the groups in the primary end point (5.9% in the reteplase group versus 5.6% in the combined reteplase and abciximab group, $p = 0.43$). However, there was a significant reduction in the number of MI complications in the group receiving combination therapy ($p < 0.0001$). The reduction in secondary end point with the combined therapy was associated with an increase in nonintracranial bleeding episodes.⁸⁵ The lack of any survival benefit with the combination therapy was also noted at 1 year.⁸⁶

A meta-analysis of the aforementioned studies (ASSENT III, ENTIRE-TIMI 23, and GUSTO V) concluded that the combination of abciximab and thrombolytic therapy had no significant reduction on short-term (30 day) or long-term (6 to 12 month) mortality. Combination therapy did cause a significant reduction in 30-day reinfarction rates. Additionally, the incidence of intracranial bleeding was not different in patients receiving abciximab and thrombolytics, but there was an increased risk of major bleeding complications with combination therapy.⁸⁷

Eptifibatide has also been studied in combination therapy with thrombolytics in patients with an acute STEMI. The INTRO AMI trial evaluated the benefit of adding eptifibatide to tPA versus tPA alone in patients with an STEMI. Similar to the abciximab trials, the incidence of death at 30 days was similar among patients receiving tPA and different regimens of an eptifibatide/tPA combination.⁸⁸

Facilitated PCI (the use of glycoprotein IIb/IIIa inhibitors with or without reduced-dose fibrinolytic therapy followed by PCI) was recently addressed in the 2007 ACC/AHA document on guidelines for management of STEMI and was given a class IIB recommendation. Per these guidelines, facilitated PCI using regimens other than full-dose fibrinolytic therapy might be considered as a reperfusion strategy when all of the following conditions are present: (1) patients are considered at high

risk, (2) PCI is not immediately available within 90 minutes, and (3) bleeding risk is low (young age, absence of poorly controlled hypertension, normal body weight). However, full-dose fibrinolytic therapy followed by planned PCI may be harmful and has a class III indication.⁸⁰

IIB/IIIA Inhibitors and Primary PCI

The use of glycoprotein IIB/IIIA inhibitors in patients undergoing nonemergent PCI has been well studied in numerous randomized trials.^{51,52,54,89} Several lessons were learned from those trials that were used in the subsequent use of those agents during primary PCI. With increasing baseline risk, the advantage of these agents in reducing ischemic complications becomes more robust.^{54,60,90} Other important lessons that came from earlier IIB/IIIA inhibitor trials include modifications in practice that have been shown to reduce bleeding complications, such as weight adjustment of the heparin dose and early removal of femoral access sheaths.

Abciximab is the most well-studied glycoprotein IIB/IIIA inhibitor used in patients receiving primary PCI. The RAPPORT trial was one of the first trials evaluating the potential benefit of abciximab in patients with an STEMI undergoing PCI, in which patients were randomized to receive abciximab ($n = 241$) or a placebo ($n = 242$). There was no difference in the primary efficacy end point of death, reinfarction, or any target vessel revascularization at 6 months. However, abciximab significantly reduced the prespecified end points of death, reinfarction, or urgent target vessel revascularization at 7 days (9.9% versus 3.3%, $p = 0.003$), 30 days (11.2% versus 5.8%, $p = 0.03$), and 6 months (17.8% versus 11.6%, $p = 0.05$). In patients receiving abciximab, at 7 days there was a significant reduction in death or reinfarction: 4.7% versus 1.4%, $p = 0.047$. Additionally, the need for unplanned urgent stenting was reduced by 42% in the abciximab group (20.4% versus 11.9%, $p = 0.008$).⁹¹

The ISAR-2, ADMIRAL, and ACE trials were subsequent trials similar in design and end results.⁹²⁻⁹⁴ In these trials, patients undergoing primary PCI with stenting were randomized to abciximab or placebo. The composite clinical end point was death, reinfarction, and target lesion revascularization, with stroke being included in the ACE trial. In all trials, there was a significant reduction in 30-day ischemic events in patients receiving abciximab after PCI. This benefit was demonstrated up to 6 months in some trials, but none of these trials was individually powered to detect a mortality benefit. In ISAR-2 the composite end point was reached in 5.0% of the abciximab group and 10.5% of the control group ($p = 0.038$). There was no statistically significant difference in the composite end point at 1 year.⁹² In ADMIRAL, the composite end point was reached in 6.0% of the patients in the abciximab group versus 14.6% in the placebo group ($p = 0.01$). At 6 months, the corresponding figures were 7.4% and 15.9% ($p = 0.02$).⁹³ The reduction in the primary end point caused by abciximab use was similar in the ACE trial (4.5% and 10.5%, respectively; $p = 0.023$). Additionally, the composite of 6-month death and reinfarction was lower in the abciximab group than in the placebo group (5.5% and 13.5%, respectively; $p = 0.006$).⁹⁴

The CADILLAC trial was the largest clinical investigation evaluating the role of abciximab in patients undergoing primary PCI.⁹⁵ This trial randomized 2082 patients in a 2-by-2 factorial design whereby patients were allocated to PTCA alone (518 patients), PTCA plus abciximab therapy (528), stenting alone

(512), or stenting plus abciximab therapy (524). The primary end point was death, reinfarction, disabling stroke, and ischemia-driven target vessel revascularization. At 6 months the primary end point was achieved in 20.0% of patients after PTCA, 16.5% after PTCA plus abciximab, 11.5% after stenting, and 10.2% after stenting plus abciximab ($p < 0.001$). The benefit observed with abciximab in CADILLAC was due entirely to differences in the rates of urgent target-vessel revascularization. There were no significant differences in the rates of death, stroke, or reinfarction.⁹⁵ The lack of benefit of abciximab in reducing ischemic events in CADILLAC may have been driven by the relatively low risk of the patient population in this particular study, which was evidenced by the very low mortality (approximately 2%) and reinfarction (approximately 0.8%), irrespective of therapy.

Despite the lack of a 30-day mortality benefit in any of these individual trials, the meta-analysis of De Luca and colleagues that included randomized comparisons of abciximab versus a placebo in both primary and facilitated PCI, demonstrated a statistically significant reduction in 30-day (2.4% versus 3.4%, $p = 0.047$) and 6-month (4.4% versus 6.2%, $p = 0.01$) mortality with abciximab use.⁸⁷ The benefit of abciximab was offset by a significant increase in the risk of bleeding when abciximab therapy was combined with fibrinolysis. However, the risk of bleeding was not increased when abciximab was used with primary PCI (i.e., when no thrombolytic therapy was administered). This led to a statistically significant reduction in adverse ischemic events that was not offset by the bleeding complications (Fig. 37-7). More recently, a large prospective randomized controlled clinical trial (FINESSE) was designed to further define and establish the benefit of abciximab in acute management of STEMI patients.⁹⁶ In that trial, 2452 patients were randomized to one of three treatment arms: primary PCI with abciximab administered in the catheterization laboratory facilitated PCI with abciximab administered before arrival in the catheterization laboratory, and facilitated PCI with abciximab and half-dose reteplase administered before arrival in the catheterization laboratory. The primary end point of the trial was a composite of all-cause mortality, readmission for heart failure, ventricular fibrillation, or cardiogenic shock. At 90 days, there was no difference in efficacy between the treatment arms: the primary end point was met in 10.7%, 10.5%, and 9.8%, respectively ($p = \text{NS}$). There were no differences in rates of death or any of the individual components of the primary end point. The rate of TIMI major bleeding was highest in the facilitated PCI group (4.8%), which was significantly higher than the 2.6% in those receiving primary PCI with abciximab in the catheterization laboratory ($p = 0.025$). There was also a strong trend toward increased intracranial hemorrhage through discharge or day 7 of treatment. Although the full report of the trial results is still not published, it does appear that it provides more evidence against the use of the combination of IIB/IIIA inhibitors and thrombolytic agents. It also raises questions about the importance of early administration of abciximab and seems to suggest that there is no clear clinical benefit from early compared to catheterization laboratory administration of abciximab for primary PCI.

There is significantly less data on the benefit of small molecule IIB/IIIA inhibitors in primary PCI. Many laboratories have been using eptifibatide as a cheaper substitute for abciximab in the context of primary PCI, although the data supporting that approach have been very scarce and not well controlled.^{97,98} More recently, two publications lent some credence to this

Figure 37-7. In a meta-analysis of 11 randomized trials comparing abciximab with placebo as an adjunct to mechanical or pharmacologic reperfusion of ST segment elevation myocardial infarction, abciximab was associated with a significant reduction in short-term (30 days) mortality (*left plot*) and long-term (6 to 12 months) mortality (*right plot*) in patients undergoing primary PCI, but not in patients treated with fibrinolysis or in all trials combined. (Data from De Luca G, Suryapranata H, Stone GW, et al: *Abciximab as adjunctive therapy to reperfusion in acute ST-segment elevation myocardial infarction: a meta-analysis of randomized trials*. *JAMA* 2005;293:1759-1765.)

approach by demonstrating noninferior outcomes with eptifibatide compared with abciximab. In a retrospective analysis of hospital outcomes from a statewide database of primary PCI over 4 years, 3541 patients who underwent primary PCI for STEMI were treated with abciximab ($n = 729$) or with eptifibatide ($n = 2,812$). There was no difference in the incidence of hospital death (4.1% versus 3.5%, $p = 0.39$), recurrent MI (0.8% versus 1.2%, $p = 0.42$), or stroke (0.7% versus 0.6%, $p = 0.80$). As for safety measures, there was no difference in the need for blood transfusion (12.4% versus 11.7%, $p = 0.61$), but the incidence of gastrointestinal bleeding was significantly higher with abciximab (4.8% versus 2.8%, $p = 0.01$). Even with parsimonious risk-adjusted models, no significant difference between abciximab and eptifibatide in efficacy and safety measures could be identified.⁹⁹ In a more recent smaller but prospective and randomized trial, 400 STEMI patients were randomized to a double bolus plus 24-hour infusion of eptifibatide or a single bolus plus 12-hour infusion of abciximab. All patients received aspirin, clopidogrel, and heparin or enoxaparin. Because of the small number of randomized patients, the primary end point was the surrogate of ST resolution 1 hour post-PCI. Using this end point, the eptifibatide strategy was noninferior compared with abciximab. In addition, in-hospital events, including death, reinfarction, heart failure, and target vessel revascularization were similar between the two groups. Major and minor bleeding rates were not different between the two strategies, although the 24-hour infusion of eptifibatide may have contributed to an increased bleeding risk in the eptifibatide strategy.¹⁰⁰

Some evidence of benefit of tirofiban in primary PCI was also demonstrated in a small study of 100 patients, in whom large

bolus-dose tirofiban was compared with abciximab. Because of the small size, the study used the surrogate primary end point of change in the infarct-zone wall motion between the initial and 30-day follow-up echocardiograms. Secondary end points included before and after TIMI grade flow, TIMI grade myocardial perfusion, and corrected TIMI frame count. In all primary and secondary end points, there was no statistically significant differences between the abciximab and tirofiban patients.¹⁰¹ More recently, a prospective randomized trial was conducted to evaluate the potential of high dose tirofiban as an adjunct to primary PCI. The MULTISTRATEGY trial was a multicenter, open-label, 2×2 factorial trial of 745 patients having STEMI or new left bundle branch block who were then randomized in a 2×2 factorial design to high-dose bolus tirofiban versus abciximab and a sirolimus-eluting stent versus a bare metal stent implantation. For drug comparison, the primary end point was a 50% ST segment elevation resolution at 90 minutes post-PCI, with a prespecified noninferiority margin of 9% difference (relative risk, 0.89). The results demonstrated an ST segment resolution of 83.6% of patients in the abciximab group versus 85.3% in the high-dose tirofiban group (relative risk 1.02; 97.5% CI, 0.96 to 1.09; $p < 0.001$ for noninferiority). Ischemic and hemorrhagic outcomes were similar in the tirofiban and abciximab groups,¹⁰² although the small size of the study does not definitively rule out a possibility of increased risk of bleeding with high-dose tirofiban.

Despite the aforementioned studies suggesting that all currently used IIB/IIIa inhibitors have comparable benefits when used in primary PCI for STEMI, abciximab has the most evidence supporting its use. Adequately powered comparative trials

would be prohibitively large and expensive to conduct. It is likely that these small prospective trials and retrospective reports from large databases maybe the only data to guide clinicians in this area.¹⁰³ Per the ACC/AHA 2004 guidelines, abciximab should be given as early as possible before primary PCI (Class IIa). Eptifibatide and tirofiban can also be considered before PCI as an alternative to abciximab, but these agents receive a Class IIb indication because of the paucity of data.¹

Antiplatelet Therapy and Bleeding Complications

With dramatic progress in reducing mortality and ischemic complications in patients with acute coronary syndromes, more attention is focused on the increased risk of complications of modern therapy. Potent antiplatelet therapies are by default associated with a risk of bleeding. It is the balance between the reduction in ischemic complications and the incidence and severity of bleeding complications that determines the value and clinical utility of a specific antiplatelet agent. This becomes more of an issue when antiplatelet therapy is used in addition to other antithrombotics and/or fibrinolytic agents. In the CCU, acute coronary syndrome patients in whom one or more of all these agents are used, symptoms and signs of bleeding should be monitored diligently.

The literature on bleeding complications related to antiplatelets, antithrombotics, and/or interventional procedures is quite extensive. However, it is plagued by the lack of uniform methodology in assessing and reporting bleeding complications, which makes it difficult to compare efficacy and safety of each of the agents and/or procedures.

Aspirin

It has been well established that aspirin increases the risk of gastrointestinal hemorrhage; however, this appears to occur with chronic use and not acute therapy. In a meta-analysis of 66,000 patients on chronic aspirin therapy, gastrointestinal hemorrhage occurred in 2.47% of patients taking aspirin compared with 1.42% taking a placebo (odds ratio 1.68; 95% CI 1.51 to 1.88); the number needed to harm was 106 (82 to 140) based on an average of 28 months of therapy.¹⁰⁴ Importantly, however, as demonstrated in the ISIS-2 trial, when used alone in patients with acute MI, aspirin was not associated with an increase in intracerebral hemorrhage or bleeding requiring transfusion.⁷⁰ Nonetheless, it should be emphasized that acute MI patients are rarely treated with aspirin alone.

As previously discussed in this chapter, numerous investigations have demonstrated an increased risk of bleeding with larger doses of aspirin with no clear reduction in ischemic events (see Table 37-1, see Fig. 37-2).^{12,26}

Clopidogrel

Not surprisingly, the combination of aspirin and clopidogrel has been found to increase the likelihood of bleeding. In CURE, major bleeding occurred more frequently in patients receiving clopidogrel compared with a placebo (3.7% versus 2.7%; relative risk, 1.38; $p = 0.001$). There were no increased episodes of life-threatening bleeding requiring surgical intervention or hemorrhagic stroke. The most common cause of bleeding was gastrointestinal hemorrhage and bleeding at arterial puncture sites.³¹

The heightened risk of bleeding becomes a significant issue when and if patients are transferred for surgical revascularization soon after admission with the diagnosis of ACS. At least in the United States, such transfers are usually done within one or a few days and the effect of clopidogrel administered at the time of admission cannot be reversed. Clopidogrel has been found to increase the risk of bleeding in patients undergoing coronary bypass surgery if taken within 5 days of surgery. This was initially demonstrated in CURE, whereby 910 patients who stopped taking clopidogrel at least 5 days before bypass surgery had no increase in bleeding complications (4.4% in patients taking clopidogrel and 5.3% for those taking placebo). However, if clopidogrel was stopped less than 5 days before surgery, the likelihood for bleeding was higher within 7 days after bypass surgery (9.6% clopidogrel versus 6.3% placebo; relative risk, 1.53; $p = 0.06$).

These observations were subsequently confirmed in other studies. When 59 patients received clopidogrel within 7 days of bypass surgery were compared with 165 patients who did not receive clopidogrel, there was a significant increase in chest tube output, blood, platelet, and fresh frozen plasma transfusions, and reoperation.¹⁰⁵ These outcomes were supported in a similar study that subdivided patients into three groups: those receiving clopidogrel within 4 days of bypass surgery, 5 to 8 days of bypass surgery, greater than 8 days, or never. The group receiving clopidogrel within 4 days had greater chest tube losses and more transfusions.¹⁰⁶ Therefore the AHA/ACC guidelines recommend that CABG surgery be postponed, if possible, for at least 5 days after administration of clopidogrel. On clinical grounds, this is not always feasible and many patients still undergo bypass surgery with this 5-day period.¹⁰⁷ It is therefore imperative that there is full communication, understanding, and preparation among the medical and surgical teams caring for such patients in the operating room and the postoperative intensive care unit.

Glycoprotein IIb/IIIa inhibitors

Glycoprotein IIb/IIIa inhibitors have also demonstrated an increased risk of bleeding, although the incidence and severity of such bleeding complications varied from one study to another. In EPILOG, abciximab with standard dose heparin was found to increase minor TIMI bleeding.⁵² However, when using weight-adjusted dosing, in addition to early removal of arterial access sheaths, the increased bleeding risk was eliminated. Based on the lessons learned from EPILOG, heparin dosing and sheath management with abciximab use changed. In ISAR-REACT 2, whereby NSTEMI patients were randomized to receive a 600-mg clopidogrel load, heparin, and either abciximab or placebo, there were no differences in the two groups in neither major nor minor bleeding,⁹⁰ and in the meta-analysis by De Luca and colleagues, abciximab use in management of acute STEMI was not associated with an increased risk of bleeding unless combined with thrombolytic therapy.⁸⁷ Like abciximab, the incidence of bleeding with eptifibatide varied depending on the study. In PUR-SUIT, patients receiving eptifibatide had an increased incidence of bleeding and required more blood transfusions.⁹¹ This is in contrast to IMPACT II where an increased bleeding risk was not established,⁶¹ although this difference was most likely because of the smaller eptifibatide bolus in IMPACT II.

Certain patient populations including women, the elderly, and those with acute renal insufficiency have an increased risk for

bleeding with glycoprotein IIb/IIIa inhibitor therapy. Observations from the CRUSADE registry demonstrated that women treated with glycoprotein IIb/IIIa inhibitors had higher rates of major bleeding compared with men (15.7% versus 7.3%, $p < 0.0001$). Furthermore, when compared with men, women more frequently received excess glycoprotein IIb/IIIa inhibitors (46.4% versus 17.2%, $p < 0.0001$; adjusted OR 3.81, 95% CI 3.39 to 4.27). This excess dosing caused more bleeding in women (OR 1.72, 95% CI 1.30 to 2.28) and men (OR 1.27, 95% CI 0.97 to 1.66); however, bleeding risk attributable to dosing was much higher in women (25.0% versus 4.4%).¹⁰⁸

Elderly patients are also at a higher risk for bleeding. Octogenarians are traditionally excluded from clinical trials assessing the efficacy of glycoprotein IIb/IIIa inhibitors, but are commonly prescribed one of these agents in the context of high-risk ACS and/or high-risk PCI. In a retrospective analysis of 459 patients who received glycoprotein IIb/IIIa inhibitors, the risk of bleeding was increased, with vascular access and gastrointestinal tract representing the most common sources. Events were not always related to a prior history of peptic ulcer disease and/or peripheral vascular disease in this patient population.¹⁰⁹

Patients with renal insufficiency are also known to be at an increased risk of bleeding complications and in-hospital mortality when undergoing PCI. This bleeding risk is increased further with glycoprotein IIb/IIIa inhibitors. In 4158 patients undergoing PCI, use of abciximab showed a trend towards major bleeding in patients with renal insufficiency (OR, 1.18; $p = 0.06$). There was not a significant increase in minor bleeding (OR, 1.01; $p = 0.94$).¹¹⁰ In a smaller retrospective analysis, patients with acute coronary syndrome and renal insufficiency who received any glycoprotein IIb/IIIa inhibitor had an increased risk of major bleeding ($p < 0.001$).¹¹¹

The bleeding complications associated with CABG and glycoprotein IIb/IIIa inhibitor use has been studied far less. Only one such study exists, examining abciximab administration before urgent CABG surgery and the need for platelet transfusions nearly reached statistical significance ($p = 0.059$) but there was no increase in major blood loss or transfusions. However, surgical re-exploration for bleeding occurred in 3% of patients not receiving abciximab compared with 12% who did.¹¹²

Conclusions and Future Directions

Acute arterial thrombosis is one of the world's primary causes of mortality today and antiplatelet agents remain the cornerstone of therapy to treat and prevent these events. Over the last 40 years, through hundreds of trials involving nearly a half-million patients, the benefits of antiplatelet therapies have been identified and the risks highlighted. However, despite their history of such extensive investigation, many unknowns remain. Even with aspirin, a drug that has been available for more than 100 years, there is still debate as to the best dose and a thorough understanding of the actual mechanism behind its surprising clinic benefit remains allusive.

As great as past advances have been in the application of platelet inhibitors to clinical practice, it appears that we have just begun to scratch the surface. The field is poised to advance dramatically over the next 5 to 10 years. A number of new P2Y₁₂ ADP antagonists are in phase 3 testing. Multiple platelet thrombin receptor antagonists are also entering large-scale clinical trials. In addition, agents targeting platelet receptors for novel agonists such

as serotonin, collagen, and thromboxane A₂ are entering clinical testing. At the same time, our knowledge of the biology and physiology of platelets continues to expand and with it will come a number of new agents that target yet unidentified platelet-centered processes that contribute to atherothrombotic disease.

Inotropic and Vasoactive Agents in the Cardiac Intensive Care Unit

Andreia Biolo, Wilson S. Colucci, Michael M. Givertz

CHAPTER 38

Sympathomimetic Agents
Phosphodiesterase Inhibitors
Calcium-Sensitizing Agents

Other Parenteral Inotropes
Vasodilators

INOTROPIC AND vasoactive agents often play an important role in the management of hemodynamic instability in the intensive care setting. In this chapter, we discuss the relevant pharmacology and clinical indications for the parenteral inotropic, vasodilator, and vasoconstrictor agents most frequently used in the cardiac intensive care unit.

These agents are used to correct or stabilize hemodynamic function and, therefore, in many cases their proper selection and dosing requires hemodynamic information based on a pulmonary artery catheter, an intra-arterial pressure monitor, and electrocardiographic monitoring (Table 38-1). However, the use of a pulmonary artery catheter did not show benefit in either acute decompensated heart failure patients in the ESCAPE trial¹ or a recent meta-analysis of 13 randomized trials including more than 5000 critically ill patients.² This lack of benefit may result from the absence of effective strategies to use in combination with pulmonary artery catheter information. These studies also demonstrated no increase in mortality or hospitalization associated with pulmonary artery catheter use. Based on the available data, there is no indication for routine use of a pulmonary artery catheter in patients hospitalized with acute decompensated heart failure. Nevertheless, a pulmonary artery catheter may provide valuable information and help guide therapy in specific situations (e.g., patients in whom congestion does not resolve after initial therapy, or in whom the presence of congestion is unclear or associated with worsening renal function).

Sympathomimetic Agents

Dopamine

Dopamine is the immediate precursor of epinephrine and norepinephrine. It has both cardiac and vascular sites of action, depending in part on the dose used^{3,4} (Table 38-2). At low doses (i.e., 1 to 3 $\mu\text{g/kg/min}$), dopamine directly activates dopaminergic receptors in the kidney and splanchnic arteries, thereby causing vasodilation of these beds. The resultant increase in renal blood flow leads to increased urine output and sodium excretion. At moderate doses (i.e., 3 to 8 $\mu\text{g/kg/min}$), dopamine is a weak partial agonist at myocardial β_1 -receptors and causes the release of norepinephrine from sympathetic nerve terminals in the myocardium and vasculature. The direct stimulation of myocardial β -adrenergic receptors exerts positive chronotropic and inotropic effects. The increased release of norepinephrine from nerve terminals (a tyramine-like effect) also contributes to

myocardial stimulation, but in addition may exert a mild vasoconstrictor effect due to stimulation of vascular α -adrenergic receptors. At high doses of dopamine (i.e., 5 to 20 $\mu\text{g/kg/min}$), the effect of peripheral α -adrenergic stimulation predominates, resulting in vasoconstriction in all vascular beds and leading to increases in mean arterial pressure and systemic vascular resistance. At high doses, the vasoconstrictor effect overshadows the dopaminergic vasodilator effects, so that renal blood flow decreases and urine output may decline. However, in patients with acute decompensated heart failure the dose required for improving systemic and renal hemodynamics may be higher (on the order of 4 to 6 $\mu\text{g/kg/min}$) than the usual “low dose” range, leading to the suggestion that severe heart failure may impair the renal effects of dopamine.⁵

Table 38-1. Intravenous Drug Selection in Patients with Elevated Left Heart Filling Pressures and a Reduced Cardiac Output

SVR	Low CO		
	High PCWP		
	HIGH	NORMAL	LOW

	β_1/β_2	α_1	β_2	
Dobutamine	+++	++	++	0
Dopamine (low dose)	0	0	0	+++
Dopamine (high dose)	+++	+++	0	+++
Isoproterenol	+++	0	+++	0
Norepinephrine	+++	+++	+	0

Given its varying actions, there are several potential uses for dopamine in the cardiac intensive care unit. In patients with decompensated heart failure, dopamine is frequently used at low infusion rates to improve renal function by increasing renal blood flow.^{6,7} Increased water and sodium excretion results in a decrease in right and left ventricular filling pressures. Low dose dopamine is frequently combined with one or more other inotropic (e.g., dobutamine) or vasodilator (e.g., nitroprusside) agents.⁸

In patients with severe compromise of the arterial pressure or frank cardiogenic shock, higher doses of dopamine are used to increase systemic vascular resistance. At these higher doses, the increased left ventricular afterload is partially offset by the positive inotropic action. In addition, when it is necessary to use vasoconstrictor doses of dopamine to manage systemic hypotension in the setting of myocardial failure, it is often useful to add dobutamine to augment the level of positive inotropic support beyond that provided by dopamine alone. When used alone at vasoconstrictor doses in patients with left ventricular failure, dopamine may increase both left and right heart filling pressures⁹ (Fig. 38-1 and Table 38-3). This effect reflects increased left and right ventricular afterload and increased peripheral venoconstriction, the latter causing increased return of venous blood to the heart. To counteract these actions, high dose dopamine is sometimes combined with vasodilators (e.g., nitroglycerin).¹⁰

The inotropic responses to dopamine may be attenuated because of desensitization of the β -adrenergic pathway and depletion of myocardial catecholamine stores, both of which are common in patients with advanced heart failure.^{11,12} Although generally well tolerated at low doses, higher infusion rates of dopamine may result in unwanted sinus tachycardia and/or arrhythmias (supraventricular and ventricular). Other adverse effects of dopamine include digital gangrene in patients with underlying peripheral arterial disease, tissue necrosis at sites of infiltration, and nausea at high doses. Local infiltration may be counteracted by the local injection of the α -adrenergic antagonist phentolamine.

Dobutamine

Dobutamine is a direct-acting synthetic sympathomimetic amine that stimulates β_1 -, β_2 -, and α -adrenergic receptors (see Table 38-2). Clinically, it is available as a racemic mixture in which the (+) enantiomer is both a β_1 - and β_2 -adrenergic receptor agonist and an α -adrenergic receptor competitive antagonist, and the (–) enantiomer is a potent β_1 -adrenergic receptor agonist and an α -adrenergic receptor partial agonist.^{13,14} The net effect of this pharmacologic profile is that dobutamine causes a relatively selective stimulation of β_1 -adrenergic receptors, and accordingly, dobutamine's primary cardiovascular effect is to increase cardiac output by increasing myocardial contractility. This positive inotropic effect is associated with relatively little increase in heart rate. The drug causes modest decreases in left ventricular filling pressure and systemic vascular resistance due to a combination of direct vascular effects and the withdrawal of sympathetic tone¹⁵ (see Table 38-3). Dobutamine also directly improves left ventricular relaxation (positive lusitropic effect) via stimulation of myocardial β -adrenergic receptors.¹⁶ Dobutamine has no effect on dopaminergic receptors and therefore no direct renal vasodilator effect. However, renal blood flow often increases with dobutamine in proportion to the increase in cardiac output.

Figure 38-1. Comparative effects of dopamine (●) and dobutamine (Δ) on heart rate, pulmonary capillary wedge pressure, and total systemic resistance in patients with moderate to severe heart failure. Each agent was titrated over the doses shown. These data illustrate that dopamine, when given alone at vasoconstrictor doses to patients with severe heart failure, increases left heart filling pressures. (Adapted from Leier CV: Regional blood flow responses to vasodilators and inotropes in congestive heart failure. *Am J Cardiol* 1988;62:86E.)

Dobutamine is a valuable agent for the initial management of patients with acute or chronic systolic heart failure characterized by a low cardiac output.¹⁷ It is often initiated at an infusion rate of 2 $\mu\text{g/kg/min}$ (without a loading dose) and titrated upward by 1 to 2 $\mu\text{g/kg/min}$ every 15 to 30 minutes until the hemodynamic

Table 38-3. Comparative Hemodynamic Effects of Commonly Used Positive Inotropic Agents

Levosimendan	↑	↓↓	↓↓	↑

goal is reached or a dose-limiting event, such as unacceptable tachycardia or arrhythmias, occurs. Maximum effects are usually achieved at a dose of 10 to 15 $\mu\text{g/kg/min}$, although higher infusion rates may occasionally be used. In patients with more severe decompensation, and presumably greater β -adrenergic receptor downregulation, dobutamine can be started at 5 $\mu\text{g/kg/min}$. If the maximum tolerated infusion rate of dobutamine does not result in a sufficient increase in cardiac index, a second drug (e.g., milrinone) may be added.^{8,18} In patients with elevated systemic vascular resistance and/or left heart filling pressures, the co-administration of a vasodilator such as nitroprusside or nitroglycerin may be required. In patients who remain hypotensive on dobutamine, consideration should be given to the addition of a pressor dose of dopamine and/or the use of mechanical circulatory support.

Other clinical situations in which dobutamine is effective include cardiogenic shock complicating acute myocardial infarction, low cardiac output following cardiopulmonary bypass, and as a “bridge” to cardiac transplantation.¹⁹ There is some evidence that short-term or intermittent infusions of dobutamine can result in sustained improvement in hemodynamics and functional status for days or weeks after the infusion is stopped.²⁰⁻²² However, there are limited clinical data to suggest that the intermittent use of dobutamine either has no effect on outcomes²³ or may increase mortality.²⁴ As a result, the administration of dobutamine should be limited to the inpatient setting.

Dobutamine may increase heart rate, thereby limiting the dose that can be infused. However, in some patients with very depressed cardiac output the improvement in hemodynamic function may cause a withdrawal of sympathetic tone such that heart rate falls. Hypotension is uncommon, but can occur in patients who are hypovolemic. Arrhythmias, including supra-ventricular and ventricular tachycardia, may limit the dose. Likewise, myocardial ischemia secondary to increased myocardial oxygen consumption may occur. Some patients with chronic severe heart failure may be tolerant to dobutamine, or tolerance to dobutamine may develop after several days of a continuous infusion.²⁵ In this situation, the addition or substitution of a phosphodiesterase inhibitor may be helpful. Hypersensitivity myocarditis has also been reported with chronic infusions of dobutamine and should be suspected if a patient develops worsening hemodynamics or peripheral eosinophilia.

Isoproterenol

A synthetic sympathomimetic structurally related to epinephrine, isoproterenol is a nonselective β -adrenergic receptor agonist with little or no effect on α -receptors (see Table 38-2).

Its cardiovascular effects include increased myocardial contractility, heart rate, and atrioventricular conduction due to stimulation of myocardial β_1 - and β_2 -adrenergic receptors, and vasodilation of skeletal muscle and pulmonary vasculature due to stimulation of vascular β_2 -adrenergic receptors. Isoproterenol increases cardiac output and lowers both systemic and pulmonary vascular resistance.

Because of its propensity to increase heart rate, isoproterenol has relatively limited applications in the cardiac intensive care unit. However, isoproterenol may be useful in the management of torsades de pointes that is refractory to magnesium,²⁶ inotropic and chronotropic support immediately following cardiac transplant,²⁷ and treatment of pulmonary hypertension secondary to acute pulmonary embolism.²⁸ Isoproterenol is usually administered as a continuous infusion at 0.5 to 5 $\mu\text{g/min}$. The dose of isoproterenol may be limited by tachycardia, increased myocardial oxygen consumption leading to ischemia, and atrial or ventricular arrhythmias.

Epinephrine

Like isoproterenol, epinephrine stimulates β_1 - and β_2 -adrenergic receptors in the myocardium, thereby causing marked positive chronotropic and inotropic responses. Unlike isoproterenol, it also has potent agonist effects at vascular α -adrenergic receptors causing increased arterial and venous constriction. Because of this latter effect, epinephrine (like high-dose dopamine and norepinephrine) plays little role in the acute management of heart failure, except when complicated by severe hypotension. Epinephrine may be useful for the treatment of low cardiac output, with or without bradycardia, immediately following cardiopulmonary bypass or cardiac transplantation.²⁹ Continuous infusions may be started at a low dose (0.5 to 1 $\mu\text{g/min}$), and titrated upwards to 10 $\mu\text{g/min}$, as needed. The use of epinephrine may be limited by tachycardia, arrhythmias, increased myocardial oxygen consumption leading to ischemia, and oliguria from renal vasoconstriction.

In the setting of cardiac arrest, epinephrine may be used as per the Advanced Cardiac Life Support (ACLS) protocol (1 mg intravenous push or via endotracheal tube every 3 to 5 minutes) to manage ventricular fibrillation, pulseless ventricular tachycardia, asystole, or pulseless electrical activity.³⁰ Epinephrine may also be infused at 2 to 10 $\mu\text{g/min}$ to manage symptomatic bradycardia that is unresponsive to atropine, while awaiting placement of an external or temporary transvenous pacemaker.

Norepinephrine

The myocardial and peripheral vascular effects of this endogenous catecholamine are similar to those of epinephrine except that norepinephrine causes little stimulation of vascular β_2 -adrenergic receptors and therefore causes more intense vasoconstriction (see Table 38-2). Norepinephrine may be used to provide temporary circulatory support in the setting of hemodynamically significant hypotension (e.g., following cardiac surgery or with cardiogenic shock complicating acute myocardial infarction or pulmonary embolism). Norepinephrine is titrated to improve blood pressure at doses of 2 to 10 $\mu\text{g/min}$. As with epinephrine, the use of norepinephrine in the cardiac intensive care unit may be limited by arrhythmias, myocardial ischemia, renal impairment, or tissue necrosis at the site of local infiltration. If extravasation occurs, phentolamine 5 to 10 mg may be infiltrated into the affected area.

Phosphodiesterase Inhibitors

The breakdown of cAMP is mediated by a membrane-bound enzyme, phosphodiesterase (PDE). In myocardium and vascular smooth muscle, the predominant isoform of this enzyme, termed type III, is inhibited by the type-III selective PDE inhibitors milrinone and inamrinone, leading to an increase in intracellular cAMP concentrations. In the myocardium, intracellular cAMP increases both contractility and the rate of relaxation (positive lusitropic effect). PDE III inhibitors are also potent vasodilators in the systemic and pulmonary vasculature.³¹⁻³³

In patients with acute decompensated heart failure, type III PDE inhibitors increase cardiac output by increasing stroke volume. Balanced arterial and venous dilation cause decreases in right atrial, pulmonary artery, pulmonary capillary wedge, and mean arterial pressures. Because PDE inhibitors exert both positive inotropic and vasodilator actions, their net hemodynamic effects differ from those of dobutamine and nitroprusside. Thus, for a comparable increase in cardiac output, the PDE inhibitor milrinone decreases systemic vascular resistance and left ventricular filling pressure to a greater extent than dobutamine³⁴ (Fig. 38-2; see Table 38-3). Conversely, for a comparable decrease in arterial blood pressure, milrinone increases cardiac output to a greater extent than nitroprusside³⁵ (Table 38-4).

Figure 38-2. The relative effects of dobutamine (Dob), milrinone (Mil), and nitroprusside (Ntp) on left ventricular contractility, as reflected by peak $+dP/dt$, and systemic vascular resistance (SVR) in patients with severe heart failure. (From Colucci WS, Wright RF, Jaski BE, et al: Milrinone and dobutamine in severe heart failure: differing hemodynamic effects and individual patient responsiveness. *Circulation* 1986;73:III-175.)

Table 38-4. Comparative Hemodynamic Effects of Intravenous Vasodilators

	PCWP	SVR	CO
Nitroprusside	↓↓	↓↓	↑
Nitroglycerin	↓↓	↔↓	↑↔↓
Milrinone	↓↓	↓↓	↑↑
Hydralazine	↓	↓↓	↔↑
ACE Inhibitor	↓↓	↓↓	↑
Nesiritide	↓↓	↓↓	↑

PDE inhibitors are used for the treatment of heart failure characterized by low cardiac output, high filling pressures, and elevated or normal systemic vascular resistance. They may also be useful in the management of low cardiac output following cardiopulmonary bypass and as a bridge to mechanical support or cardiac transplant,³⁶ especially in patients tolerant of β -adrenergic agonists. Chronic infusions of milrinone at home have also been used for palliative care in selected patients with end-stage heart failure. The positive inotropic effects of these drugs are additive to those of digoxin and may be synergistic with those of sympathomimetics such as dobutamine^{37,38} (Fig. 38-3).

Milrinone

In patients with heart failure, milrinone is administered as a 25 to 50 $\mu\text{g/kg}$ intravenous bolus over 10 minutes followed by a constant infusion at 0.25 to 0.75 $\mu\text{g/kg/min}$. Lower infusion rates without a bolus may be used in patients with low baseline blood pressure. If a lower bolus dose (i.e., 25 $\mu\text{g/kg}$) is used to initiate therapy and the response is not adequate, a second bolus of 25 $\mu\text{g/kg}$ may be given before increasing the infusion rate. The dose of milrinone tolerated may be limited by tachycardia or tachyarrhythmias. In addition, relatively volume-depleted patients may not tolerate its vasodilator effects and will experience symptomatic hypotension that may necessitate stopping the drug. Thrombocytopenia is rarely seen with milrinone (less than 0.5%). Milrinone has a half-life of 30 to 60 minutes in patients with heart failure. It can be used alone or in combination with other agents (e.g., dobutamine or nitroprusside).

The routine use of milrinone was assessed in a study of 900 patients admitted to the hospital with an exacerbation of heart failure. In this setting, a 48-hour infusion did not reduce the subsequent need for hospitalization and was associated with an increased risk of arrhythmias and sustained hypotension.³⁹

Figure 38-3. Hemodynamic effects of dobutamine (D), amrinone (A), and the combination (A + D) in patients with moderate to severe heart failure. As shown here, the additive effect of the two agents may exceed the effect of either agent alone. C, hemodynamics during the control periods (Adapted from Gage J, Rutman H, Lucido D, LeJemtel TH: Additive effects of dobutamine and amrinone on myocardial contractility and ventricular performance in patients with severe heart failure. *Circulation* 1986;74:367.)

It is important to note that patients requiring inotropic support (with shock or severe hypotension) were excluded from this study. Thus, milrinone, like dobutamine, should be reserved for the short-term management of patients with symptomatic hemodynamic compromise that is not responsive to diuretics and vasodilators. Patients with pulmonary hypertension secondary to chronically elevated left heart filling pressures may be particularly responsive to milrinone.

Inamrinone

Inamrinone is administered as an intravenous bolus of 0.5 to 0.75 mg/kg over 2 to 3 minutes, followed by a continuous infusion at 5 to 10 µg/kg/min titrated to hemodynamic goals. The major dose-limiting effects of inamrinone are similar to milrinone, and include tachycardia, atrial or ventricular arrhythmias, and hypotension. The latter effect is most likely to occur in patients who are hypovolemic. Thrombocytopenia, which is seldom severe, occurs in 2% to 3% of patients. This effect is dose-dependent, occurring with higher doses and/or more prolonged infusions, and appears to be due to decreased platelet survival.⁴⁰ Other adverse effects include liver function abnormalities, headache, and nausea.

Calcium-Sensitizing Agents

Positive inotropic agents, such as dobutamine and milrinone, act by increasing myocyte calcium influx, and therefore may be associated with increased arrhythmias. An alternative approach that may avoid such complications is to enhance myocardial response to a given concentration of calcium with a class of agents referred to as “calcium sensitizers.”⁴¹ Several calcium sensitizers have been studied in heart failure and acute coronary syndromes and most have additional effects such as phosphodiesterase inhibition that may contribute significantly to their clinical profile.

Levosimendan

Levosimendan, the most widely studied calcium sensitizer,⁴² increases myocardial contractility by increasing myofilament sensitivity to calcium. Levosimendan is also a potent vasodilator due to activation of adenosine triphosphate-dependent potassium channels in vascular smooth muscle cells, leading to decreases in both preload and afterload. In patients with severe heart failure, levosimendan increases cardiac output and reduces pulmonary capillary wedge pressure and systemic vascular resistance (see Table 38-3).^{43,44}

The effects of levosimendan are dose-dependent at infusion rates ranging from 0.05 to 0.6 µg/kg/min, with higher incidence of side effects (headache, nausea, and hypotension) at rates above 0.2 µg/kg/min.⁴⁵ Levosimendan is completely metabolized before excretion. Approximately 5% is converted to a highly active metabolite, OR-1896, that exhibits hemodynamic effects similar to those of levosimendan and has an elimination half-life of 75 to 80 hours (compared with 1 hour for levosimendan itself). Because of the long half-life of this active metabolite, hemodynamic effects last for up to 7 to 9 days after discontinuation of a 24-hour infusion of levosimendan.⁴³

Several clinical trials have evaluated the efficacy of levosimendan in patients with acute decompensated heart failure, in comparison with placebo⁴⁶ or dobutamine,^{47,48} and its use is approved in several European and South American countries.

The data from these trials suggest short-term symptomatic benefit with levosimendan in patients with acute decompensated heart failure, but no impact on survival compared with placebo. Levosimendan may be useful in other situations, such as the perioperative and postoperative setting, acute coronary syndromes, and cardiogenic and septic shock.⁴² In addition to positive inotropic effects, levosimendan exerts dose-dependent lusitropic effects in failing hearts.⁴⁹

Other Parenteral Inotropes

Digoxin

Although digoxin can be given intravenously, it is seldom used as a positive inotropic agent in the acute management of heart failure. Digoxin may be useful for the control of a rapid ventricular rate in patients with or without heart failure complicated by atrial fibrillation or atrial flutter.

Vasodilators

For many patients with acute decompensated heart failure characterized hemodynamically by low cardiac output, high filling pressures and elevated systemic vascular resistance and/or clinically by symptomatic congestion with normal or elevated blood pressure, a parenteral vasodilator is the initial agent of choice. As discussed later, intravenous vasodilators can be used alone or in combination with a positive inotropic agent (see Table 38-1).

Nitroprusside

Nitroprusside is a sodium salt consisting of ferricyanide and nitric acid. Its reduction by intracellular glutathione leads to the local production of nitric oxide, which mediates the drug's potent vasodilator effect.⁵⁰ The onset of action is rapid, in 1 to 2 minutes, making it an ideal agent for use in urgent situations which require rapid dose titration and a predictable hemodynamic effect. Nitroprusside is both an arterial and venous dilator and, therefore, it reduces both filling pressures and vascular resistance (systemic and pulmonary). Stroke volume and cardiac output increase, and pulmonary artery, pulmonary capillary wedge, and right atrial pressures decrease (Fig. 38-4). In patients with heart failure, heart rate is generally unchanged or may fall because of reflex sympathetic withdrawal.⁵¹

There are several indications for the use of nitroprusside in the cardiac intensive care unit.⁵² One indication is acute decompensated heart failure manifested by low cardiac output, elevated filling pressures, high systemic vascular resistance, and a systolic blood pressure adequate to maintain vital organ perfusion, usually greater than or equal to 90 mm Hg. This hemodynamic picture is often seen with heart failure in the setting of acute myocardial infarction, acute mitral or aortic regurgitation, and fulminant myocarditis. In acute myocardial infarction, nitroprusside may be particularly useful if the infarction is complicated by significant hypertension, mitral regurgitation secondary to papillary muscle rupture, or rupture of the ventricular septum.⁵³ Acute valvular regurgitation secondary to endocarditis, aortic dissection, or ruptured chordae is another situation in which nitroprusside may be used effectively, often as a “bridge” to more definitive therapy (e.g., valve replacement or repair).⁵⁴ A recent study showed increased cardiac output with nitroprusside administration in patients with severe aortic stenosis and left ventricular dysfunction occurring with severe heart failure,

Figure 38-4. The comparative effects of nitroprusside (N), dobutamine (D), and milrinone (M) on cardiac index, mean arterial pressure, right atrial pressure, and pulmonary capillary wedge pressure in patients with severe heart failure.⁷⁹ The agents were administered in doses that caused comparable increases in cardiac index. Under these conditions, nitroprusside and milrinone significantly reduced mean arterial pressure, but dobutamine had no effect. All three agents reduced right atrial pressure, although the effect of dobutamine was less pronounced. Nitroprusside and milrinone significantly reduced pulmonary capillary wedge pressure, and this effect was significantly more pronounced than the effect of dobutamine. B, baseline hemodynamics (Adapted from Monrad ES, Baim DS, Smith HS, Lanoue AS: Milrinone, dobutamine, and nitroprusside: comparative effects on hemodynamics and myocardial energetics in patients with severe congestive heart failure. *Circulation* 1986;73:III-168.)

suggesting it may also be useful in this context as a bridge to aortic valve replacement.⁵⁵

Nitroprusside is also used in patients with chronic heart failure due to dilated cardiomyopathy, both to manage acute decompensation and to determine whether pulmonary hypertension is acutely reversible during the evaluation for cardiac transplantation.^{56,57} Following optimization of hemodynamics with intravenous nitroprusside and diuretic therapy, patients should be titrated on to oral vasodilator/diuretic therapy before discharge. Finally, nitroprusside is often the parenteral agent of choice for treating hypertensive emergencies as it can be rapidly titrated to blood pressure goals.⁵⁸

The infusion of nitroprusside should be guided by close hemodynamic monitoring, ideally with a pulmonary artery catheter and radial or femoral arterial line. Nitroprusside may be started at a rate of 10 to 20 $\mu\text{g}/\text{min}$ (or 0.1 to 0.2 $\mu\text{g}/\text{kg}/\text{min}$) and increased by 20 $\mu\text{g}/\text{min}$ every 5 to 15 minutes until the

hemodynamic goal is achieved (e.g., a systemic vascular resistance of 1000 to 1200 dynes-sec-cm⁻⁵ and a pulmonary capillary wedge pressure of less than or equal to 16 to 18 mm Hg) while maintaining an adequate systolic blood pressure (generally, >80 mm Hg). Doses of 300 $\mu\text{g}/\text{min}$ (5 $\mu\text{g}/\text{kg}/\text{min}$) or higher are seldom required and increase the risk of toxicity.

Nitroprusside is a potent vasodilator and its use may be limited by hypotension. In patients with underlying coronary artery disease, drug-induced hypotension accompanied by reflex tachycardia may worsen myocardial ischemia. In patients with acute decompensated heart failure, hemodynamic deterioration may occur following the withdrawal of nitroprusside, apparently due to a transient “rebound” increase in systemic vascular tone.⁵⁹ Other adverse effects of nitroprusside are due to the accumulation of its metabolites: cyanide and thiocyanate.⁶⁰ The build-up of cyanide results in lactic acidosis and methemoglobinemia, and may manifest itself as nausea, restlessness, and dysphoria.

Cyanide toxicity is most likely to occur in patients with liver dysfunction or following prolonged infusions, but may occur even in patients with normal hepatic function who have received the drug for only a few hours. If cyanide toxicity is suspected, serum levels should be drawn and the infusion stopped. In severe cases, treatment with sodium nitrate, sodium thiosulfate, or vitamin B₁₂ may be necessary. Cyanide is converted in the liver to thiocyanate, which is cleared by the kidney. The half-life of elimination of thiocyanate is 3 to 7 days. Thiocyanate toxicity generally occurs gradually and is manifested by nausea, confusion, weakness, tremor, hyperreflexia and, rarely, coma. Thiocyanate toxicity is more likely to occur in patients with renal dysfunction and with prolonged infusions or high rates of infusion. If mild, it can be managed by cessation of the drug; in severe cases, hemodialysis may be necessary.

Nitroglycerin

When administered parenterally, nitroglycerin has an immediate onset of action and a plasma half-life of 1 to 4 minutes. It is cleared by vascular endothelium, hydrolyzed in the blood, and metabolized in the liver. At lower infusion rates, its main cardiovascular effect is venodilation, with a resultant fall in ventricular volumes and filling pressures. At higher infusion rates, nitroglycerin also causes arterial dilation, resulting in decreases in both pulmonary and systemic vascular resistance⁵¹ (see Table 38-4).

Nitroglycerin plays several important roles in the cardiac intensive care unit.⁵² In the setting of cardiogenic pulmonary edema, especially when due to myocardial ischemia or infarction, nitroglycerin provides immediate symptomatic relief and improves both hemodynamics and oxygen saturation.⁶¹ By causing direct coronary vasodilation, nitroglycerin also has the theoretical advantage of improving myocardial perfusion and limiting infarct size.⁶² Intravenous nitroglycerin is often useful in the management of patients with new onset heart failure or acute decompensation of chronic heart failure, particularly in patients who are refractory to diuretic therapy and continue to manifest elevated right- and left-sided filling pressures, in patients with disproportionate right-sided failure, and in patients in whom nitroprusside is not tolerated.

Intravenous nitroglycerin is usually started at a low infusion rate of 20 to 30 µg/min, and increased by 10 to 20 µg/min every 5 to 10 minutes until the desired response is observed or a dose of 400 µg/min is reached. In patients with acute decompensated heart failure, upward titration should be guided by filling pressures and systemic vascular resistance or, if invasive monitoring is not available, by signs and symptoms of pulmonary and/or systemic venous congestion. While awaiting intravenous access, nitroglycerin can be administered by the sublingual, buccal, or transdermal route.

Use of nitroglycerin may be limited by hypotension, which may require discontinuation of the drug and/or supportive care with intravenous fluids and leg elevation. Other common side effects related to vasodilation include headache, flushing and diaphoresis. Some patients with heart failure will not respond to the acute administration of nitroglycerin.⁶³ This resistance is usually seen in patients with significant right-sided failure and peripheral edema, and often resolves following diuresis.⁶⁴ In addition, patients may develop pharmacologic tolerance to nitroglycerin. Strategies to prevent the development of such tolerance include avoidance of excessive dosing, limiting fluid retention, and the use of intermittent dosing.^{65,66}

Nesiritide

Nesiritide (recombinant human B-type natriuretic peptide) is identical to and mimics the actions of the endogenous BNP molecule. Clinical studies with intravenous infusion of nesiritide in patients with acute decompensated heart failure have shown that it exerts potent, dose-related vasodilator effects that are rapid in onset and sustained for the duration of drug infusion.⁶⁷ Balanced arterial and venous vasodilation is reflected by decreases in systemic vascular resistance, systemic arterial pressure, pulmonary capillary wedge pressure, and right atrial pressure. Vasodilation in the absence of symptomatic hypotension occurs without a change in heart rate and is associated with increases in stroke volume and cardiac output.

Administration of nesiritide in the short-term treatment of decompensated heart failure resulted in dose-dependent reductions in pulmonary capillary wedge pressure and improved clinical status compared with placebo.⁶⁸ When compared with standard vasoactive therapy such as dobutamine, nesiritide produced a similar improvement in clinical status and dyspnea. In another randomized, controlled trial, nesiritide reduced pulmonary capillary wedge pressure significantly more than nitroglycerin, and resulted in a similar improvement in dyspnea and clinical status.⁶⁹

When compared with dobutamine, nesiritide is less likely to cause ventricular arrhythmias and may be associated with clinical benefit, including reduced 6-month mortality and a trend toward lower heart failure readmission rates.^{70,71} However, there has been concern about the possible adverse effects of nesiritide on survival and renal function. Pooled meta-analyses found a trend to increased 30-day mortality and a greater degree of worsening renal function among patients treated with nesiritide.^{72,73}

In general, nesiritide is given as an initial intravenous bolus of 2 µg/kg, followed by a continuous infusion of 0.01 µg/kg/min. For patients with systolic blood pressures between 90 and 100 mm Hg, it is more prudent to initiate nesiritide at a dose of 0.005 µg/kg/min without a bolus. In hypertensive patients or those with marked congestion, the dose may be increased (usually by 0.005 µg/kg/min, preceded by a bolus of 1 µg/kg) if there is no therapeutic response, after 3 to 24 hours, up to a maximum of 0.03 µg/kg/min. The main adverse effect is dose-related hypotension. If it occurs, the infusion should be discontinued and restarted when the blood pressure has stabilized, at a 30% to 50% lower dose without a repeat bolus.

Given the concerns about safety, nesiritide is reserved for patients with severe acute decompensated heart failure who remain dyspneic despite diuretics, and who are not hypotensive or in cardiogenic shock.

Hydralazine

Hydralazine is a potent direct-acting arteriolar smooth muscle dilator that causes both pulmonary and systemic vasodilation. Although nitroprusside and nitroglycerin are generally preferred as parenteral vasodilators in the acute management of heart failure, there are specific situations in which hydralazine given intravenously may be a useful or necessary alternative. In particular, hydralazine may be useful in patients who have become toxic with nitroprusside or continue to have an elevated systemic vascular resistance despite the use of a maximally tolerated dose of nitroprusside or nitroglycerin. In addition, hydralazine may be safely administered to pregnant women with heart failure⁷⁴ or severe hypertension.^{75,76}

When used parenterally, hydralazine should be started at a low dose (5 mg given as an intravenous bolus every 4 to 6 hours), and increased gradually up to 25 to 30 mg, as tolerated. The onset of action is rapid, and the magnitude of the hemodynamic effects may be unpredictable. Patients should therefore be monitored with an intra-arterial line. Nausea may be a limiting side effect in the acute setting.

Enalaprilat

Enalapril, a commonly used oral angiotensin-converting enzyme inhibitor, is cleaved by plasma and tissue esterases to form enalaprilat, the active form of the drug. When given parenterally, enalaprilat acts as a balanced vasodilator resulting in decreased right and left heart filling pressures.⁷⁷ Enalaprilat is given as an intravenous bolus (0.625 to 1.25 mg every 6 hours). Although the onset of action is rapid (minutes), the duration of effect is prolonged (several hours). The major adverse effect is hypotension, which is more commonly seen in patients who are volume-depleted.

Enalaprilat may be of value in the treatment of acute decompensated heart failure or hypertensive urgencies.⁷⁸ However, because of the somewhat unpredictable magnitude of the response and its prolonged duration of action, enalaprilat is not a first-line agent for the treatment of patients with myocardial infarction or new onset heart failure. Enalaprilat is contraindicated in pregnancy.

Decompensated Heart Failure and Edema
Pharmacokinetics of Diuretic Therapy
Practical Considerations
Supplemental Therapies for Sodium and Edema Management

Refocusing Therapy: Acute Decompensated Heart Failure Syndromes
Conclusion

FREQUENTLY, ACUTE cardiac decompensation is the clinical expression of left ventricular dysfunction, occurring as the result of diverse etiologies. Even at advanced stages, many patients initially thought to require transplantation due to acute decompensation, can continue to be managed with medical therapy. Many factors contribute to progression of heart failure, from mild forms to the advanced or refractory condition. However, the precise characteristics which govern the rate of progression will vary from patient to patient. As a result, the onset of decompensation or refractory presentation is difficult to predict, and may be abrupt in onset. In this regard, evidence of deterioration must be monitored carefully. For patients with chronic heart failure, fluid retention is typically considered the primary cause of abrupt decompensation, and surveys of hospital admissions support this observation. However, it is important to remember that fluid retention is just one of many factors that can result in abrupt decompensation (Table 39-1). The hallmark of acute cardiac decompensation is pulmonary edema, which results from excessive sodium retention, acute left ventricular dysfunction, or mechanical disorders of the left ventricle. Sodium retention results from the inability of the body to excrete sodium at a rate commensurate with dietary sodium intake. In fact, the characteristics which are identified as the hallmark of acute cardiac

decompensation are for the most part findings of excess sodium retention: pulmonary congestion, peripheral edema, increased jugular venous pressure, an S3 gallop, and hepatomegaly/ascites. In addition to urgent care measures, the most common therapy of acute cardiac decompensation is the use of diuretics. In recent years, newer approaches to sodium and fluid management have been developed, which may improve clinical outcomes and reduce hospital morbidity during the time of acute decompensation. In this chapter, emphasis will be placed upon acute therapy with diuretics, and the transition to a more stable chronic regimen. Newer classes of therapy will also be highlighted.

Decompensated Heart Failure and Edema

Clinical Conditions

Acute pulmonary edema is often the result of the many presentations of coronary artery disease and its complications. A patient may have a massive myocardial infarction, and subsequently develop papillary muscle dysfunction or a ventricular septal defect, which could each contribute to worsening left ventricular dysfunction and pulmonary edema. Also, a patient with previous left ventricular dysfunction may have worsening left ventricular function with myocardial ischemia or infarction with resultant acute pulmonary edema. Although coronary artery disease is probably the most common etiology of acute cardiac decompensation with resultant pulmonary edema, other etiologies include aortic stenosis and diastolic dysfunction in hypertensive crisis.

Mechanisms

Cardiac decompensation is characterized by decreased left ventricular systolic function, and in most cases, abnormal diastolic function. The resultant decrease of cardiac output and increased ventricular end-diastolic pressure set the stage for sodium retention (Fig. 39-1). Decreased cardiac output and increased

Philadelphia, Saunders, 1994, p 37.)

systemic resistance produce decreased renal blood flow, and magnitude of renal blood flow reduction is correlated with decreased cardiac output,^{1,2} and diminished renal blood flow is a stimulus for activation of neurohormonal vasoconstriction pathways, particularly the renin system,^{3,4} which produces vasoconstriction and aldosterone secretion. Total body water, extracellular fluid, and plasma volume are increased compared with controls.⁵ Even within the heart failure population, there may be a spectrum of blood volume expansion (Fig. 39-2). When this is moderate to severe, impaired renal function and increased cardiac filling pressures occur. These hemodynamic responses become the basis for sodium retention.

The reduction of the glomerular filtration rate in heart failure is highly correlated with hemodynamic parameters, where the greatest reduction of cardiac output and renal blood flow are associated with the greatest reduction of the glomerular filtration rate.^{1,6} Renal blood flow and function tend to decrease with age in normal subjects, and an age effect can be superimposed on the overall reduction in renal blood flow and function due to the heart failure process.⁶ The resultant diminished delivery of sodium to the distal nephron at the level of the macula densa becomes a potent stimulus for renin release.⁷ Aldosterone further increases sodium retention at the distal nephron at the expense of potassium excretion. Although current therapy for

heart failure may improve cardiac output and renal blood flow, no current oral therapy has uniformly improved the glomerular filtration rate.

Neurohormonal factors that promote retention of sodium and water include aldosterone, vasopressin, angiotensin II, norepinephrine, and the vasoconstrictor prostaglandins; in contrast, prostacyclin, dopamine, and atrial natriuretic factor favor sodium excretion.^{3,4} The effect of vasopressin is primarily the promotion of free water retention, rather than sodium retention, and this typically contributes to hyponatremia.

Pharmacokinetics of Diuretic Therapy

Response to Diuretic Administration for Acute Cardiac Decompensation

The sites of diuretic actions and their role in the edema of cardiac decompensation have been reviewed.^{10,11} In the last decade, there have not been substantial breakthroughs in new diuretic development or mechanisms. The hemodynamic response to diuretic therapy has been characterized primarily in the setting of pulmonary edema. The acute hemodynamic response revealed a vasodilator effect¹²⁻¹⁴ and reduction of cardiac filling pressures.¹²⁻¹⁵ During acute decompensated heart failure, changes in cardiac output varied from increased or no change to

Figure 39-2. Blood volume, measured by ^{125}I albumin, is given on the x axis as a percent of normal blood volume. Four groups of heart failure patients receiving digoxin and diuretics but no angiotensin-converting enzyme inhibitors are identified: patients with contracted blood volume ($n = 4$; $-12 \pm 6\%$ < normal); patients with a mild increase in blood volume ($n = 8$; $14 \pm 3\%$ > normal); patients with a moderate increase in blood volume ($n = 7$; $25 \pm 3\%$ > normal); and patients with a severe increase in blood volume ($n = 8$; $40 \pm 10\%$ > normal). Systemic vascular resistance does not differ among the groups, but cardiac index decreases with blood volume expansion. Pulmonary capillary wedge and right arterial pressures increase. The expansion of blood volume is associated with progressive reduction of renal blood flow and compensatory increase of renal filtration fraction. Urine flow rate is also decreased in patients with increased blood volume, but is not significantly reduced compared with patients with contracted blood volume. With progressive increase of blood volume, plasma renin activity (ng/mL/hr) is suppressed. Despite diuretic therapy, there may be a range of blood volume expansion, which influences cardiac and renal function. * $P < .05$ by analysis of variance.

significant reduction, and changes in hemodynamics could proceed, or lag, production of diuresis. Such evaluations were conducted in diverse patient populations and must be interpreted accordingly. It has been stated that the vasodilator effect could precede the occurrence of diuresis, but the database for this effect is limited. Studies have reported either vasoconstriction,¹⁶ or initial vasodilation followed by vasoconstriction¹⁷ with acute or short-term follow-up. A review of the cited literature therefore reveals a fully divergent range of hemodynamic response to diuretics, although the majority of acute studies demonstrate a reduction of cardiac filling pressures.¹²⁻¹⁵ Loop diuretics have been shown to decrease renal vasculature resistance and to increase total and cortical renal blood flow.^{13,18,19} However, this may be related to severity of heart failure.²⁰ It is difficult to isolate a single neurohormonal factor as being primarily responsible for the overall hemodynamic and regional hemodynamic response to diuretics. Acute diuretic therapy may increase renin and aldosterone.^{16,17,20,21} Sympathetic nervous system activity also increases in response to diuretics.^{20,21} The impact of neurohormonal activation is an attenuation of the otherwise favorable effects of diuretics.

Loop Diuretics

As this chapter focuses on acute cardiac decompensation, the response to parenteral diuretic therapy will be emphasized (Table 39-2), without an extensive review of pharmacology. The term loop diuretic has evolved to encompass pharmacologic compounds which exert their primary action on the thick ascending loop of Henle. To reach the intraluminal site of action, these organic acids must first be secreted into the proximal tubule via the organic acid pathway. Once in the lumen, active reabsorption of chloride is inhibited in both the medullary and cortical portions of the loop of Henle. Decreased sodium reabsorption also occurs since the chloride ion is cotransported with sodium and potassium.

The three loop diuretics traditionally used in the United States to treat the edema of heart failure are furosemide, bumetanide, and torsemide. They are of equal efficacy but vary in pharmacokinetic properties.^{11,22} Ethacrynic acid remains available, but has a progressively diminishing role for edema management.²³⁻²⁵ Despite equal efficacy among loop diuretics, clinicians will often substitute one for the other with the hope of improved efficacy. Torsemide has a greater duration of action than its counterparts, but in general, the strategy of changing from one loop diuretic to another is typically not effective.

After oral administration, furosemide has 40% bioavailability, bumetanide has 80%, and torsemide has greater than 80% bioavailability. A diminished diuresis and a prolonged renal elimination of the drug may be expected in heart failure when renal dysfunction is evident. Torsemide has two active metabolites, which probably accounts for its longer elimination half-life of 3 hours. Residual loop diuretic concentration is eliminated by nonrenal mechanisms, including hepatic degradation and excretion. Because of the differences in bioavailability and potency, equivalent doses of bumetanide, furosemide, and torsemide are 1 mg, 40 mg, and 20 mg, respectively. All three agents are extensively bound to plasma proteins and are rapidly secreted by the organic acid pathway of the proximal tubule. In chronic renal failure, competition for this pathway by exogenous and accumulated endogenous organic acids causes lower peak concentration of the drug at its site of action. Therefore, a diminished diuresis and a prolonged renal elimination of the drug may be expected in heart failure when renal dysfunction is evident. The diuretic effect is apparent within 30 minutes after oral administration and peaks in 1 to 2 hours.²⁶⁻³⁰ Bumetanide has a somewhat shorter duration of action than that of furosemide or torsemide. Torsemide, like other loop diuretics, must be secreted into the urine by the organic acid secretory system in the proximal tubule to be effective.²³ It produces a maximum sodium excretion rate at approximately the same time with either intravenous or oral administration. Although the pharmacokinetics of torsemide are linear, increases in doses above 50 mg do not appear to increase the maximum sodium excretion rate but do increase the duration of the pharmacodynamic effect. One study has defined a ceiling dose of 100 mg of torsemide in patients with renal insufficiency and has recommended that repeated administration of torsemide is more effective than increasing the dose at this point.²³ It has been shown in another study that 20 mg of intravenous torsemide is approximately as effective as 40 mg of intravenous furosemide.²⁴ However, additional well-controlled trials of torsemide are necessary to determine whether it provides clinical benefit beyond current loop diuretics.

Thiazides and Potassium-Sparing Diuretics

Thiazide diuretics are derivatives of the benzothiadiazine structure.^{11,22} Like loop diuretics, they are organic acids and are highly protein-bound. Since they cannot be filtered, they gain access to the tubular lumen via the organic acid secretory pathway of the proximal tubule. Chlorothiazide is the only thiazide available in a soluble form that permits intravenous administration. This

Table 39-2. Pharmacokinetics of Intravenous Diuretics: Are there appreciable differences?

Drug	Route	Onset	Peak	Duration	Dosage*
Loop Diuretics					
Ethacrynic acid	IV	5 min	15-30 min	2 hr	50-100 mg
Furosemide	IV	5 min	30 min	2 hr	20-120 mg
Bumetanide	IV	5 min	30-45 min	2 hr	0.5-1 mg
Torsemide	IV	5 min	15-30 min	4-6 hr	20-100 mg.
Thiazide					
Chlorothiazide	IV	15 min	30 min	2 hr	250-500 mg

formulation has recently been discontinued and limited stores remain. Its appreciable benefits, combined with an intravenous loop diuretic, are now of historical interest. Oral hydrochlorothiazide or metolazone are effective in most cases, but delayed gastric and small bowel absorption are common in the presence of severe edema. Despite this limitation, the combination of loop and thiazide diuresis appreciably augments diuresis. Experimental animal data demonstrate reactive hypertrophy of the distal nephron during long-term sodium depletion.³¹ With distal nephron tubular hypertrophy, the blockade of sodium reabsorption produced by a loop diuretic at the thick ascending limb is often attenuated. This adverse structural adaptation is overcome by the addition of a thiazide type of diuretic, which blocks sodium reabsorption at the distal nephron.

Although potassium-sparing diuretics uniformly act at the distal nephron and collecting duct, their effect is achieved by two different mechanisms.^{11,22} Active sodium reabsorption in the distal tubule and the collecting duct occurs in exchange for potassium and hydrogen. One mechanism is mediated by aldosterone and may be antagonized by spironolactone, which is a competitive receptor antagonist. The effects of triamterene and amiloride are independent of mineralocorticoids, and they act by direct inhibition of sodium transport. Differing from spironolactone, these two drugs must first reach their site of action by means of glomerular filtration and the organic base secretory pathway of the proximal tubule. Overall, these agents decrease sodium reabsorption, potassium excretion, and theoretically potentiate hyperkalemia, although the latter is uncommon in heart failure. Pharmacokinetic properties of the potassium-sparing diuretics help explain their differences in onset and duration of action. Onset of diuretic action occurs rapidly, 2 to 4 hours with amiloride and triamterene. This effect may persist for 24 hours despite early peak plasma concentrations and an elimination half-life of 6 to 9 hours. Following a single oral dose of spironolactone, peak serum concentrations of the parent drug are seen in 1 to 2 hours, whereas the active metabolites peak in 2 to 4 hours.

Although spironolactone is traditionally considered a potassium diuretic, its greatest benefit is as an antialdosterone agent. The RALES trial demonstrated significant clinical and survival benefit, independent of a diuretic effect. Survival included a significant reduction of sudden cardiac death compared with a placebo.

Practical Considerations

The Cycle of Sodium and Water Management in Heart Failure

When a patient can no longer be managed as an outpatient—for persistent severe edema, weakness, fatigue, or dyspnea, or when acute decompensation occurs in an otherwise stable heart failure patient—hospitalization is warranted. A decision to pursue parenteral therapy should be initiated from the moment of admission, while diagnostic studies are pending (Table 39-3). This should include intravenous diuretics and electrolyte replacement. This includes intravenous inotropic support such as dobutamine.⁸ When afterload reduction is desired, intravenous nitroprusside can be used. An alternate approach to vasodilation is the use of intravenous milrinone, which has both inotropic and direct vasodilator properties. Intravenous nitroglycerin is frequently used to treat acute decompensation of heart failure, but it is important to remember that most patients demonstrate hemodynamic tachyphylaxis within the first 24 hours of administration, so that hemodynamics return toward baseline and are not significantly different than a placebo. In view of the diverse causes of acute cardiac decompensation, the initial therapeutic intervention should be accompanied by appropriate diagnostic studies to identify the etiology of cardiac decompensation to plan more tailored therapeutic interventions.

Optimizing Intravenous Diuretic Response

Intravenous diuretic therapy may be used acutely in several clinical situations. In pulmonary edema, the obvious benefit of acute intravenous diuretic therapy is the rapid clearance of pulmonary congestion, likely mediated by natriuresis and diuresis, a reduction of intravascular volume, and vasodilation. As subacute decompensation is a prelude to pulmonary edema, the goals of intravenous diuretic therapy are similar to the treatment of pulmonary edema. The primary goal of intravenous diuretic therapy is the elimination of edema; concerns regarding adverse activation of neurohormonal activity and electrolyte depletion are of lesser importance, although potassium and magnesium intake should be supplemented. For acute reversal of sodium retention and fluid overload, therapy with a loop diuretic is indicated. It should be given intravenously to a ceiling dose that is twice the normal dose (e.g., furosemide 80 mg; bumetanide

Table 39-3. Fluid Management to Minimize Hospitalization Frequency and Duration

Outpatient Management	Inpatient Management	
	At Admission	At Discharge
- Identify target diuretic dosage - Daily weights 2000 mg sodium intake limit 2-3 liter fluid Limit - Phone check for patient status - BNP measurement* - Patient and family education regarding fluid retention	- Identify contributing etiologies for decompensation - Intensify diuretic therapy: - intravenous route - combination of diuretics - Fluid restriction - Inotropic agents? - AVP antagonist (hyponatremia) - Additional supporting therapy?	- Treat/correct/mitigate factors producing edema - Reset oral diuretic regimen - Resume/reset ACE inhibitor dosage - Add thiazide diuretic if necessary - Add spironolactone for survival benefit and electrolyte effects - Patient and family education regarding fluid retention

*At the time of this writing, BNP measurement is not recommended for routine follow-up of all patients. However, for problematic management issues, for long distance telemanagement, and for patients with significant chronic lung disease, the status of BNP plasma levels provides very useful information for trends of fluid retention and pulmonary congestion.

2 mg; torsemide 40 mg) and increased as necessary, combined with other agents. A thiazide type of diuretic in combination with a loop diuretic is often very effective.³²⁻³⁵ However, an oral thiazide type of diuretic, particularly metolazone, may require several days to achieve its maximal favorable response because of delayed absorption. The ability to use intravenous chlorothiazide (Diuril) is often overlooked. Unlike hydrochlorothiazide, chlorothiazide can be given intravenously in a dose of 250 to 500 mg, which is equivalent to oral hydrochlorothiazide dosage of 25 to 50 mg; when combined with a loop diuretic, it will produce greater diuresis than the loop diuretic alone. This is further discussed in the section dealing with resistance to diuretics.

Diuretic-Induced Electrolyte Imbalance

Electrolyte abnormalities in congestive heart failure are due to both the underlying pathophysiology and the concurrent administration of diuretic therapy.²² The pathologic factors predisposing to electrolyte abnormalities include abnormal neurohormonal activation and marked reduction of renal blood flow and function. Angiotensin II will impede the excretion of a given sodium load by direct effects on the tubular cells of the nephron. The enhanced stimulation of aldosterone secretion because of angiotensin II results in potassium excretion and sodium retention at the distal nephron. This not only contributes to sodium retention, but also results in total body potassium depletion and hypokalemia. Magnesium excretion is coupled with potassium excretion in the exchange for sodium. Hyponatremia is a hallmark of heart failure. Although well-correlated with activation of the renin system (and a good surrogate of this activity), its occurrence is the result of enhanced arginine vasopressin activity at the D2 vasopressin receptor site of the distal nephron tubule. Activation of the D2 receptor reduces free water clearance. This solute-free retention of water, combined with excessive dietary intake of sodium and water, results in hyponatremia; this is a common chronic occurrence in heart failure.^{44,45} In addition to the imbalance produced by abnormal neurohormonal activation, electrolyte imbalance is sustained by the chronic renal insufficiency that occurs in the majority of heart failure patients. Furthermore, diuretics produce hypokalemia, hyponatremia, hypocalcemia, hypomagnesemia, hyperuricemia, and metabolic alkalosis.^{46,47} Hypokalemia is the most common electrolyte disturbance, mediated by direct tubular mechanisms and hypersecretion of aldosterone. Hypokalemia and hypomagnesemia may be associated with myalgias, leg cramps, and an increase in ventricular arrhythmias. Most patients require the concomitant use of potassium supplements to correct hypokalemia; converting enzyme inhibitors may also reduce potassium loss. Most commonly, diuretic-induced hypokalemia is associated with a metabolic alkalosis and a coexisting chloride deficit. Administration of potassium by the intravenous route is recommended to correct moderate to severe potassium deficits, with or without the occurrence of cardiac arrhythmias. This route is also useful when oral replacement is not feasible or not tolerated because of a decrease in gastrointestinal motility. Oral, slow-release potassium chloride preparations are employed in the chronic management of diuretic-induced hypokalemia. Currently there is no dosage form that is superior to another with respect to the ulcerative effect on the gastrointestinal mucosa. The dosage of KCl is adjusted on an individual basis and is dependent on the use of other medications, such as angiotensin-converting enzyme inhibitors or concomitant diuretics. Generally, patients require

between 40 to 120 mEq/day to maintain potassium homeostasis, but requirements may be increased in the setting of acute diuretic administration.

Acute diuretic therapy also leads to hypomagnesemia.⁴⁸ Magnesium, primarily an intracellular ion, plays a pivotal role in mitochondrial functions, oxidation-phosphorylation reaction, and neuromuscular transmission.⁴⁹ Potassium and magnesium have an interrelationship, whereas magnesium is a cofactor in the appropriate function of the sodium-potassium ATPase pump. Therefore, hypokalemia may persist until the magnesium deficiency is corrected. Although normal serum magnesium concentrations range from 1.6 to 2.0 mEq/L, only 1% of magnesium is found in the extracellular compartment. The potential problem of magnesium deficiency in the heart failure population is the occurrence of lethal cardiac arrhythmias. Intravenous supplementation is essential in this situation. The administration of 2 to 5 g (equal to 16 to 40 mEq) of MgSO₄ by slow IV infusion, at 1 g/hr, to be repeated in 12 hours if needed, will correct magnesium at a satisfactory rate.

Diuretic-Resistant Edema

Patients should be considered to have *diuretic resistance* when they demonstrate progressive edema despite escalating oral or intravenous diuretic therapy.¹¹ Diuretic resistance should be contrasted to *diuretic adaptation*, which involves the activation of counterbalancing endogenous structural or functional mechanisms which tend to limit the clinical effects of diuretics.

The factors which contribute to diuretic resistance have been summarized.^{35,36} Renal insufficiency can reduce tubular secretion of the diuretic and the filtered load of sodium. Therefore, patients with decreased renal function due to heart failure¹ or superimposed age,^{1,6} frequently have reduced responses to diuretics. In addition, studies have demonstrated that indomethacin and other nonsteroidal anti-inflammatory agents reduce the maximal response to furosemide.³⁷ Mesenteric congestion may limit the absorption and bioavailability of orally administered medications.

Escalating dosage of intravenous loop diuretics is the most common approach, and the dosage should be rapidly doubled until the desired effect is produced. An ultra-high dose of loop diuretic may be effective^{38,39}; however, the overall response to ultra-high doses is often unimpressive. Also, continuous intravenous infusion of furosemide after a loading dose has been shown to be as effective at least as intermittent bolus therapy in producing diuresis and natriuresis.

An additional approach is based upon the concept that a continuous infusion of a loop diuretic may be more effective than intermittent bolus administration in terms of net sodium excretion.^{40,41} Careful metabolic studies have demonstrated a greater net sodium excretion using this approach, compared with intermittent bolus administration, despite comparable amounts of bumetanide appearing in the urine.⁴¹ In chronic renal insufficiency, continuous intravenous bumetanide has been shown to produce a greater natriuresis than equivalent bolus intravenous doses. Continuous bumetanide produces lower peak levels and therefore may decrease toxicity of the diuretic in patients with impaired renal function.

Alternatively, and perhaps more physiologic, is the combination of a thiazide and a loop type of diuretic, in view of the structural hypertrophy of the distal nephron described earlier. Although precise dose limits are difficult to define when a patient

achieves a requirement, for instance, of 240 mg of furosemide daily, addition of an intravenous (chlorothiazide) or oral thiazide type of diuretic will be more effective than further increases of the loop diuretic. The combination of loop/thiazide diuretic will be more effective than ultra-high doses of a loop diuretic alone.

In severe acute decompensation, when response to parenteral diuretics is completely attenuated, or in the patient who requires rapid fluid removal, acute ultrafiltration and hemodialysis can be used.^{42,43}

When Diuretics Fail

In acutely decompensated heart failure with edema, the failure of diuretics to adequately reduce edema and improve symptoms is a palpable risk. Several clinical features characterize the patient with diuretic failure. These include severe hypotension, renal impairment and hyponatremia, coexistent disorders such as diabetes, and hypertensive nephrosclerosis which further impair the effective effects of diuretics. This profile is accelerated in the elderly, where reduction of glomerular filtration is a common recurrence factor of the aging process, even in the absence of heart failure. In such circumstances mechanical intervention is necessary.

Ultrafiltration provides the most common and accessible form of sodium and water clearance in the setting of diuretic failure. It requires high flow vascular access and adequate systemic blood pressure to be effective. It can often be accomplished without adverse effects on baseline hemodynamics and renal function. Newer approaches to bedside fluid removal exist, but are sufficiently recent that standardized recommendations cannot be given. In the setting of electrolyte imbalance and insufficient clearance of metabolic catabolic products, hemodialysis is necessary.

To avoid the risk of diuretic failure, associated nephrotoxic agents should be identified and avoided. These include nephrotoxic antibiotics and anti-inflammatory agents with known adverse renal effects. The most notorious among the latter is indomethacin. Agents that also produce interstitial nephritis should be identified and avoided. Paradoxically, long-term administration of loop diuretics in excessive doses may produce interstitial nephritis, and the discontinuance of such therapy may result in spontaneous recovery of diuresis.

Supplemental Therapies for Sodium and Edema Management

Aldosterone Antagonists

There are numerous studies that now confirm the specific benefit of blocking aldosterone through use of spironolactone or eplerenone.⁵⁰ Most trials have examined the chronic effect of aldosterone antagonists, but have also demonstrated that these compounds can be administered safely in the acute care situation. Specific attention should be given to serum potassium in the setting of ACE inhibitor or angiotensin receptor blocker therapy to avoid hyperkalemia. However, most patients receiving large doses of loop diuretics are more at risk for hyperkalemia as indicated previously. Therefore, aldosterone antagonists may aid the correction of hypokalemia.

Vasopressin Antagonists

In contrast to natriuretic peptides, compounds that block arginine vasopressin are associated with a water diuresis (aquaresis) by reversing the retention of solute-free water that is produced

by high circulating levels of vasopressin in heart failure.⁵¹ Early attempts to commercialize effective antagonists of vasopressin over the last 2 decades met with a variety of obstacles. Currently, three vasopressin antagonists have been developed for oral or intravenous administration and are at various stages of development. This class is now being referred to as *vaptans*, and they may block both the D₁ receptor, which regulates vasoconstriction, and the D₂ receptor, which blocks free water clearance by the kidney. Alternatively, vasopressin antagonists may specifically block the D₂ receptor.⁵¹ Administration of these agents has been associated with substantial weight reduction, aquaresis, and correction of serum sodium levels.

The use of this class of agents may bring particular benefit to the management of acute decompensation and edema of heart failure, where extensive edema and clinical compromise cannot be effectively managed by diuretics because of the presence of profound hyponatremia, and one is left with the rather unsatisfactory option of slowly waiting for sodium correction by means of stringent fluid restriction.

Natriuretic Peptides

Since the initial discovery and clinical assessment of natriuretic peptides more than 20 years ago, the anticipation has been that pharmaceutical agents derived from these peptides would provide a physiologic approach to sodium and water management in edema-forming states. In small controlled studies of heart failure, one may demonstrate a small but statistically significant increase of sodium excretion in response to natriuretic peptides.^{52,53} However, these agent do not mount a clinically significant diuresis in heart failure. From the time of initial characterization until the present, heart failure patients should have a blunted response of sodium and water excretion compared with normal subjects when exposed to either oral or intravenous administration of natriuretic peptides. In contrast, the direct vasodilator properties of the natriuretic peptides are retained in heart failure; of the natriuretic peptides, the intravenous formulation of brain natriuretic peptide produces a vasodilator effect that is statistically greater than nitroglycerin, in comparative trials. Based on smaller studies, a small but significant increase of sodium excretion can be detected compared with the placebo. However, the magnitude of the response is meager compared with the response to a dose of loop diuretic, and certainly less than the augmentation that one identifies when a thiazide type diuretic is added to a loop diuretic.

Adenosine Antagonists

It is well recognized that the greatest sodium and water absorption occurs in the proximal nephron. Since loop diuretics work primarily in the thick ascending limb of the loop of Henle, their effectiveness is compromised by the limited amount of sodium that reaches their primary site of action. Blocking the proximal nephron site of sodium reabsorption by antagonizing the adenosine receptor is a well-recognized concept. Newer approaches to the design and delivery of adenosine antagonists have yielded potential adenosine antagonists for intravenous and, potentially, oral administration. Clinical trials of these agents are in progress.¹¹

Positive Inotropic Agents: Augmented Diuresis?

A recurring question is whether dobutamine and milrinone can augment diuresis in the edematous patient with decompensated heart failure. A rationale for this concept can be developed based

on the pathophysiology of decompensated heart failure. Many patients with advanced heart failure have impaired renal function due to hypoperfusion. In that setting, reduction of glomerular filtration produces proximal sodium and water retention, and limits tubular transport of sodium to the loop of Henle, where loop diuretics are effective. It is thus rational to postulate that increasing cardiac output and cardiac decompression produces improved regional perfusion and responsiveness to diuretic therapy. However, adequately controlled studies have not demonstrated improved diuresis attributable to inotropic therapy.

Refocusing Therapy: Acute Decompensated Heart Failure Syndromes

In view of the morbidity and mortality associated with recurring acute heart failure, and its associated heavy economic burden, there is a refocusing of effort toward improving the therapy of patients having acute decompensated heart failure syndromes (ADHFS).^{54,55} This is not a new disease or new constellation of diseases. ADHFS represent the features of heart failure, either acute, or decompensated chronic heart failure, that usually necessitate hospitalization. Because this is a heterogeneous group of patients, it is necessary to remember that there is no single therapy that can be prescribed for all patients. However, diuretics, and newer agents that augment free water clearance (aquaretics) and sodium excretion (natriuretics) will be at the forefront of this therapy, together with traditional diuretics, since excessive fluid retention typically is a major contributing factor to the acutely decompensated state of heart failure.⁵⁶

Conclusion

Diuretics remain the most poorly characterized class of heart failure therapy. These agents are diverse, maximal doses are often exceeded, and guidelines for optimal combinations do not exist. The use of diuretics in acute cardiac decompensation remains a combination of science and art form. The desired end point, in the absence of more objective changes, remains the relief of the symptoms related to edema: dyspnea and congestion. However, a careful use of diuretics in appropriate combination with other more specific therapies of acute cardiac decompensation will produce clinical improvement without adverse consequences.

Sicilian Gambit
Antiarrhythmics of Clinical Relevance in the CCU
Conclusion

CARDIAC ARRHYTHMIAS continue to be a significant cause of morbidity and mortality in the developed world and add to the complexity of management of critically ill patients. Over the past 2 decades treatment strategies have expanded to include other approaches such as catheter ablation and implantable cardiac defibrillators. Although these strategies have demonstrated significant superiority over antiarrhythmics, they have not eliminated the problem of cardiac arrhythmias. Furthermore, these approaches can be difficult to apply to patients in the acute setting. Antiarrhythmic agents continue to be a vital adjunct to these therapeutic approaches.

Despite the important role that antiarrhythmics play to combat cardiac arrhythmias, it has been difficult to overcome the stigma associated with these drugs. This stigma has stemmed from earlier published trials such as the CAST and CAST II trials evaluating class IC antiarrhythmics and the SWORD trial evaluating sotalol in patients with coronary artery disease and left ventricular dysfunction. These trials demonstrated increased mortality, significant side effects, and marginal efficacy.^{1,2,3} The Achilles heel of these agents is their propensity for proarrhythmia that results in more dangerous arrhythmias than the ones they were initially intended to treat. This led to a re-evaluation of the wisdom of using relatively simple agents that took aim at single molecular targets, such as sodium or potassium channels. Subsequently, researchers pursued the development of newer antiarrhythmic agents that target multiple molecules or complex arrhythmogenic pathways, such as amiodarone or d,l-sotalol. There was a renewed interest and emphasis on the use of β -blockers, which do not specifically target ion channels. In addition there has been significant interest in understanding the genetic basis of susceptibility to serious arrhythmias in individuals with genetic syndromes such as long QT and Brugada syndromes.

Despite their potentially serious side effects, antiarrhythmics continue to be a valuable tool when used appropriately and in a targeted manner. The aim of this chapter is to provide a clear and concise overview of the physiologic basis and applicable pharmacology that makes these drugs useful, and to discuss the ones most clinically relevant to the management of the acutely ill patient.

Physiology

Normal cardiac electrical activity is determined by the shape of the cardiac action potential. Antiarrhythmic agents exert both desirable therapeutic effects and undesirable side effects by their capacity to alter the shape of the action potential. These actions are mediated by their ability to affect the ion channels that control it. Therefore, a review of the basic physiology of the cardiac action potential is imperative to understanding the mechanism of action of these drugs.

Over the past 2 decades our knowledge and understanding of cardiac cellular electrophysiology has increased as a result of cutting edge techniques, such as the cloning and sequencing of proteins and ion channels. A detailed description of the many ion channels discovered to date, and their respective roles, is beyond the scope of this chapter. A more fundamental approach to the basic principles that produce the action potential is described.

A simplified model of the His-Purkinje action potential (fast response tissue) is discussed first followed by descriptions of the action potential of the sinoatrial (SA) and atrioventricular (AV) nodes (slow response tissue).

His-Purkinje Action Potential

The His-Purkinje action potential can be conceptually divided into periods of depolarization, repolarization, and resting states. However, the action potential is traditionally divided into five different phases (phases 0-4) to describe the activity of various ion channels that bring about any of these three states (Fig. 40-1, A and B). Phase 4 corresponds to the resting state when the cell is not being stimulated and is ready for subsequent depolarization. Phase 0 corresponds to depolarization of the myocardial cell. It initiates a cascade of events involving the influx and efflux of multiple ions, leading to phases 1-3, manifesting in repolarization and refractoriness.

Phase 4

The normal resting membrane potential in the ventricular myocardium is between -85 to -95 mV. This membrane potential is determined by the balance of inward sodium (Na^+) and calcium

Figure 40-1. **A**, Ion channels responsible for the His-Purkinje action potential. This diagram shows the action of the various ion channels responsible for the His-Purkinje action potential over the time it takes for a complete cycle of depolarization and repolarization. **B**, Ion flux responsible for the His-Purkinje action potential. This diagram shows the influx and efflux of various ions in the His-Purkinje action potential over a single complete cycle of depolarization and repolarization; this corresponds to the action of their respective ion channels seen in **A**.

(Ca^{2+}) currents and outward potassium (K^+) current. The equilibrium potential for a given ion is determined by the concentrations of that ion inside and outside the cell. K^+ is the principal cation intracellularly, whereas phosphate and conjugate bases of organic acids are the dominant anions. Extracellularly, Na^+ and chloride (Cl^-) are the principal cation and anion, respectively. Therefore, when K^+ channels open, K^+ ions flow outside the cell along their concentration gradient, leaving the cell with a more negative membrane potential.

The resting membrane potential is generated by the inward rectifier current (I_{K1}), the predominantly open channel during this phase. The maintenance of this electrical gradient is because of various ion pumps and exchange mechanisms, such as the Na^+ - K^+ ion exchange pump and the Na^+ - Ca^{2+} exchanger current.

This phase of the action potential is associated with cardiac diastole.

Phase 0 (Depolarization)

Rapid depolarization occurs when the resting cell is brought to threshold causing activation (opening) of fast Na^+ channels. This results in rapid influx of Na^+ ions caused by increased cell

membrane permeability to Na^+ . The slope of phase 0 represents the maximum rate of cell depolarization (V_{max}) and governs the conduction velocity of a cardiac impulse through cardiac cells. This can be altered by drugs such as the class I antiarrhythmics, which retard conduction velocity, and V_{max} .

Voltage-gated Na^+ channels can exist in either the resting, open (phase 0), or inactive state. The response of these Na^+ channels is dependent on the membrane potential at the time of stimulation. If the membrane potential is at baseline (-95 mV), then all resting Na^+ channels open simultaneously, resulting in a dramatic influx of Na^+ ions. If, however, the membrane potential is above baseline (less negative), then some Na^+ channels may be in the inactive state and unable to open, resulting in a smaller response with less influx of Na^+ ions (lower V_{max}). This has clinical relevance as class I antiarrhythmics prefer binding to inactive Na^+ channels. Furthermore, this reduced cellular excitability may render cardiac cells prone to variable refractoriness, delayed conduction, and various arrhythmias.

Phase 1 (Early-Rapid Repolarization)

This phase represents the initial stages of cellular repolarization and is caused predominantly by closure of the fast acting Na^+ channels. However, the net downward deflection of the action potential is also attributable to transient outward flux of K^+ ions as a result of two K^+ channels ($I_{to, fast}$ and $I_{to, slow}$) opening and then closing.

Phase 2 (Plateau)

Although this phase may appear to be a particularly stagnant part of the action potential, it is in fact one of the most complex and dynamic portions. Multiple ions make small contributions resulting in a relatively constant, positive value of the membrane potential. The predominant forces are outwardly directed K^+ ions and inwardly directed Ca^{2+} ions, which maintain an equal balance. The outward flux of K^+ through the delayed rectifier K^+ channel (I_{Kur}) and through the ADP activated K^+ channel (I_{KATP}), is balanced against rapid inflow of Ca^{2+} through L-type Ca^{2+} channels ($I_{Ca, L}$).

The plateau phase is unique to the cardiac cell and represents an interruption to rapid repolarization, extending the duration of the action potential and therefore the refractoriness of the cardiac cell. The benefit of this is to allow for a single contraction of myocardium to occur before the generation of a subsequent action potential, thus the heart can never be "tetanized," which would be incompatible with cardiac function.⁴

Phase 3 (Repolarization)

L-Type Ca^{2+} channels are now closed while slow delayed rectifier K^+ (I_{Ks}) channels are open and trigger opening of other channels, such as the rapid delayed rectifier K^+ channel (I_{Kr}). This results in a net outward flux of positive cations, thereby facilitating cellular repolarization. The I_{K1} channel is activated late in phase 3 and continues on to contribute to the resting membrane potential of phase 4.

SA Node and AV Node Action Potential

SA and AV nodal action potentials are very similar with only minor differences between them in phase 0. They are significantly different from fast response tissue's action potentials

Figure 40-2. **A**, Ion channels responsible for the sinoatrial/atrioventricular (SA/AV) node action potential. This diagram shows the action of the various ion channels responsible for the SA/AV node action potential (slow response tissues) over the time it takes for a complete cycle of depolarization and repolarization. **B**, Ion flux responsible for the SA/AV node action potential. This diagram shows the influx and efflux of various ions responsible for the SA/AV node action potential (slow response tissues) over a single complete cycle of depolarization and repolarization; this corresponds to the action of their respective ion channels seen in **A**.

previously described. These slow response tissue action potentials are divided into three phases instead of five (Fig. 40-2, A and B). Phase 4 is the spontaneous depolarization (pacemaker potential) phase that triggers the action potential once the membrane potential reaches threshold (between -40 and -30 mV). Phase 0 is the depolarization phase of the action potential. This is followed by phase 3 repolarization. Once the cell is completely repolarized at about -60 mV, the cycle is spontaneously repeated.

Phase 4—Spontaneous Depolarization (Pacemaker Potential)

The unique firing of pacemaker cells is attributable to their capacity to slowly and spontaneously depolarize. The resting potential of a pacemaker cell (-60 mV to -70 mV) is caused by ongoing efflux of potassium ions. Potassium permeability decreases with time, contributing to the slow depolarization. Additionally a slow inward flow of sodium, called the “funny

current” (I_f) and an inward flow of calcium through T-type calcium channels (ICa_T) all make the cell more positive. When the threshold potential (-40 mV to -50 mV) is reached, the cells enter the depolarization phase.

Phase 0—Depolarization

The predominant ion activity during this phase is dependent on the influx of calcium through L-type calcium channels as opposed to sodium influx in fast response tissues. In fact I_{Na} channels are largely absent from these cells.

The upstroke (V_{max}) and therefore the conduction velocity in a pacemaker cell is significantly slower than in the fast response tissue cells, with the AV node action potential demonstrating a faster V_{max} than that of the SA node.⁵

Phase 3—Repolarization

Calcium channels are rapidly inactivated with simultaneous decrease in sodium permeability. This is combined with increased potassium permeability with resultant efflux of potassium, slowly repolarizing the cell once more to its resting potential.

Autonomic Innervation

Both sympathetic and parasympathetic nerve fibers are abundantly found in both the SA and AV nodes; however, parasympathetic nerve fibers are only minimally located in fast response tissue. Therefore, parasympathetic tone fluctuations are notable in the SA and AV nodes with minimal or no effect on fast response tissue.

Increased sympathetic tone results in enhanced automaticity, increased conduction velocity (V_{max}), and decreased refractoriness. These effects combine to produce an increased number of action potentials that are propagated faster. Increased parasympathetic (vagal) tone has the opposite effect, with diminished automaticity and conduction velocity but increased refractoriness. These observations have an important impact on clinical arrhythmias and their management.

It is helpful to keep in mind the various roles of ion channels on the different stages of the action potential, in both fast and slow response cells, to achieve an understanding of the potential key effects of antiarrhythmic agents. In addition, the Vaughan-Williams classification of antiarrhythmic drugs is based upon which ion channels they affect.

Classification

Vaughan-Williams

This is currently the most widely used classification of antiarrhythmic drugs (Table 40-1). This classification was initially introduced by Vaughan Williams^{6,7} and was based on the electrophysiologic effects of antiarrhythmics. It was later modified by Harrison⁸ with the recognition that drugs in the same class have different potencies and that the same drug may exert multiple class effects.

Amiodarone has effects across all classes, blocking Na^{+} channels in depolarized tissues, but is also capable of affecting Ca^{2+} and K^{+} channels and adrenergic receptors. This makes it an extremely versatile drug capable of affecting a wide variety of arrhythmias. Sotalol has a significant β -blocker effect in addition to its class III action. Ibutilide can also enhance the slow delayed sodium current. Although moricizine has diverse effects

Table 40–1. Vaughan-Williams Classification of Antiarrhythmics and Their Mechanism of Action

Class	Mechanism	Drugs
I	Na ⁺ channel blockers	
A	Slows conduction velocity (V _{max}) and prolongs action potential. Results in decreased conductivity and increased refractoriness.	Quinidine, procainamide, disopyramide
B	Minimal effect on conduction velocity (V _{max}) and shortens action potential duration. Results in decreased refractoriness.	Lidocaine, mexiletine
C	Significant slowing of conduction velocity (V _{max}), minimal effect on action potential duration. Results in decreased conductivity and no change in refractoriness.	Flecainide, propafenone, moricizine
II	β-blockers Decrease sympathetic tone affecting SA and AV nodes	Atenolol, esmolol, propranolol
III	K ⁺ channel blockers No effect on conduction velocity with significant increase in action potential duration. Results in no change in conductivity but marked increase in refractoriness.	Amiodarone, sotalolol, dofetilide, ibutilide, azimilide
IV	Ca ²⁺ channel blockers Affect SA and AV node by direct cell membrane effects	Verapamil, diltiazem (non-dihydropyridine)
V	Other mechanisms Affect SA and AV nodes by increasing vagal tone	Digoxin, adenosine

across different classes, this drug is not currently used because it has been demonstrated to increase mortality.

Class I Antiarrhythmics and Use Dependence

Class I drugs are all Na⁺ channel blockers with varying potency and are classified based on their effect on the action potential upstroke or V_{max} and therefore their ability to alter conduction velocity. They can prolong it, shorten it, or have no net effect (Fig. 40-3). Their different potency is due to variable rates of binding and dissociation from the channel receptor.⁹ Class IC are the most potent Na⁺ channel blockers because they have the slowest binding and dissociation from the receptor; class IA are the least potent (fastest binding and dissociation); and class IB are moderately potent. Faster heart rates allow less time for drug-receptor dissociation, resulting in an increased total number of blocked receptors and more effective antiarrhythmic action. This is known as “use dependence” and is most noted with class IC agents.¹⁰ These effects can result in prolonged conduction velocity and manifest by widening of the QRS complex on the surface electrocardiogram (ECG), especially during tachycardia.

Class III Antiarrhythmics and Reverse Use Dependence

Class III antiarrhythmic agents extend the plateau phase of the action potential by blocking K⁺ channels. They effectively prolong repolarization and the action potential duration with a resultant increase in refractoriness without a change in conductivity (Fig. 40-4). This manifests as prolongation of the Q–T interval on the surface ECG. These effects are most pronounced during slow heart rates. This is known as “reverse use dependence” and thus, longer Q–T intervals are noted at slower heart rates.¹¹ This provides the potential for dangerous arrhythmias such as torsades de pointes.¹² This is known as proarrhythmia and is one of the most serious, life-threatening side effects associated with antiarrhythmic drug use. Amiodarone, however, appears to be the exception, with proarrhythmia being reported only uncommonly.¹³

Figure 40-3. Effect of class I antiarrhythmics on the His-Purkinje action potential. All class I antiarrhythmics retard the slope of phase 0 of the action potential resulting in a decrease of V_{max} and a decrease in the conduction velocity of the cardiac cell. Class IC agents slow the upstroke of the action potential (V_{max}) the most, resulting in prolongation of the action potential. This prolongation causes a marked decrease in conductivity, but has little overall effect on the effective refractory period. Class IC agents do not alter refractoriness significantly. Class IA agents slow the upstroke (V_{max}) moderately, prolonging the action potential, decreasing conduction velocity, and increasing refractoriness. Class IB agents have a very small effect on the V_{max}, shortening the action potential, which results in an overall decrease in refractoriness.

Class II Antiarrhythmics

These drugs act by competitive inhibition of the β-adrenergic receptor, and largely affect the SA and AV node. Yet they also have mild Na⁺ channel inhibitory effects. There is a preponderance of data demonstrating the antiarrhythmic properties of β-blockers. β-blockers have played an increasingly important role in increasing survival in patients with coronary heart

Figure 40-4. Lengthening of effective refractory period on class III antiarrhythmics. All class III agents cause a blockade of K^+ channels. As a result, the rate of outward flux of K^+ is slowed down during phases 2 and 3, which causes a prolongation of the time it takes a cardiac cell to return to the resting membrane potential. This prolongs the effective refractory period of the cardiac cell, resulting in an increased time before it is ready for the subsequent depolarization.

disease and congestive heart failure, along with adjunctive therapy to implantable cardiac defibrillators (ICDs) by decreasing the incidence of sudden cardiac death (SCD). Although not all of the beneficial effects of β -blockers are understood it is likely that they essentially work by reversing or preventing the proarrhythmic actions of sympathetic activity.¹⁴ These include increased automaticity because of enhanced phase 4 depolarization in the SA and AV nodes, increased membrane excitability in phase 2 and 3 of the His-Purkinje action potential, increased V_{max} , and increased delayed afterpotentials, which can lead to increased triggered activity type arrhythmias. They are therefore most effective in tissue under intense adrenergic stimulation (e.g., in ischemia) and it is not surprising that their effects are most obvious in patients having acute myocardial infarction and decompensated heart failure.

Class IV

The non-dihydropyridine calcium channel blockers (verapamil and diltiazem) are the only ones that exhibit significant electrophysiologic and antiarrhythmic properties. These are mediated through their ability to block the slow calcium channel. Their antiarrhythmic properties are exerted through two main effects. Their most prominent activity is to block the slow calcium channel in the action potential of the SA and AV node, effectively slowing phase 4 spontaneous depolarization. This results in a variable slowing of the heart rate (similar to β -blocker-induced adrenergic blockade)¹⁵ and slowing conduction through the AV node, manifested by bradycardia and prolongation of the P-R interval on the surface ECG.

The other action is their ability to shorten the plateau phase of the action potential of ventricular myocytes, therefore inhibiting early afterdepolarizations (EADs).¹⁶ EADs are due to fluxes in calcium and appear to occur mostly under conditions that prolong the action potential (e.g., hypoxia, drug induced), giving rise to torsades de pointes. Therefore, calcium channel blockers may play an active role in the prevention of these types of arrhythmias.

Atypical Agents (Class V)

Although there is no designated class V in the Vaughan-Williams classification of antiarrhythmics, it is unofficially used to place atypical agents whose antiarrhythmic properties do not belong

to any of the other ion-based antiarrhythmics. These include drugs such as digoxin and adenosine and will be discussed individually later in the chapter because of their potential utility in the critical care setting

Sicilian Gambit

Although the merits of the Vaughan-Williams classification are its simplicity and wide recognition, providing a useful mode for communication regarding the use of antiarrhythmics, it does not take into account several complexities. These include drugs' ability to exert effects that cross into different classes, having variable potencies within the same class, and causing other effects such as changes in metabolism, autonomic stimulation, or hemodynamics. The Sicilian gambit¹⁷ (Table 40-2) was introduced as a method of rationalizing the approach to the use of antiarrhythmics. Although not widely known and far more complex in its original format, it is included here for its emphasis on approaching antiarrhythmic drug choice based on the mechanism of each individual arrhythmia and the perceived "vulnerable parameter" that can be affected to terminate it.

Pharmacology

Pharmacologic concerns of drug therapy can be divided into two main disciplines. The first is pharmacokinetics, which describes the process of drug delivery to its target site. It encompasses the processes of drug absorption, distribution, metabolism, and elimination. This can be summarized in the relationship between drug dose and plasma concentration over time. This should not be confused with pharmacodynamics, which describes target-specific drug interaction, and the resultant downstream whole body effects. This can be thought of as the relationship between drug concentration and magnitude of drug effect.

Obviously, both of these processes can then be impacted by various factors such as drug absorption, bioavailability, volume of distribution, drug clearance, elimination, and half-life. Due to the complexity of drug transport and activity, genetic variability, and the heterogeneous and often abnormal metabolic milieu of the critically ill patient, significant interpatient variability can be expected in their response to the same drugs.

Drug Absorption

This is the process by which orally administered drugs are taken up from the gastrointestinal tract and enter into the systemic circulation. Bioavailability describes the percentage of drug that reaches the circulation unchanged, as compared with intravenous drug administration, which represents 100% bioavailability.

In general, bioavailability can be altered by two main factors. The first considers the successful gut uptake of the drug, which can be affected by various factors such as drug dissolution rates, different formulations, gastric pH levels, and bacterial flora. The second main factor is presystemic (first pass) clearance through the liver, where drugs may undergo metabolism, alteration, or excretion by hepatocytes into the bile, thereby affecting bioavailability.

With rare exceptions, most drugs administered in the critical care setting are administered in the intravenous form and therefore many of the issues surrounding drug absorption do not apply in this circumstance.

Table 40–2. Sicilian Gambit (Modified)*

Mechanism	Arrhythmia	Vulnerable Parameter (Effect)	Drugs (Effect)
Automaticity			
Enhanced automaticity	Inappropriate sinus tachycardia Some idiopathic ventricular tachycardias	Decrease phase 4 depolarization	β -blockers Na^+ channel blockers
Abnormal automaticity	Atrial tachycardia	Maximum diastolic potential (hyperpolarization)	Muscarinic receptor agonists
	Accelerated idioventricular rhythms	Phase 4 depolarization (decrease)	Ca^{2+} or Na^+ channel blockers
Triggered Activity			
Early afterdepolarization (EAD)	Torsades de pointes	Shorten action potential duration Suppress EAD	β -blockers Ca^{2+} channel blocker; Mg^{2+} ; β -blockers
Delayed afterdepolarization (DAD)	Digitalis-induced arrhythmias	Calcium overload (unload) DAD suppression	Ca^{2+} channel blockers Na^+ channel blockers
	Right ventricular outflow tract ventricular tachycardia	Calcium overload (unload) DAD suppression	β -blockers Ca^{2+} channel blockers
Na^+ Channel-Dependent Re-entry			
Long excitable gap	Typical atrial flutter	Depress conduction and excitability	Class IA, IC Na^+ channel blockers
	AV reciprocating tachycardia	Depress conduction and excitability	Class IA, IC Na^+ channel blockers
	Monomorphic VT	Depress conduction and excitability	Na^+ channel blockers
Short excitable gap	Atypical atrial flutter	Prolong refractory period	K^+ channel blockers
	Atrial fibrillation	Prolong refractory period	K^+ channel blockers
	AV reciprocating tachycardia	Prolong refractory period	Amiodarone, sotalol
	Polymorphic and uniform ventricular tachycardia	Prolong refractory period	Class IA Na^+ channel blockers
	Bundle branch reentry	Prolong refractory period	Class IA Na^+ channel blockers; amiodarone
Ca^{2+} Channel-Dependent Re-entry			
	Atrioventricular nodal reentrant tachycardia	Depress conduction and excitability	Ca^{2+} channel blockers
	AV reciprocating tachycardia	Depress conduction and excitability	Ca^{2+} channel blockers
	Verapamil-sensitive ventricular tachycardia	Depress conduction and excitability	Ca^{2+} channel blockers

*Classification of drug actions on arrhythmias based on their ability to modify a vulnerable parameter of the arrhythmia.

Adapted from the Task Force of the Working Group on Arrhythmias of the European Society of Cardiology: The Sicilian gambit: a new approach to the classification of arrhythmic drugs based on their actions on arrhythmogenic mechanisms. *Circulation* 1991;84(4):1831-1851.

Distribution

A drug is distributed to the best perfused tissues first, termed the central compartment, such as the heart, lungs, and brain. Subsequently, it reaches less perfused tissues such as the skin and muscle—the peripheral compartment. Some drugs such as amiodarone have very slow distribution to tissues such as adipose, termed the deep compartment, which prevent it from reaching a steady state until these tissues are saturated.

The volume of distribution (Vd) of a particular drug refers to a theoretical space or volume into which the drug is distributed and can be used to describe the relationship between drug dose and plasma concentration. This can in turn be affected by changes in the actual plasma volume reflected by tissue

perfusion, as can be noted in cases of congestive heart failure or shock. Alternatively, tissue affinity, fraction of drug bound to proteins (only the free portion of a drug produces the desired effect) and degree of lipid or water solubility can all play a role in altering the volume of distribution.

A classic example is lidocaine administration in heart failure patients. The Vd may be reduced by 40%¹⁸ because of decreased perfusion and therefore unless lidocaine bolus doses are reduced in these patients, lidocaine toxicity can result.

Most antiarrhythmics are bound to α_1 -glycoprotein. This protein's concentration increases with acute and critical illness (such as shock, trauma, or severe bacterial infection). The result may be decreased effectiveness of the antiarrhythmic agent

despite an unchanged plasma concentration, as the fraction of unbound (free) active drug is smaller.

Metabolism and Elimination

Most antiarrhythmics are metabolized hepatically by the cytochrome P450 system, and many undergo extensive first pass metabolism. This accounts for the large ratio of oral to intravenous doses of such medicines as verapamil, metoprolol, or propafenone. Others such as lidocaine are so completely eliminated by the first pass effect that oral dosage is useless.¹⁹

Metabolism of the parent drug produces metabolites that may or may not be active. Furthermore, these metabolites may have similar or different effects than the parent drug. Classic examples include amiodarone metabolism to desethylamiodarone, which accounts for a persistent drug effect beyond the drug's half-life. Procainamide, however, a class Ia agent, is metabolized to *N*-acetylprocainamide (NAPA), which has a predominant class III effect.

A drug's half-life describes the time required to reduce a plasma drug concentration by 50%. This may be secondary to either drug metabolism and elimination or redistribution. It typically requires five half-lives to eliminate a drug from the plasma completely and five half-lives to achieve a steady state. Since only three doses are required to achieve greater than 90% steady state plasma concentrations, drug loading doses should only be used when such an interval is clinically unacceptable such as in life-threatening arrhythmias in critically ill patients. In such situations, a loading dose may be given to achieve desirable plasma concentration levels much faster.²⁰

Antiarrhythmics of Clinical Relevance in the CCU

Although detailed accounts of every antiarrhythmic are available elsewhere, the focus of this review is to discuss the antiarrhythmics that have the most clinical relevance to the management of the critically ill patient in the acute care setting. Older medications no longer in current use and those that cannot be administered intravenously or are contraindicated in critical illness are not discussed (Table 40-3).

Class IA

Of the drugs in this class, procainamide is the only agent with a potential role in the modern critical care setting.

Procainamide

Procainamide is a Na⁺ channel blocker that results in reduced V_{max} associated with decreased conduction velocity and prolongation of the His-Purkinje action potential, and therefore the effective refractory period.²¹ Its effect on prolongation of the action potential is mediated through its active metabolite *N*-acetylprocainamide (NAPA), which is a class III antiarrhythmic agent. In addition it can suppress automaticity in slow response tissues (SA and AV nodes)²² and triggered activity in normal Purkinje fibers.²³

Clinical Effects

The surface ECG may reflect prolongation of the P-R interval and QRS intervals without significant effect on the RR interval.²⁴ Widening of the QRS is increased at faster heart

rates or high plasma concentrations.²⁵ Widening of the QRS to greater than 25% has been recommended as a useful end point of procainamide's myocardial effect.²⁶ In addition, prolongation of the Q-T interval can be seen and may herald proarrhythmia.

Indications

Intravenous procainamide continues to be the drug of choice for the acute treatment of atrial fibrillation in Wolf-Parkinson-White syndrome. However, ibutilide, as an alternative, has also been shown to be effective for this.²⁷ Procainamide's effect is achieved through suppression of both antegrade and retrograde conduction across accessory pathways, which reflects its ability to increase refractoriness and decrease conduction velocity in cardiac tissue.

Procainamide has been recommended above amiodarone and lidocaine (level of evidence IIA) for acute resuscitation of hemodynamically stable wide complex tachycardia in patients with normal cardiac function.²⁸⁻²⁹ Amiodarone, however, has been advocated as an alternative. This is because of the fact that both agents are effective in the treatment of ventricular and supraventricular tachycardias.

A versatile drug, procainamide can be administered in both an oral and intravenous form. Prolonged oral use of procainamide, however, is not advocated because it is more poorly tolerated than other currently available alternatives and is contraindicated in renal failure. Furthermore, the EVSEM trial demonstrated procainamide and other class I agents to be less effective in the treatment of ventricular tachyarrhythmias than sotalol and amiodarone.³⁰

Dosage and Administration

In the acute setting, it is administered with a loading dose of 15 to 18 mg/kg over 20 to 30 minutes, but this dose should be reduced to 12 mg/kg in significant renal or cardiac impairment. Blood pressure and continuous ECG monitoring is mandatory to detect acute hypotension, QRS, and Q-Tc prolongation. Alternatively, it can be administered intravenously at a dose of 100 to 200 mg over 5 minutes to a maximum dose of 1000 mg. ACLS guidelines suggest infusing 20 mg/min until arrhythmia is controlled, hypotension occurs, QRS complex widens by 50% of its original width, or a total of 17 mg/kg is given. Maintenance intravenous infusion is administered at a dose of 1 to 4 mg/min.

Pharmacokinetics

Procainamide is acetylated in the liver by *N*-acetyltransferase to *N*-acetylprocainamide (NAPA), an electrophysiologically active product with antiarrhythmic class III properties. This product has a plasma half-life of 4 to 15 hours and is renally cleared. Rate of acetylation varies individually and variation in renal clearance makes monitoring of both procainamide and NAPA levels mandatory (sum of <80 μM) to prevent proarrhythmia, especially torsades de pointes.

Side Effects

Procainamide is associated with a host of side effects that include blood dyscrasia with potentially life-threatening pancytopenia and agranulocytosis, which may be mediated by either allergic, hypersensitive, or immunologic mechanisms. This can occur days to weeks after drug initiation, and necessitates immediate

Table 40–3. Commonly Used Antiarrhythmic Agents in the ICU

Drug	Usual Dosage Ranges				Half-Life (hr)	Bioavailabil-ity (%)	Metabolism	Pregnan- cy Class
	Intravenous (mg)		Oral (mg)					
	Loading	Maintenance	Loading	Maintenance				
Procain- amide	12-18 mg/kg at 0.2-0.5 mg/kg/min	1-4 mg/min	500-1000	250-1000 q4-6h	3-5	70-85	Kidneys	C
Lidocaine	1-3 mg/kg at 20-50 mg/ min	1-4 mg/min	N/A	N/A	1-2	N/A	Liver	B
Propranolol	0.25-0.5 mg q 5 min to ≤ 0.20 mg/ kg			10-200 q6-8h	3-6	35-65	Liver	C
Amiodarone	15 mg/min for 10 min, 1 mg/min for 6 hr, 0.5 mg/min thereafter	0.5-1 mg/min	800-1600 qd for 7-14 days	200-600 qd	56 day	25	Liver	D
Ibutilide	1 mg over 10 min	N/A	N/A	N/A	6		Kidneys	C
Dofetilide	2 to 5 µg/kg infusion	N/A	N/A	0.125-0.5 q12h	7-13	90	Kidneys	C
Verapamil	5-10 mg over 1-2 min	0.005 mg/kg/ min		80-120 q6-8h	3-8	10-35	Liver	C
Adenosine	6-18 mg (rapidly)	N/A	N/A	N/A				C
Digoxin	0.5-1.0 mg	0.125-0.25 qd	0.5-1.0	0.125-0.25 qd	36-48	60-80	Kidneys	C

discontinuation of the drug. Cardiac side effects include left ventricular dysfunction, hypotension, and proarrhythmia with Q–T prolongation and torsades de pointes. Other nonspecific systemic side effects include gastrointestinal disturbances with nausea and vomiting, induced systemic lupus erythematosus syndrome, pyrexia, headache, and psychosis.

Class IB

Both lidocaine and mexiletine are included in this classification; however, mexiletine is only available in an oral form, which limits its use in the critical care setting. It may be helpful in suppressing automatic or re-entrant ventricular arrhythmias but this is only as an adjunct to other primary antiarrhythmics.

Lidocaine

Lidocaine is a Na⁺ channel blocker of intermediate potency and results in a decrease in V_{max} and therefore decreased conduction velocity. In contrast to class IA or IC antiarrhythmics, lidocaine causes a shortening of the action potential duration probably through an increase in I_{K1} activity.³¹ It also depresses automatic activity by decreasing the slope of phase 4 diastolic depolarization. These effects are limited to Purkinje fibers

and little or no effect is seen on atrial myocardium or on slow response tissues (SA and AV nodes).³² Interestingly, published data from prior trials demonstrated an increased incidence of asystole and bradycardia with lidocaine use³³; however, this has been debated.

Clinical Effects

Lidocaine is typically very well tolerated hemodynamically. Only rarely, with very high doses, is blood pressure and cardiac output depressed due to reduced contractility and ejection fraction. At therapeutic doses, there are no detectable changes on the ECG.³⁴

Indications

The role of lidocaine use and its potential benefits in acute myocardial infarction has been the source of heated debate as far back as the 1960s. Although earlier studies pointed to a decreased incidence of primary ventricular fibrillation and therefore reduced mortality, they were limited by lack of randomization and small sample sizes. Subsequent studies using prophylactic lidocaine in acute myocardial infarction demonstrated a decreased incidence of ventricular fibrillation but no significant decrease in all-cause mortality.³⁵⁻³⁶ Subsequent

meta-analyses also demonstrated a decreased incidence of ventricular fibrillation but not overall mortality.^{33,37-39} These findings were further compounded by an increasing body of evidence associating prophylactic antiarrhythmics with increased mortality, including the IMPACT study.⁴⁰ Mexiletine is often considered to be an “oral” form of lidocaine. As a result, prophylactic lidocaine use in acute myocardial infarction is no longer recommended.⁴¹

Currently, ACLS guidelines only recommend the use of lidocaine in the setting of shock-refractory ventricular fibrillation or pulseless ventricular tachycardia, and it is still not the preferred agent, coming in after amiodarone.²⁸ There is good evidence that other agents are more effective.⁴²

Lidocaine can be used in hemodynamically stable patients with recurrent polymorphic ventricular tachycardia and prolonged Q–Tc at baseline (torsades de pointes), since amiodarone and other Q–T prolonging agents should be avoided. However, evidence suggests that administration of magnesium, rapid rate ventricular pacing to 100 to 120 beats per minute, and isoproterenol infusion are more effective.⁴³

Lidocaine can be used as adjunctive therapy in patients having acute ischemic ventricular tachycardia or ventricular fibrillation, after reversing the acute ischemic cause, and if refractory to β -blocker and amiodarone therapy.

Dosage and Administration

A loading dose of 1.5 mg/kg is administered over 2 to 3 minutes, followed by a maintenance infusion rate of 1 to 4 mg/min. Since the bolus dose has a half-life of 15 minutes and the maintenance infusion requires 2 to 3 hours to achieve a steady state, repeated boluses may be required to achieve the desired effect.⁴⁴ A reduced dose is necessary in liver impairment or heart failure. Lidocaine can also be injected intramuscularly at a dose of 4 to 5 mg/kg, achieving therapeutic concentrations more reliably via the deltoid than the gluteal muscle.⁴⁴

Pharmacokinetics

Lidocaine undergoes extensive first pass metabolism and is therefore only administered in an intravenous form. It has a short half-life of 3 hours and is metabolized to metabolites with weak class I antiarrhythmic properties: glycinexylidide and monoethylglycinexylidide. It is highly bound to α_1 -acid glycoprotein, which may be increased in heart failure, making the free active drug less readily available. On the other hand, reduced clearance and volume of distribution in heart failure result in higher levels of the active drug, requiring a dosage reduction. Therapeutic plasma lidocaine levels range between 1.5 to 5.0 $\mu\text{g/mL}$ and should be monitored.

Side Effects

The most common side effects are related to central nervous system toxicity,⁴⁵ with various mental status changes that are usually mild and resolve with dose reduction. These are most frequently seen in the elderly, patients with heart failure, and those with liver impairment. Tremors are an early bedside sign of toxicity. High plasma levels have been shown to provoke generalized seizures.⁴⁶ Primary cardiovascular side effects include sinus slowing, asystole, hypotension, and shock. These occur with overdosing or with the overly rapid administration of lidocaine.

Figure 40-5. Relationship between the highest reductions in mortality in patients receiving β -blocker therapy with the greatest reductions in heart rate (HR). (Adapted from Kjekshus JK: Importance of heart rate in determining beta-blocker efficacy in acute and long-term acute myocardial infarction intervention trials. *Am J Cardiol* 1986;57:43F-49F.)

Class IC

This class of antiarrhythmics is not used in the modern day critical care setting. This is primarily due to the results of both of the CAST and CAST II trials.^{1,2} Both trials were ended prematurely after investigators noted a significant increase in arrhythmic deaths in patients treated with encainide, flecainide, and moricizine versus a placebo for suppression of premature ventricular contractions following myocardial infarction.

Class II

β -blockers have had a major impact on the treatment of cardiac arrhythmias. They are the only antiarrhythmics with a proven mortality benefit in the treatment of patients with acute myocardial infarction, coronary artery disease, and congestive heart failure. Although there are many different β -blockers, they are generally considered to possess a class effect with most of them providing equal benefit when titrated to equivalent therapeutic dosage. They may be generally classified into those with selective β_1 (cardiac) and those with β_2 (noncardiac) activity. Some have both. In addition, carvedilol also possesses α_1 -blocking activity and is seen as primarily beneficial in patients with congestive heart failure.

Some β -blockers such as pindolol also exert an intrinsic sympathomimetic action, which results in moderate activation of the β -receptor. This can ultimately result in an attenuated bradycardic effect or even a tachycardic response. This may have an adverse effect in patients with ischemic heart disease, and in fact the best mortality benefit has been demonstrated in β -blockers with the most bradycardic effects (Fig. 40-5).

The electrophysiologic effects of β -blockers are numerous but are thought to be predominantly due to blockade of the deleterious effects of adrenergic stimulation. These deleterious effects include abnormal automaticity due to enhanced phase 4 spontaneous depolarization, delayed after depolarizations (DADs) and triggered activity, and re-entrant excitation.⁴⁷ β -blockers have a profound effect on both the SA and AV nodes because of their dense adrenergic innervations, whereas they have a minimal to moderate effect on atrial, ventricular, and accessory pathway tissues unless these tissues are ischemic.

They also exert a membrane-stabilizing effect, which depresses excitability, delays conduction velocity, and prolongs refractoriness. In addition, β -blockers have been shown to

Table 40–4. Commonly Used β -blockers in the Critical Care Setting

Drug	β_1 Potency	β_1 Selectivity	IV Dosage	Half-Life	Elimination	Other Properties
Atenolol	1.0	++	5 mg every 10 min up to 10 mg	6–9 hr	Renal	None
Metoprolol	1.0	++	5 mg every 2–5 min up to 15 mg	3–4 hr	Hepatic	None
Esmolol	0.02	++	500 μ g/kg loading dose then 50–300 μ g/kg/min	9 min	Blood esterases	None
Propranolol	1.0	0	1 mg/min up to 5 mg	3–4 hr	Hepatic	Membrane stabilizing action
Labetalol	0.3	0	20 mg IV push then 40–80 mg every 10 min up to 300 mg, or infusion at 2 mg/min up to 300 mg	3–4 hr	Hepatic	α -Blocker

increase the ventricular fibrillation threshold, making ventricular tachycardia less likely to degenerate into ventricular fibrillation. This is probably the reason for the reduced incidence of sudden cardiac death noted in congestive heart failure trials using β -blockers.^{48,49,50}

Indications

β -blockers can be used for a wide variety of cardiac arrhythmias. These include supraventricular arrhythmias such as sinus tachycardia without an underlying reversible cause such as that seen in inappropriate sinus tachycardia or temporarily in hyperthyroidism until the primary disorder is addressed.⁵¹ They are also useful in slowing the ventricular response in arrhythmias such as atrial fibrillation, atrial flutter, or atrial tachycardia.⁵¹ They should not be used with the aim of converting these rhythms to sinus rhythm because they are ineffective, given their modest effects on nonischemic atrial and ventricular muscle tissue. Their activity is most effective on adrenergically innervated tissue, such as the SA and AV nodes.

Ventricular arrhythmias in the peri-infarct or post-coronary artery bypass surgery period, likely related to ischemic tissues, respond well to β -blocker therapy. They are also effective in suppression of adrenergically mediated or exercise induced ventricular arrhythmias such as right ventricular outflow tract tachycardias. β -blockers have also been shown to be effective in reducing sudden cardiac death in patients with long QT syndrome.

Dosage, Administration, and Pharmacokinetics

Multiple β -blockers are currently available for intravenous administration to critically ill patients. Listed here are the most commonly available of these drugs, appropriate doses, and routes of elimination (Table 40-4).

Side Effects

There is concern about exacerbating heart failure in patients with borderline compensation, as sympathetic drive may play an important role in maintaining cardiac output. Despite this concern, the evidence is that β -blockers are beneficial in heart failure patients and this effect of exacerbating heart failure was only observed in 6% of patients treated with carvedilol.⁵² Although increased dizziness and hypotension may occur, the absolute increase of these side effects was small and did not necessitate drug discontinuation in studies.⁵³ Significant bradyarrhythmias

have been noted in patients with SA node dysfunction or pre-existing AV node disease and may require back-up pacing if drug administration is necessary for the treatment of concomitant tachyarrhythmias.

Noncardiac adverse effects include exacerbation of bronchospastic disease, but this is typically observed with nonselective β -blockers. β_1 selective agents do not confer complete protection and should be used cautiously in these patients initially. The same applies to the use of β -blockers in patients with severe peripheral vascular disease because the drugs may exacerbate their symptoms; however, this is less noted with β_1 selective agents.⁵⁴

Retarded response to hypoglycemia due to blockade of epinephrine has been observed; however, data suggest that this is less serious with β_1 selective agents.⁵⁵ Although fatigue, depression, and sexual dysfunction are often-cited side effects, a systematic review of randomized trials found only small increases in these effects.⁵⁶

Class III

This class includes amiodarone, ibutilide, sotalol, dofetilide, azimilide, and bretylium. It is important to note that while classified as a class III agent, amiodarone has multiple actions across different classes. Since neither intravenous sotalol or azimilide have been approved by the Food and Drug Administration in the United States, they are unavailable for use in this country. In the presence of amiodarone and ibutilide availability, there is little use for dofetilide in the critical care setting. Bretylium is not currently used in modern medicine; therefore a discussion of the first two drugs only will be addressed in this chapter.

Amiodarone

Amiodarone is considered by some to be the most effective antiarrhythmic agent currently available. It is available in both intravenous form and oral tablets. Its wide range of effects across different antiarrhythmic classes makes it suitable for both acute therapy and long-term management of a host of arrhythmias with different mechanisms. These range from automatic to re-entrant supraventricular and ventricular arrhythmias. It has a very low incidence of proarrhythmia,^{57–5} making it ideal for administration in acute critical illness or for outpatient initiation. Its Achilles heel is its wide range of side effects that become more common with long-term therapy.

Initially developed in Belgium as an anti-anginal agent in 1962, it was later approved by the FDA for the treatment of ventricular arrhythmias in 1985. It is classified as a class III antiarrhythmic agent because of its effect of prolonging the action potential duration and increasing the refractory period of atrial and ventricular tissue.⁶⁰ It has this effect by virtue of its ability to block I_{Kr} , but also I_{Ks} with chronic use. In addition, it inhibits Na^+ and Ca^{2+} currents, which are class I and IV properties, respectively.⁶⁰ Its class I properties can result in widening of the QRS complex. It also has weak class II (β -blocker) activity and α_1 -blocking action with resultant bradycardia and vasodilation, which may mediate its anti-ischemic effects. Finally, it decreases peripheral conversion of T_4 to T_3 and impairs T_3 binding to myocytes, resulting in hypothyroid metabolism in cardiac cells.⁶¹

The degree of amiodarone's various properties and antiarrhythmic effects varies depending on whether it is given in an intravenous or oral preparation. Compared with the intravenous form, the oral preparation of amiodarone results in a more significant increase in action potential duration of atrial and ventricular tissues, slowing of phase 4 depolarization and automaticity, ventricular refractoriness, prolongation of the Q-Tc interval, and blockade of T_4 to T_3 conversion.⁶²

Clinical Effects

As a result of the various effects of amiodarone, the ECG may reflect slowing of the sinus rate, prolongation of the P-R interval and earlier Wenckebach block due to increased AV node refractoriness. In addition, widening of the QRS may also be noted. Q-Tc prolongation is also observed but is generally well tolerated and rarely causes proarrhythmia.

Due to its ability to prolong the action potential and increase refractoriness, it affects a re-entrant circuit of arrhythmia by prolonging the wave length and decreasing the excitable gap. This results in the leading edge of the re-entrant circuit colliding with the wake of the tail edge of the circuit, thereby extinguishing the re-entrant circuit and terminating the arrhythmia. As with other class III agents, it exhibits reverse use dependence properties with less efficacy noted at higher heart rates and more Q-Tc prolongation and proarrhythmia noted at slower heart rates.

In addition to its bradycardic effect, amiodarone results in a drop in blood pressure probably secondary to its β -blocker, calcium channel blocker, and α_1 -blocking actions. This can result in increased cardiac output secondary to a reduction in afterload.^{63,64} In addition, its smooth muscle relaxation effect results in coronary artery vasodilation, thereby potentially decreasing coronary ischemia, which may also contribute to its antiarrhythmic properties. It does not depress left ventricular function,⁶⁵ thereby avoiding heart failure exacerbations. For these reasons, it is safe and approved for use in patients with left ventricular dysfunction.

Indications

Amiodarone is a unique antiarrhythmic agent because of its multiple class effects. It is effective in the acute treatment of both ventricular and atrial arrhythmias; however it is currently approved by the FDA for the treatment of life-threatening ventricular arrhythmias only.

The most recent ACLS guidelines recommend amiodarone for the treatment of ventricular fibrillation or pulseless ventricular

tachycardia after cardioversion shocks. It is also recommended for treatment of stable monomorphic ventricular tachycardia or stable polymorphic ventricular tachycardia with a normal Q-T interval on the baseline ECG.²⁸

Part of the controversy surrounding the use of amiodarone has been the conflicting results of different antiarrhythmic trials. For the secondary prevention of sudden cardiac death, the CASCADE trial demonstrated amiodarone to be more effective than conventional therapy.⁶⁶ On the other hand, both the EMIAT and CAMIAT studies for the primary prevention of sudden cardiac death demonstrated amiodarone reduced cardiac death compared with a placebo but had no effect on all-cause mortality.^{67,68} The GESICA trial concluded that amiodarone significantly reduced mortality in a population of mostly nonischemic cardiomyopathy,⁶⁹ but this was contradicted by the CHF-STAT study that had more ischemic cardiomyopathy patients and showed no mortality difference.⁷⁰ The more recent SCDHeFT trial had both ischemic and nonischemic cardiomyopathy patients and showed amiodarone was no more effective than a placebo in the primary prevention of sudden cardiac death.⁷¹

Amiodarone is very effective for the treatment of atrial arrhythmias, especially atrial fibrillation. In the CTAF study, amiodarone was more effective at maintaining sinus rhythm than sotalol or propafenone.⁷² This was also echoed by findings from the SAFE-T trial, which compared amiodarone to sotalol or a placebo.⁷³ The ability to use amiodarone in critically ill patients for rate control, maintaining sinus rhythm, and improving hemodynamics, makes its use even more applicable to the acute care setting. Similar to β -blocker therapy, multiple studies have shown amiodarone to be effective in decreasing the incidence of postoperative atrial fibrillation following cardiac surgery, possibly resulting in shorter hospital stays, cost reduction, and decreased morbidity.⁷⁴

Dosage and Administration

In the critical care setting, intravenous administration is the most relevant route of administration. Whether for recurrent hemodynamically unstable ventricular tachycardia or for atrial fibrillation with a rapid ventricular response, a loading dose of 150 mg given over 10 minutes is recommended. This is followed by an intravenous infusion at a rate of 1 mg/min for 6 hours and then 0.5 mg/min, delivering a total of 1050 mg in 24 hours. Central venous access catheter delivery is preferable since concentrations above 2 mg/mL can result in significant peripheral vein phlebitis.

Oral administration of amiodarone is associated with a delayed onset of action of approximately 2 to 3 days because of its highly lipophilic nature, resulting in a very large volume of distribution. This is also the reason for its prolonged half-life, which can be up to 25 to 100 days.

Pharmacokinetics

Amiodarone undergoes deiodination and is metabolized in the liver to desethylamiodarone, an active metabolite with properties similar to the parent drug but a much longer elimination half-life. It is subsequently excreted via hepatic and gastrointestinal routes. Dose adjustment is necessary in patients with hepatic impairment and routine hepatic liver function monitoring is required. Renal metabolism or elimination does not occur at all and amiodarone is not removed by either peritoneal or hemodialysis. Consequently no dosage adjustment is

required in patients with renal insufficiency or in those receiving hemodialysis.

Intravenous amiodarone can achieve peak drug levels in as little as 30 minutes to a few hours following administration. With oral long-term administration it may take several weeks or months to achieve a steady state. This is due to amiodarone's highly lipophilic nature causing it to have a large volume of distribution. Consequently, complete saturation of peripheral tissues, such as adipose, muscle, liver, and spleen, needs to occur before achieving a steady state.

Side Effects

In the acute care setting, amiodarone is typically given to critically ill patients with significant arrhythmias. Hemodynamic and arrhythmia monitoring is the rule in such patients to detect potential side effects such as significant hypotension with intravenous administration of the drug. Regular Q-Tc monitoring is important to detect rare episodes of torsades de pointes (1% to 2% incidence). Telemetry allows the detection of bradyarrhythmias because of decreased automaticity or AV node refractoriness, although this is less common with the intravenous form of amiodarone.

Long-term oral therapy with amiodarone is associated with a host of potential side effects. These include cardiac bradyarrhythmias, pulmonary fibrosis, hepatic dysfunction and cirrhosis, hyperthyroidism and hypothyroidism, skin discoloration, optic neuritis, CNS dysfunction, peripheral neuropathy, and many others. This underscores the need for routine physical examinations and biannual blood tests.

Ibutilide

Ibutilide is a class III agent that is available only in an intravenous formulation because of extensive first pass metabolism making an oral formulation ineffective.⁷⁵ It blocks I_{Kr} during phase 3 of the action potential with a resultant increase in action potential duration and refractoriness of both atrial and ventricular tissue. This is manifested by Q-Tc prolongation and the potential risk for proarrhythmia. It also blocks a slow sodium current during the repolarization phase of the action potential. Like other class III agents, it exhibits reverse use dependence with longer Q-Tc prolongation at slower heart rates.

Clinical Effects

Ibutilide has minimal effects on heart rate and its major effect on the surface ECG is prolongation of the Q-Tc. It is very well tolerated hemodynamically and is not associated with hypotension.

Indications

Ibutilide is indicated for the acute conversion of atrial fibrillation or atrial flutter to sinus rhythm. Although electrical cardioversion is far more successful, ibutilide can be used to achieve chemical cardioversion without necessitating anesthesia typically required for electrical cardioversion. It is most successful in treating atrial fibrillation or atrial flutter of relatively short duration.⁷⁵ It can also be given to facilitate electrical cardioversion in patients that are difficult to cardiovert electrically and have required multiple shocks or exhibit early recurrence of atrial fibrillation after electrical cardioversion.⁷⁶ In addition, ibutilide has been shown to be as effective as procainamide in terminating atrial fibrillation with WPW syndrome.⁷⁷

Dosage and Administration

Due to its potential for proarrhythmia, ibutilide should be administered with continuous telemetry. Electrolytes should be optimized (especially serum magnesium and potassium levels), and an external defibrillator should be available in case of polymorphic ventricular tachycardia.

The typical dose is 1 mg to be infused over 10 minutes, which can be repeated again in 10 minutes if the first dose was ineffective and if there is no significant lengthening of the Q-Tc. In patients less than 60 kg, the recommended dose is 0.01 mg/kg. If marked prolongation of the Q-Tc is noted during administration of the infusion, or if cardioversion occurs, the infusion should be stopped. Continuous telemetry monitoring is mandatory for at least 4 hours and preferably 6 hours following the end of the infusion.

Pharmacokinetics

Available only in an intravenous form, it is metabolized hepatically into many metabolites, although only one has a weak antiarrhythmic effect. These metabolites are renally excreted. The half-life ranges between 2 to 12 hours and can be quite prolonged in hepatic dysfunction.

Side Effects

The most common side effect of this intravenous agent is proarrhythmia. Torsades de pointes has been observed in various studies with an incidence that varied between 3.6% and 8.3%, with episodes requiring emergency cardioversion occurring in 1.7% to 2.4%.^{78,79} The risk of developing proarrhythmia was highest in patients with heart failure.

Class IV

Only the nonhydropyridine agents in this group of medications, verapamil and diltiazem, appear to exert electrophysiologically significant cardiac effects. Their effects are mediated through their ability to block the slow calcium channel in slow response cardiac tissue (SA and AV nodes), resulting in slow phase 4 depolarization and decreased conduction velocities. This property makes them ideal for slowing the ventricular response in atrial arrhythmias, such as atrial fibrillation or atrial flutter. In addition they seem to have antiadrenergic properties very similar to those seen with β -blockers, which also contributes to slowing of the heart rate. Although they typically do not affect ventricular tissue, they have been noted to affect calcium flux across the cell membrane in conditions of metabolic disturbance. This milieu is thought to be responsible for the occurrence of early after depolarizations (EADs), which are the arrhythmic mechanism of torsades de pointes. This property seems directly related to their ability to shorten the plateau phase of the ventricular action potential.

Clinical Effects

Calcium channel blockers cause slowing of phase 4 depolarization in the SA and AV node, in addition to increasing refractoriness of the AV node. Both the sinus and the ventricular response rate slow down. Sinus slowing and P-R interval prolongation are noted on the surface ECG. Typically there are no other changes in the duration of the QRS complex and Q-T interval. They exhibit use dependence properties with increasing efficacy at higher heart rates.

Calcium channel blockers can also induce peripheral vasodilation through their smooth muscle relaxation properties. This

is noted slightly more with diltiazem than it is with verapamil and may result in hypotension. They also exert a mild negative inotropic effect, making them unsuitable in the management of hemodynamically unstable patients or patients with heart failure exacerbations having supraventricular tachycardias.

Indications

The most common indication for using calcium channel blockers is for the treatment of supraventricular tachycardia. Intravenous verapamil or diltiazem are probably equally effective. They are also commonly used for slowing the ventricular rates in atrial fibrillation or atrial flutter.

Although they are typically not used in the treatment of ventricular tachycardias, they do have a role in the treatment of certain ventricular tachycardia entities, such as right ventricular-outflow tract tachycardia or rare tachycardias, such as verapamil-sensitive ventricular tachycardia or familial catecholaminergic polymorphic ventricular tachycardia.

Dosage and Administration

Both verapamil and diltiazem can be administered intravenously with equal efficacy when rapid control of ventricular rate in atrial arrhythmias, or termination of paroxysmal supraventricular tachycardia, is desirable.⁸⁰ The verapamil loading dose is 5 to 20 mg administered over 2 minutes and lasts for up to 6 hours. A maintenance intravenous infusion at a rate of 0.005 mg/kg/min can be administered in patients who cannot take the oral form. Short acting or extended release tablets are available and the daily dose ranges between 240 mg to 480 mg daily. Diltiazem can be loaded with a 20 mg bolus administered over 2 minutes, and a maintenance infusion of 5 to 15 mg can then be used if required. Repeated boluses can be given, if necessary, 15 minutes following the initial bolus. Extended release oral tablets are available starting at a dose of 180 mg up to a maximum of 540 mg daily.

Pharmacokinetics

Both verapamil and diltiazem undergo extensive first pass effect, with only 35% to 40% bioavailability noted with the oral formulations. Both are metabolized in the liver but diltiazem is only partially excreted by the kidney (35%), and the rest is excreted through the gastrointestinal tract. Verapamil on the other hand is mostly excreted by the kidney.

Side Effects

Both drugs are generally well tolerated orally with only mild effects noted as a result of mild hypotension, such as facial flushing or dizziness. Intravenous administration can cause significant hypotension. Diltiazem does not appear to have the same drug interaction noted with verapamil, which interacts with amiodarone and dofetilide, resulting in excessive sinus rate slowing and possible sinus arrest. Both drugs can potentiate the hypotensive effects of β -blockers and increase the degree of AV node refractoriness in patients receiving digoxin.

Atypical Antiarrhythmics

Digoxin

Digoxin is the most readily available form of digitalis and is derived from the foxglove plant. The use of this cardiac glycoside has been documented for hundreds of years. It is listed as an atypical antiarrhythmic agent because its electrophysiologic

effects do not conform to any of the other previously described antiarrhythmic classes.

Digoxin has direct actions such as decreasing automaticity of the SA node and increasing the refractoriness of the AV node. Its most prominent effects, however, are its indirect effects of increasing parasympathetic activity and inhibiting sympathetic activity.⁸¹ This explains why it has little or no effect in transplanted hearts and has decreased efficacy in critically ill patients with elevated levels of sympathetic activity commonly encountered in the critical care setting.

In the atria it shortens the plateau phase, which results in decreased refractoriness with resultant increased atrial depolarization rates. It can also decrease the refractory period of accessory pathways. This combination of effects makes it contraindicated in patients with Wolff-Parkinson-White syndrome because it may facilitate an accelerated ventricular response to atrial fibrillation in these patients, which may precipitate ventricular fibrillation.

Clinical Effects

At therapeutic doses there are typically no obvious ECG effects. Sinus rate, P-R, and QRS intervals are usually unchanged. Patients with significant sinus rate slowing are those with pre-existing sinus node dysfunction. A well-known positive inotropic agent, this property has been attributed to digoxin's ability to inhibit Na^+/K^+ ATPase, which results in increased intracellular calcium that affects excitation-contraction coupling favorably. This may also be the basis for some of the drug's proarrhythmic effect. This positive inotropic activity can result in diuresis in patients treated with digoxin. Although digoxin may improve the symptoms of heart failure and decrease hospitalizations, it has been shown not to decrease mortality in heart failure patients.⁸²

Indications

The most common indication for digoxin is to slow the ventricular rate of atrial fibrillation or atrial flutter. In this modern era, however, it should not be used as first-line therapy for this indication. An understanding of the electrophysiologic effects of this medication reveals why it is not ideally suited for treatment of patients in the acute care setting. Furthermore, better and more reliable rate control can be achieved with other medications, such as β -blockers or calcium channel blockers, which can be more tightly titrated and are readily available. Infrequently, digoxin can be used as adjunctive therapy in patients with atrial fibrillation and rapid ventricular response refractory to a combination of β -blocker and calcium channel blocker therapy. Also, in patients who are hemodynamically intolerant of β -blocker therapy or calcium channel blocker therapy due to hypotension, digoxin may be useful because it generally does not cause significant hypotension.

Dosage and Administration

When rapid therapeutic serum levels are required, digoxin can be loaded with a dose of 0.5 to 1.0 mg intravenously to be divided over 18 to 24 hours, with a resultant peak effect in 2 to 4 hours. Typically the first administered dose is 0.5 mg followed by 2 doses of 0.25 mg. Daily maintenance doses are 0.125 to 0.25 mg orally, but the equivalent intravenous dosage should be reduced by 20% to 25%. These doses should be reduced in the elderly and in patients with renal insufficiency. Digoxin serum

levels can be helpful initially to ascertain that a therapeutic level has been achieved after loading. Serum concentrations of 0.8 to 2.0 ng/mL are the goal. A serum concentration higher than 2.0 indicates toxicity and the potential for proarrhythmia.

Pharmacokinetics

Oral administration results in absorption by the stomach and small intestine with resultant bioavailability of 60% to 80%. Although digoxin is metabolized in the liver, it is excreted by the kidney almost unchanged. It has a 36 to 48 hour half-life, but this may be longer in patients with renal insufficiency. Digoxin levels are not significantly altered by hemodialysis because it is extensively protein-bound.

Side Effects

Digoxin has significant drug-to-drug interactions with a host of medications but notably with amiodarone and verapamil because both decrease its metabolism and can result in elevated levels of digoxin. Digoxin toxicity is more likely to occur in the presence of renal failure, advanced age, and electrolyte abnormalities such as hypomagnesemia and hypokalemia. The latter does so by decreasing renal tubular secretion of digoxin and increasing tissue binding of the drug. Elevated levels of calcium can predispose to increased delayed afterdepolarizations, which is one of the main proarrhythmic mechanisms of digoxin, in addition to increased sympathetic activity with enhanced automaticity.

Noncardiac manifestations of digoxin toxicity include anorexia, nausea, and vomiting. Gastrointestinal symptoms are typically early signs of toxicity. Central nervous system symptoms include headaches and visual disturbances, such as halo vision, scotoma, and altered color perception.

Cardiac toxicity is typically in the form of various arrhythmias. Almost any type of arrhythmia has been reported with digoxin toxicity; however, classical examples include atrial tachycardia with advanced AV block and accelerated junctional rhythms, in addition to bidirectional ventricular tachycardias.

Treatment of toxicity usually involves stopping the medication in patients who are hemodynamically stable along with correction of electrolyte abnormalities. Administering calcium should be avoided as this can precipitate life-threatening arrhythmias by further increasing potassium levels in a setting of preexisting hyperkalemia secondary to digoxin toxicity. In patients who are unstable as a result of their arrhythmias, digoxin immune FAB antibody can be administered to bind digoxin, which can be lifesaving.⁸³ Cardioversion should be avoided in digoxin toxicity and if absolutely necessary, should be done at low energy as this may precipitate ventricular fibrillation because of the pre-existing myocardial increased excitability.

Adenosine

Adenosine is an endogenous nucleoside found throughout the whole body. It has become the drug of choice for aiding in the diagnosis of supraventricular tachycardias and terminating both AV reciprocating tachycardia and AV nodal re-entrant tachycardia.

It plays an important role as a biochemical intermediate and regulator of cellular metabolism. Its actions are mediated through its interaction with A1 and A2 receptors, in addition to G proteins, to exert effects on potassium and calcium channels.

Adenosine primarily activates the I_{KAdo} outward potassium current, which is absent in ventricular tissue but present in atrial tissue,⁸⁴ causing shortening of the action potential in the atria. It inhibits the “funny” channel (I_f), which results in decreased sodium influx in SA and AV node tissue. This decreases automaticity in these tissues and therefore has a negative chronotropic effect. Its indirect actions include inhibition of intracellular cAMP generation, which in turn decreases the catecholamine driven inward calcium current and transient inward current. These essentially anti-adrenergic effects may play a role in its antiarrhythmic properties. It also has the ability to decrease the sinus node rate by decreasing sinus node and atrial automaticity, in addition to decreasing both sinus node and AV node conduction properties.

Indications

Adenosine is indicated for the rapid termination of supraventricular re-entrant tachycardias. It affects the antegrade slow pathway more readily than the retrograde fast pathway in patients with dual pathway physiology. Similarly, it affects the antegrade fast pathway limb of bypass mediated tachycardias more than the retrograde bypass limb of the tachycardia. This means that administration of adenosine can terminate both types of these re-entrant supraventricular tachycardias, which are AV node dependent, by affecting the antegrade limb of the tachycardia. Typically the last cardiac activation noted is atrial activity manifested by a nonconducted P wave at the break of the tachycardia before resumption of normal sinus rhythm. This may be difficult to see, however, as sometimes the P wave is obscured by the preceding QRS complex.

In atrial tachycardias or atrial flutter, the typical response to an adenosine bolus is the occurrence of complete AV node block, which can be profound sometimes, without termination of the atrial arrhythmia itself. The atrial arrhythmia may now be seen more clearly because of the absence of QRS complexes. The caveat is that approximately 10% of atrial tachycardias are adenosine sensitive and can terminate with administration of adenosine resulting in a misleading diagnosis of the mechanism of the arrhythmia.

Adenosine is also useful in terminating a type of idiopathic ventricular tachycardia that typically has left bundle inferior axis morphology and occurs in structurally normal hearts.⁸⁵ These tachycardias originate from the right ventricular outflow tract and are adrenergically driven. They are thought to be due to delayed afterdepolarizations caused by cAMP-mediated triggered activity.

Although adenosine can be given to differentiate hemodynamically stable wide complex tachycardia into supraventricular tachycardia with aberrancy and ventricular tachycardia, this can be misleading and is no substitute for expert electrocardiographic consultation.

Dosage and Administration

Intravenous boluses are given at a dose of 12 mg in a peripheral vein but should start at 6 mg when administered via a central venous catheter. Tachycardia termination is typically seen within 15 to 30 seconds of administering the bolus. If the initial dose is ineffective at terminating the arrhythmia or producing transient complete AV block, it can be repeated at the same dose or at a higher dose up to 18 mg. Its half-life of 6 seconds allows such rapid clearance of the drug that it can be readministered

within 30 seconds without accumulation of the drug. Hypotension is not typically noted as the drug has usually been cleared before it reaches the systemic circulation.

Pharmacokinetics

Adenosine undergoes immediate and rapid clearance in the bloodstream secondary to cellular uptake and enzymatic degradation. Although its half-life is difficult to determine, it has been estimated to be between 0.5 to 6 seconds.⁸⁶ Therefore, it is best suited for rapid bolus administration for termination of arrhythmias or potentially to aid in the diagnosis for arrhythmias as opposed to ongoing therapy for arrhythmias.

Side Effects

Adenosine's short half-life makes side effects very mild and transient. Most patients report facial flushing, which is related to transient vasodilation, and chest pain. It can also precipitate bronchospasm, resulting in dyspnea, and should be used with caution in patients with significant bronchial airway disease. Frequent premature atrial or ventricular contractions have been observed in addition to precipitation of atrial fibrillation in up to 15% of patients.⁸⁷

Conclusion

Antiarrhythmics have an important role in the treatment of a wide variety of arrhythmias that are associated with significant morbidity and mortality. It is important to remember, however, that these drugs are also associated with a host of side effects and limitations. Novel antiarrhythmics are constantly being evaluated in search of the holy grail of combined high efficacy and high safety in the treatment of cardiac arrhythmias. In the meantime, we will have to continue to rely on currently available medicines and use them in a targeted way to derive the greatest therapeutic benefit coupled with the highest safety in the management of critically ill patients.

CHAPTER 41

Opioid Analgesics

Antipsychotic Agents

THE CORONARY CARE UNIT (CCU) has evolved drastically over the past several decades from an area primarily limited to the management of the acute coronary insufficiency patient to a full-fledged cardiac intensive care unit (CICU) concerned with a multitude of life-threatening cardiovascular diseases. With this development has also occurred the parallel need for more adequate and flexible analgesia and sedation because many of these critically ill patients undergo invasive procedures, such as balloon angioplasty and placement of intra-aortic balloon pumps, pulmonary artery catheters, and ventricular assist devices. In addition, many require long-term mechanical ventilation. The goal of therapy in the CICU is frequently more complicated than the simple relief of myocardial ischemia or infarction pain and the anxiety that accompanies it. For example, today's CICU practitioner is more likely to encounter an older and frailer patient, and although the elderly may benefit greatly from analgesic or sedative medications, they are also more likely to suffer the side effects of these medications.¹ Likewise, CICU practitioners today are likely to encounter patients who require sedation for long-term mechanical ventilation.

Only a few decades ago, the options for analgesic and sedative therapy in the CICU were essentially limited to the narcotic morphine sulfate and the benzodiazepine chlordiazepoxide. Since that time, many new agents have been developed for the treatment of pain, anxiety, and delirium, and these often possess more desirable pharmacokinetic and pharmacodynamic properties than their predecessors. Although some of the older agents, especially morphine, have retained clinical usefulness because of their unique and beneficial pharmacokinetic and hemodynamic properties, many agents have been replaced by new drugs that have improved efficacy and safety.

This chapter describes the analgesic and sedative agents available for use in the critical care setting, with special attention paid to those drugs of greatest usefulness in the CICU. Intramuscular and other injection routes of administration are not discussed here because the absorption, bioavailability, and pharmacokinetic properties of agents not administered by intravenous injection are highly unpredictable in critically ill patients. Agents used specifically for the induction of anesthesia also are not discussed in detail. Readers are referred to more standard anesthesia texts for information regarding these drugs.

Within each classification of medication discussed, basic mechanisms of drug function (e.g., receptor physiology, site of action) are reviewed, and the pharmacokinetics and pharmacodynamics of each agent are discussed. Clinical uses of the

agents, with special attention paid to those indications most germane to the CICU, are addressed. Finally, established agents that have found new clinical applications in the CICU patient are described.

Opioid Analgesics

Morphine

History and Structure

Morphine has been used for analgesia and sedation for many centuries, but it has only been used by the intravenous route for approximately 150 years.⁴ Morphine is the only naturally occurring opiate agent obtained from the poppy plant, *Papaver somniferum*, still used with frequency in the critical care setting. Its proper chemical class is the phenanthrene group, which it shares with the agent codeine.⁵ Morphine occurs in essentially a rigid, pentacyclic type of structure.

Site of Action and Receptor Physiology

Since the first description of the opiate receptor in 1973, the mechanism for sedation and pain relief has been investigated.⁶ The initial system included only the μ -receptor; since then, a number of different opiate receptors have been discovered and named, including β -, κ -, σ -, and ϵ -receptors (Table 41-1).⁷⁻⁹ Additional investigations have shown that the μ -receptor system actually includes two subtypes: the μ_1 -receptor and the μ_2 -receptor. Although research is ongoing, it appears that the μ_1 -receptor is responsible primarily for analgesia and sedation, whereas the μ_2 -receptor may be responsible for euphoria and addiction in addition to analgesia.^{9,10} Both the δ - and κ -receptors may be responsible for mediating respiratory depression. The σ -receptor seems to be related to those physiologic responses usually associated with acute withdrawal syndromes, specifically dysphoria, hallucinations, mydriasis, tachycardia, and hypertension.¹¹ Based on these findings, opioid agents have been designed as selective agonists of certain receptors to maximize beneficial physiologic effects while minimizing deleterious ones. The greater μ -specificity of the synthetic opioid fentanyl compared with morphine is an example. Furthermore, agents with partial antagonist properties (e.g., nalbuphine) have been designed to simultaneously act on several opiate receptors, in this case the κ - and μ -receptors, to prevent respiratory depression while allowing analgesia.

The different opiate receptors are located in diverse anatomic sites throughout the central nervous system so it is apparent

Table 41-1. Characteristics of Opioid Receptors

that anatomy and receptor type dictate the pharmacodynamic effects of opiate agents. Whereas opiate receptors are located in a number of distinct areas in the brain and spinal cord, the highest density of receptors is located in the substantia gelatinosa of both the cerebral cortex and spinal cord, the periaqueductal gray areas, the thalamus, and the hippocampus.¹² Of these areas, laminae II through V of the substantia gelatinosa and the periaqueductal gray areas appear to have the highest concentrations of μ -receptors and hence the greatest input with respect to analgesia. As a general rule, the gray matter of the central nervous system contains more opiate receptors than does the white matter.¹³

Pharmacokinetics, Pharmacodynamics, and Metabolism

Morphine has a rapid initial redistribution phase of 1 to 1.5 minutes and an initial elimination half-life ($t_{1/2\alpha}$) of 10 to 20 minutes. Its terminal elimination half-life ($t_{1/2\beta}$) is much longer (between 2 and 4.5 hours).¹⁴ Morphine is unique compared with the other commonly used opioid agents in that it has relatively low lipid solubility (Table 41-2). Interestingly, the shape of the morphine elimination curve is nearly identical to that of fentanyl, even though it is well known that the clinical behavior of the two drugs (e.g., onset time, offset time, duration of action) is quite different. This is explained by the following comparison between fentanyl and morphine, which is intended to illustrate how two drugs with similar pharmacokinetic properties can have different pharmacodynamic profiles. Compared with fentanyl, morphine has low lipid solubility (it is approximately 40 times less lipid soluble than fentanyl) and therefore has slow penetration of the blood-brain barrier.⁵ In contrast, the high lipid solubility of fentanyl allows rapid penetration of the blood-brain barrier, which leads to a peak effect within several minutes. Conversely,

it is this same property (lipid solubility) that allows fentanyl's rapid redistribution away from the brain and hence its short duration of action. Morphine, with its greater water solubility, crosses the blood-brain barrier much more slowly than fentanyl, resulting in a slower time to peak effect (20 to 30 minutes; Fig. 41-1). Similarly, once morphine has entered the brain, its lower lipid solubility prevents rapid redistribution and hence allows a longer clinical duration of action than fentanyl. Even though morphine appears to be pharmacokinetically similar to fentanyl, it typically has a slower onset time and longer duration of action.

Morphine is metabolized by both the liver and the kidneys. Although the liver is responsible for the majority of its metabolism, 40% is metabolized by the kidneys.¹⁵ The major metabolic byproduct of morphine metabolism is morphine-3-glucuronide, which is known to have intrinsic opiate activity roughly one half that of morphine.¹⁶ When using morphine in patients with renal failure, the presence of this compound is important because cases of prolonged sedation do occur.^{17,18}

Cardiovascular and Hemodynamic Effects

For many years, morphine has been used in the management of acute myocardial ischemia and infarction pain and for sedation in patients with underlying myocardial disease.¹⁹ Morphine has distinct pharmacodynamic and hemodynamic properties that make it advantageous in cardiac patients. Perhaps the most important of these is morphine's ability to decrease venous and arterial tone.^{20,21} It appears that the increase in venous capacitance produced by morphine is relatively greater than the decrease in arterial resistance.²² This effect on venous capacitance is dose-related, and with large doses it is possible to decrease preload to the point of hypotension.²³ In certain cardiac patients, a modest decrease in preload, as occurs with a dose of

Figure 41-1. Serum and brain decrement curves in normocarbic dogs show the relationship of morphine concentrations in the brain to morphine concentrations in serum. Serum and brain morphine decrement curves intersect at approximately 1 hour. Vertical bars are standard error ($n = 7$). (From Nishitaten K, Ngai SH, Finck AD, Berkowitz BA: Pharmacokinetics of morphine: concentrations in the serum and brain of the dog during hyperventilation. *Anesthesiology* 1979;50:520-523.)

intravenous morphine, is desirable. It appears that in the dosages commonly used in the critical care setting, morphine has no direct effect on the inotropic state of the heart.²⁴ An exception to this is the negative inotropic state caused by histamine release when morphine is administered rapidly or when large

doses are given (discussed later).⁵ Finally, the net chronotropic effect of morphine is to slow the heart rate under usual conditions. The exact mechanism by which morphine achieves this action is not certain, but it is thought to involve both a stimulation of the central vagal nucleus and a direct depressive effect on the sinoatrial node.^{25,26} Morphine has also been observed to secondarily increase heart rate by causing histamine release (discussed later).

Side Effects, Complications, and Toxicity

Many of morphine's side effects are dose-related and can be minimized by reducing the size of doses administered to patients. The most important and potentially dangerous side effect of morphine administration is respiratory depression. The opiate agonists all share the ability to depress ventilation; this is primarily accomplished by decreasing the central ventilatory response to CO_2 .⁵ Specifically, the ventilatory response curve to an increasing PaCO_2 is shifted to the right, and the slope is decreased (Fig. 41-2). This means that for a given rise in PaCO_2 , the patient compensates with a less-than-expected minute ventilation rate.⁵ The typical breathing pattern is one of slow respiratory rate with preserved or even increased tidal volume. This effect is dose-related, and although apnea can occur with high doses, it is usually preceded by a period of progressive hypoventilation and therefore can be identified early and prevented.

The central nervous system side effects of morphine include drowsiness, lethargy, and potentially excessive sedation. In addition to the direct central respiratory depression described previously, excessive sedation with morphine can worsen respiratory compromise by causing upper airway obstruction and obstructive apnea. Euphoria with morphine use has been noted but is less common than that occurring with some other opioid agents. Dysphoria can also occur. As in respiratory depression, the central depressant effects are dose-related and progressive.

The other organ systems most commonly affected by morphine (or any of the opioid agents) are the gastrointestinal (GI)

Figure 41-2. Ventilatory responses to CO₂. In control subjects, increases in alveolar PCO₂ produce increases in alveolar ventilation. After morphine administration, the response to CO₂ is shifted to the right, and the slope of the response is decreased.

and genitourinary (GU) systems. Morphine has many GI effects, including nausea, emesis, constipation, generalized slowing of the GI tract, and spasm of the sphincter of Oddi. Morphine has been reported to cause urinary retention by increasing urethral sphincter and detrusor tone.²⁷ Hyponatremia secondary to the syndrome of inappropriate secretion of antidiuretic hormone is also occasionally seen with the administration of large doses of morphine.²⁸ When morphine is given to patients with renal failure, prolonged narcotic effect from the accumulation of the active metabolite morphine-3-glucuronide can cause excessive sedation or respiratory depression.¹⁷

Although true allergic reactions to morphine are quite rare, morphine is known to cause the release of histamine.²⁹ The release of histamine is from mast cells rather than the basophils, and the mechanism, although not thoroughly understood, is nonimmunologic.³⁰ The release of histamine can lead to a warm flushing sensation, intense pruritus, hypotension, and tachycardia. When hypotension related to histamine release occurs, treatment includes discontinuing morphine infusion, ruling out other causes of anaphylactic or anaphylactoid type of reactions, administering intravenous fluids for hypotension, and administering histamine type 1 and type 2 blocking agents.⁵ One study has demonstrated that pretreatment with histamine type 1 and type 2 receptor antagonists in patients who have received morphine and tubocurarine (another agent associated with histamine release) significantly decreases hypotension when compared with similar patients pretreated with a placebo, although skin flushing was not reduced.³⁰ Other side effects, including respiratory depression, sphincter of Oddi spasm, excessive sedation, and pruritus, can be reversed by the administration of the opiate antagonist naloxone. By titrating small doses of naloxone, it is possible to reverse the side effects of morphine without completely reversing the analgesia. It is prudent to avoid giving large doses of naloxone to cardiac patients because complete reversal of opiate effect can result in dangerous increases in sympathetic tone and, rarely, has been reported to cause pulmonary edema.³¹

Clinical Indications

The main reason to administer intravenous morphine in the CICU is to produce analgesia and sedation, especially in the setting of acute myocardial ischemia or infarction or acute cardiogenic pulmonary edema. As mentioned previously, the acute venodilatory effects of intravenous morphine, combined with its analgesic and sedative properties, make it useful in cardiac patients. In contrast to fentanyl, morphine, with its long clinical duration and low lipid solubility, is best suited to administration by intermittent boluses rather than continuous infusion. Morphine may best be avoided altogether in the hemodynamically unstable patient because it is more likely to induce hypotension than is fentanyl.

Fentanyl

History and Structure

Fentanyl and meperidine are probably the best known of the synthetic opioid analgesic agents. These agents, along with sufentanil and alfentanil, are members of the phenylpiperidine class of opiate agents. They are named for the phenylpiperidine skeleton in their chemical structure.⁵ In terms of analgesic properties, fentanyl is approximately 80 times more potent than morphine because of its greater affinity for the μ -opiate receptor.¹⁵

Fentanyl was introduced in 1959 and has been in clinical use since the early 1960s, when it was first used in a combination preparation with the butyrophenone agent droperidol (Innovar) for the technique of neuroleptanesthesia.^{32,33} For many years, fentanyl was used almost exclusively in the operating room by anesthesiologists because of safety concerns related to its high potency and rapid onset. In the past few decades, fentanyl has found greater use as an analgesic and sedative in the critical care setting.

Pharmacokinetics, Pharmacodynamics, and Metabolism

The initial redistribution half-life for fentanyl is short (1 to 2 minutes), the $t_{1/2\alpha}$ is longer (10 to 30 minutes), and the $t_{1/2\beta}$ is 2 to 4.5 hours.¹⁴ Therefore, pharmacokinetically, fentanyl behaves similarly to morphine; this fact is supported by the nearly identical elimination curve shared by the two drugs. Fentanyl is approximately 40 times more lipid-soluble than morphine, leading to significant differences in the pharmacodynamics between these two drugs. Fentanyl's great lipid solubility allows rapid entry of this drug into the brain, causing a peak effect minutes after a bolus administration.⁵ Peak effect parallels the serum level for this agent.¹⁴ As a corollary, fentanyl redistributes away from the brain very quickly, resulting in a short clinical duration of action of only 30 to 60 minutes after a bolus dose. For these reasons, fentanyl administered by constant infusion leads to more consistent analgesia.³⁴ Prolonged narcotic effect may be observed with fentanyl after prolonged infusions or frequent bolus dose administration.³⁵ The reason for this prolongation of half-life with long-term infusion of fentanyl is thought to be that the high lipid solubility of this agent allows absorption of large amounts of drug into poorly perfused fatty tissue. When this occurs, termination of effect no longer depends on redistribution but rather is dependent on the terminal half-life of the drug. In a situation analogous to that seen with prolonged infusions of sodium thiopental, fatty uptake leads to a prolonged $t_{1/2\beta}$ and a long clinical duration of effect.^{5,36,37}

Fentanyl is metabolized primarily by the liver and somewhat by the kidney. Active metabolites of fentanyl are probably of minimal or no clinical significance.¹⁵

Cardiovascular and Hemodynamic Effects

When used in analgesic doses, fentanyl has developed a reputation for causing minimal hemodynamic effects. It has been demonstrated that fentanyl does not have negative inotropic effects.^{38,39} Although its occurrence is unusual, fentanyl can cause hypotension. The etiologies of fentanyl-related hypotension are likely fentanyl-induced bradycardia and a decrease in central sympathetic tone. The cause of the bradycardia is thought to be direct stimulation of the central vagal nucleus by fentanyl.⁴⁰ Furthermore, the magnitude of the bradycardia is believed to be related to both the total dose administered and the rate of infusion.^{5,40} Fentanyl is also known to cause hypotension indirectly by decreasing central sympathetic outflow.⁴¹ This mechanism is supported by the observation that patients with high basal levels of sympathetic tone are more likely to become hypotensive when given fentanyl.⁵ Patients with relative or absolute hypovolemia are more prone to hypotension after receiving fentanyl. Although fentanyl administration has minimal hemodynamic effects, it is important to note that reports have suggested that the combination of synthetic opioids and benzodiazepines, especially midazolam, can cause significant decreases in blood pressure.⁴² It is possible that lorazepam combined with fentanyl may cause less hypotension than does the combination of midazolam and fentanyl.⁴³

Side Effects, Complications, and Toxicity

The side effect and toxicity profile of fentanyl is similar to that of morphine, with several exceptions. The cardiovascular and hemodynamic effects of fentanyl have been discussed previously. The respiratory, central nervous system, GI, and GU side effects are similar to those previously discussed for morphine. The pharmacodynamic properties of fentanyl result in apnea and oversedation quickly; therefore, this drug should be used only in a monitored situation. Fentanyl does not release histamine from mast cells in humans.⁴⁴ It has been rarely reported to cause true anaphylactic reactions in humans.⁵ The respiratory, GI, and GU side effects of fentanyl are responsive to treatment with the narcotic antagonist naloxone. The same cautions described for the use of naloxone with morphine also apply to its use with fentanyl.

Clinical Indications

There are few studies that formally address the role of fentanyl in the CICU. Although this is also technically true with morphine, that agent, in comparison with fentanyl, has a long history of safety and familiarity in the CICU. Furthermore, the beneficial hemodynamic effects of morphine in the setting of myocardial ischemia or acute cardiogenic pulmonary edema have also strengthened its role as the primary opiate analgesic-sedative for the cardiac patient. Even so, it appears that those properties that make fentanyl a desirable agent in the operating room also make it attractive in the critical care setting. Fentanyl's rapid onset and short duration of action make it a useful analgesic and sedative agent for invasive procedures, with the caveat that it *must* be administered by experienced personnel in a monitored setting. Pharmacokinetically, fentanyl is more suitable for constant-infusion administration than is morphine, and it can be

easily and rapidly titrated to the desired analgesic effect. During long infusions of fentanyl, $t_{1/2\beta}$ increases as poorly perfused tissues are saturated. Adjustments in infusion rate must be made to compensate for this effect to prevent an undesired prolonged narcotic effect. The resulting bradycardia seen after fentanyl administration is a beneficial effect in some medically managed cardiology patients. Finally, the more neutral hemodynamic profile of fentanyl may make it a better choice for analgesia-sedation in the hemodynamically unstable patient.

Benzodiazepines

History and Structure

The benzodiazepines, which are the most commonly used sedative agents in the critical care unit, have been in use for several decades. The first benzodiazepine, chlordiazepoxide, was formulated in 1955, but it was not noted to have sedative properties until 1957 and was not released for clinical use until 1959.⁴⁵ Chlordiazepoxide was followed in 1959 by the synthesis of diazepam, in 1971 by the formulation of lorazepam, and in 1976 by the synthesis of midazolam.^{46,47} In addition to its unique pharmacologic properties (discussed later), midazolam is of great interest to intensivists and anesthesiologists in that it is the first benzodiazepine formulated primarily for use in anesthesia and the critical care setting. The benzodiazepines as a group are relatively small, lipid-soluble molecules that act as agonists at the benzodiazepine receptor.⁴⁶

Site of Action and Receptor Physiology

In 1977, 18 years after their clinical introduction, it was discovered that the site of action of the benzodiazepines was at a receptor complex that it shared with another important class of central nervous system depressants, the barbiturates.⁴⁸ This receptor, named the BNZ receptor, along with the barbiturate receptor, forms part of a larger receptor system known as the γ -aminobutyric acid (GABA) receptor complex.¹⁴ The benzodiazepines act agonistically at this receptor. GABA, one of the primary inhibitory neurotransmitters of the human central nervous system, acts as an agonist at the GABA complex, causing a net influx of chloride ion into the cell, which results in hyperpolarization and resistance to excitation.⁴⁹ It appears that there are two main GABA receptors in the central nervous system: a GABA_A complex and a GABA_B complex. The benzodiazepines appear to have their main activity at the GABA_A complex.¹⁴ When a benzodiazepine binds at its BNZ receptor, the conformation of the GABA_A complex is altered such that the binding of the neurotransmitter GABA is facilitated.⁴⁶ Benzodiazepine receptors are found in greatest concentration in the olfactory bulb, cerebral cortex, cerebellum, hippocampus, substantia nigra, and inferior colliculus.⁴⁶

Pharmacokinetics, Pharmacodynamics, and Metabolism

In the United States, the three benzodiazepines most widely available for intravenous administration, and hence most commonly used in the CICU, are diazepam, lorazepam, and midazolam. Although these agents work similarly at the receptor level, they are quite different with respect to their pharmacology and physical properties (Table 41-3). For example, these agents differ in potency. Midazolam is roughly three times more potent than diazepam, whereas lorazepam is five times more potent than diazepam.⁴⁶ In general, all three compounds are highly lipid soluble, but lorazepam is less so than diazepam or midazolam.⁵⁰

Table 41-3. Physicochemical Characterization of Three Benzodiazepines

	Diazepam	Lorazepam	Midazolam
Molecular weight	284.7	321.2	362
pKa	3.3 (20° C)	11.5 (20° C)	6.2 (20° C)
Water soluble	No*	Almost insoluble	Yes*
Lipid soluble	Yes,* highly lipophilic	Yes, relatively less lipophilic	Yes,* highly lipophilic

*pH dependent: pH >4 = lipid soluble, pH <4 = water soluble.

Adapted from Sasajima M: Analgesic effect of morphine-3-glucuronide. Keio Ogaka 1970;47:421.

The initial $t_{1/2\alpha}$ of these agents is similar: 1 to 2 minutes for midazolam and diazepam and about 3 minutes for lorazepam.^{51,52} The onset of peak clinical activity mirrors these half-lives; the slightly slower onset of lorazepam is related to its lower lipid solubility. The $t_{1/2\beta}$ is quite different among these three drugs and is related to a number of factors (discussed later). The absolute range in $t_{1/2\beta}$ is large; midazolam has a relatively short half-life of 2 to 3 hours, lorazepam has an intermediate half-life of 10 to 20 hours, and diazepam has a long half-life of 20 to 50 hours.⁴⁶

The benzodiazepines are metabolized in the liver where the parent compounds undergo extensive biotransformation. This often results in metabolic products that have significant benzodiazepine activity. Diazepam, the archetypal compound, undergoes biotransformation to a number of products, two of which (oxazepam and desmethyldiazepam) are potent and long-acting BNZ receptor agonists.¹⁴ This fact helps to explain the long $t_{1/2\beta}$ and prolonged sedative effect frequently seen with the use of diazepam.⁵³ Lorazepam is also highly metabolized, but it appears that none of its metabolic compounds have significant activity and that these products are rapidly excreted by the kidneys.⁵¹ Midazolam is biotransformed to compounds known as hydroxymidazolams, but controversy exists regarding whether these compounds have any intrinsic benzodiazepine activity.⁵⁴ As mentioned earlier, there have been many case reports of prolonged sedation from long-term use of diazepam, and this has been traditionally thought to be an effect of accumulation of active metabolites.⁵³ There are reports of prolonged sedation with midazolam infusions. Several studies have shown a prolongation of $t_{1/2\beta}$ and duration of sedation with midazolam administration in elderly patients and in the critically ill.^{55,56} These studies have shown a prolongation of the elimination half-life of about 2.5 times; this is thought to be caused by several factors, including increased volume of distribution and extensive fatty tissue uptake after prolonged infusion (recall that midazolam is highly lipid-soluble). One study investigating the effect of prolonged midazolam infusions in critically ill patients found that the mean time from administration to awakening in patients with renal failure was approximately 44 hours (control, 13 hours), and the time to awakening in two patients with renal and hepatic failure was greater than 120 hours.⁵⁷ Although these same principles could also theoretically apply to lorazepam, with its lower lipid-solubility and inactive metabolites, it appears less likely to cause prolonged sedation.¹⁴

Diazepam and lorazepam are water-insoluble and therefore require vehicles for intravenous injection. Diazepam injection is prepared with propylene glycol, alcohol, and benzyl alcohol as vehicles, whereas lorazepam is prepared with polyethylene glycol and benzyl alcohol vehicles.⁴⁶ The specific toxicities of these agents are discussed later. Midazolam for injection is a simpler solution to commercially prepare and administer because of the drug's pH-dependent water solubility.

A study of prolonged midazolam infusion in critically ill patients has noted a need for a progressive increase in dose that appears consistent with the development of acute benzodiazepine tolerance.⁵⁸ A convincing model for acute benzodiazepine tolerance has also been developed in the dog, showing tolerance with very short-term, albeit high-dose, benzodiazepine exposure.⁵⁹ The clinical significance of this phenomenon, especially with respect to how it may relate to benzodiazepine addiction in critically ill patients, is uncertain.

Cardiovascular and Hemodynamic Effects

With respect to hemodynamics, the benzodiazepines have a reputation of safety in patients with cardiac disease of various etiologies, especially coronary artery disease.^{60,61} High doses of these agents have been found to be safe for the induction of anesthesia in aortic stenosis patients.⁶² When administered alone, the benzodiazepines cause a mild decrease in arterial blood pressure, which is related to a decrease in systemic vascular resistance.⁴⁶ Other cardiac indices are minimally affected, and it is believed that a maintenance of normal compensatory cardiovascular reflexes is responsible for this relative preservation in blood pressure.⁴⁶ It is notable that midazolam has a more potent blood pressure-lowering effect than the other intravenous benzodiazepines.⁶³ As was alluded to previously, it is known that when a combination of a benzodiazepine and an opioid agent are administered, there is a synergistic effect in lowering blood pressure.⁶⁴ This effect appears to be super-additive and has been demonstrated with several different combinations of benzodiazepines and opioids. The effect appears to be related to a reduction in central sympathetic tone.⁶⁵ With respect to agents commonly used in the CICU, this synergism has been demonstrated for the combinations of midazolam-fentanyl and lorazepam-fentanyl.^{66,67} Although the majority of these data are taken from the cardiac anesthesia literature and may be related to the high doses of these drugs routinely used in this setting, common sense dictates that care must also be practiced in the CICU when these combinations are used, even when the doses are significantly lower.

Side Effects and Toxicity

When used with care, the benzodiazepines are safe sedative agents, largely because of their high therapeutic index.¹⁴ The cardiovascular and hemodynamic effects of benzodiazepines were discussed previously. The main side effects of the benzodiazepines applicable to critical care populations are excessive sedation and respiratory depression. Excessive sedation is generally a dose-related phenomenon. It is of greatest concern in the scenario of awake sedation in the nonintubated patient, when it may lead to inability to protect or maintain a patent airway. Central respiratory depression occurs with the benzodiazepines, but again, it appears to be a dose-related phenomenon that is relatively infrequent with reasonable dosages. Although the benzodiazepines flatten the ventilatory response curve to

hypercarbia, they do not shift the curve to the right as do opioids.^{46,68} Apnea does occur with benzodiazepines, but it is most commonly seen with the administration of large doses, as in the induction of anesthesia, and is not common with lower sedative doses used in the CICU.

Analogous to the blood pressure–lowering effect seen with opioid-benzodiazepine combinations, it is likely that these combinations also have a synergistic central respiratory depressive effect.⁴⁶ The sedative and respiratory side effects of benzodiazepines can be reversed by the BNZ receptor antagonist flumazenil, which has a very high affinity for the BNZ receptor.⁶⁹ Flumazenil has proved effective at acutely reversing benzodiazepine toxicity, but it must be used with caution. It has a relatively short elimination half-life compared with the longer-acting benzodiazepines; therefore, its reversal effect may be short-lived in comparison to the sedative effects of these agents, allowing the patient to become resedated after the flumazenil effect has terminated.⁴⁶ Additionally, seizures and acute withdrawal symptoms have been reported in patients with benzodiazepine tolerance treated with flumazenil.⁷⁰

The solvents used to provide an intravenous vehicle for the water-insoluble agents diazepam and lorazepam are known to cause phlebitis with peripheral intravenous injection.⁴⁶ Propylene glycol toxicity has also been reported with high-dose intravenous diazepam administration.⁷¹

Recently, it has been found that the prolonged administration of benzodiazepines to critically ill patients, particularly lorazepam, was found to be an independent risk factor for the development of delirium.⁷² Furthermore, plasma concentrations of benzodiazepines, or other sedatives, did not correlate well with sedation scores, suggesting that the effects of the drug are influenced by other factors, including age.^{72a} These reports should decrease practitioners' enthusiasm for infusions of benzodiazepines in critically ill elderly patients.

Clinical Indications

The benzodiazepines have three main uses in the CICU: as anxiolytics, as sedatives for mechanically ventilated patients, and as anticonvulsants.⁵⁸ Benzodiazepines are also useful for the treatment of acute alcohol withdrawal and may be useful in the treatment of acute cocaine intoxication.¹⁴ A secondary but beneficial property of the benzodiazepines in the critical care setting is amnesia, especially when painful invasive procedures or prolonged mechanical ventilation is necessary. Benzodiazepines do not, by themselves, have analgesic properties. Therefore, if painful procedures (e.g., placement of intra-aortic balloon pump or central lines) are anticipated, the benzodiazepines should be used in conjunction with an opioid analgesic. With respect to anxiolysis, the three commonly used benzodiazepines are equally efficacious and differ only with respect to their potency. The same statement also applies to their efficacy when used for sedation during mechanical ventilation. As discussed previously, because of its pharmacokinetic and pharmacodynamic properties, midazolam may be the best choice for long-term sedation in the mechanically ventilated patient if an intravenous infusion is to be used.⁵⁸ All of the benzodiazepines are effective when used for the acute termination of seizures. It is believed that lorazepam may be the drug of choice in the termination of status epilepticus because its longer half-life allows treatment with another longer-acting anticonvulsant (i.e., phenytoin) to be begun before seizures can recur.^{72b}

With respect to amnesia, all three of these agents appear to be efficacious. Lorazepam maintains a reputation for being a more potent amnestic than either diazepam or midazolam, but this is not fully supported by the literature. Lorazepam and midazolam have been compared in a randomized, controlled fashion with respect to anterograde amnesia, and it is clear that lorazepam provides a longer period of amnesia.⁷³ Likewise, diazepam was compared with midazolam in a similar study that demonstrated that at equal doses, midazolam was a more potent amnestic agent⁷⁴; however, the doses of midazolam and diazepam were equal but not equipotent in this study. Another study demonstrated the amnestic efficacy and safety of lorazepam when used for procedures in the critical care setting.⁷⁵ It appears that flumazenil is not as effective at reversing the amnestic effects of the benzodiazepines as it is at reversing the other side effects.⁷⁶

Propofol

History and Structure

Propofol is a unique hypnotic agent that was first introduced into clinical use in 1977.⁷⁷ It has an alkylphenol structure that is water-insoluble at room temperature. Because of this water-insolubility, propofol was first formulated in a Cremophor solution for anesthetic use, but was then changed to a lipid vehicle because of anaphylactic responses to cremophor.^{46,78} Since its introduction as an anesthetic agent, propofol has enjoyed progressively greater use in clinical areas outside of the operating room. Propofol is a rapid-acting, highly lipid-soluble central nervous system depressant with hypnotic and amnestic properties, but its exact site and mode of action are not fully understood.

Pharmacokinetics, Pharmacodynamics, and Metabolism

When administered by bolus or infusion, propofol follows a two-compartment pharmacokinetic model with a rapid $t_{1/2\alpha}$ of 2 to 8 minutes and a slower $t_{1/2\beta}$ of 1 to 3 hours.⁷⁹ A three-compartment model with a prolonged $t_{1/2\beta}$ of 4 to 7 hours has been postulated, implying uptake of propofol by poorly perfused fatty tissue.^{80,81} Although this would seem to imply that a prolonged period of sedation would occur with constant infusions (as is known to occur with fentanyl and midazolam, discussed previously), this does not seem to be the case with propofol. A study using propofol for sedation in mechanically ventilated CICU patients demonstrated a rapid time to extubation and full recovery (1 and 2 hours, respectively) in patients who were receiving infusions of propofol.⁸² This rather unique ability is thought to be related to extremely high clearance, which is higher than liver blood flow.⁷⁹ Therefore, although propofol has high hepatic clearance, it appears that other routes of elimination must exist to explain its short clinical duration of action. It is postulated that respiratory elimination may be partially responsible for this phenomenon.⁸³

Cardiovascular and Hemodynamic Effects

The majority of the data regarding the cardiovascular and hemodynamic effects of propofol have been generated in the setting of general anesthesia or sedation for surgery. The most prominent effect of propofol on hemodynamics is a decrease in arterial blood pressure, and several studies have found the average decrease in systolic blood pressure with an induction dose of propofol to be in the range of 25 to 40 mm Hg.^{84,85} During the maintenance phase of anesthesia with propofol infusion

(a situation more similar to propofol sedation in the CICU), systolic blood pressure was maintained at a level 20% to 30% below preinduction levels.^{84,85} This hypotension appears to be related to both peripheral vasodilation and a negative inotropic effect of the drug.⁴⁶ Propofol infusions appear to decrease both myocardial blood flow and myocardial oxygen demand.⁸⁶ These decreases are of roughly equal magnitude.⁴⁶ Various chronotropic responses have been reported in patients receiving propofol, including an increase, a decrease, and no change in heart rate.⁸⁶⁻⁸⁸

Side Effects, Complications, and Toxicity

Propofol is an agent of high potency that was previously used almost exclusively in the operating room by trained personnel (usually anesthesiologists) in a closely monitored setting. In many aspects, propofol behaves similarly to sodium thiopental. Propofol, like sodium thiopental, has a narrow therapeutic range between desired clinical effect and serious toxicity. The most serious of these side effects include arterial hypotension and central apnea; this apnea may be more prolonged than that seen with thiopental.⁸⁹ Propofol is a potent compound with a narrow therapeutic index and several dose-related effects, which if managed incorrectly, are potentially life-threatening. Propofol use should be limited to experienced personnel in a closely monitored setting. If propofol is used in nonintubated patients, it can lead to apnea or airway obstruction. Additionally, patients anesthetized with propofol have reported intense dreams in the immediate postoperative period.⁹⁰ Patients emerging from propofol anesthesia have also been observed to commonly display adventurous or merry behavior compared with patients who have been anesthetized with thiopental.⁹¹ Dystonic or choreiform movements not associated with abnormal EEG activity are observed in patients anesthetized with propofol.⁹²

An irritating side effect of propofol is pain at the site of infusion. This can be prevented by avoiding infusion into small hand veins.⁹³ Phlebitis is also occasionally seen.⁴⁶

Another important possible toxicity is seen after infusion of propofol: the propofol infusion syndrome, PRIS, is associated with some or all of the following: metabolic acidosis, refractory heart failure, progressive and refractory bradycardia, fever, lipemia, and increased creatine phosphokinase, myoglobinemia, and/or myoglobinuria.^{93a} The maximum recommended dose from the manufacturer is 4 mg/kg/hr for adults and all reported cases of PRIS apparently received higher doses than this.^{93b} Propofol infusions are no longer used in many pediatric intensive care units because of PRIS,^{93c} and all practitioners have been encouraged to adhere to the maximum limits suggested and to be watchful for signs of PRIS.^{93b}

Clinical Indications

The two most common indications for propofol in the CICU have been sedation for elective electrical cardioversion and sedation for mechanical ventilation.⁹⁴ A study comparing propofol, methohexital, and midazolam as sedatives for the elective electrical cardioversion of patients with supraventricular arrhythmias demonstrated that all three agents were efficacious, but that time to awaken was much more rapid in the propofol and methohexital groups.⁹⁵ It is notable that in this study two patients in the propofol group experienced recall of their cardioversion, whereas no patients in the methohexital or midazolam treatment groups reported awareness. Although hemodynamics

were well maintained in this group of stable patients, it seems prudent to avoid the use of propofol in the setting of cardioversion accompanied by hemodynamic instability because of propofol's known cardiovascular depressive effects.

There have been no randomized, controlled studies specifically investigating the safety or efficacy of propofol for sedation in the CICU patient. There are, however, a number of studies addressing its use in the medical-surgical intensive care unit (ICU) patient⁹⁶⁻¹⁰¹ and in the postoperative cardiac surgery patient.¹⁰²⁻¹⁰⁵ The experience from these studies suggests that when propofol is used in sedative doses ranging between 3 and 50 $\mu\text{g/kg/min}$, there is excellent patient tolerance and minimal side effects.

In a study directly comparing propofol and midazolam for short-term sedation of mechanically ventilated patients after coronary artery bypass graft (CABG) surgery, there was no difference in the number of hypotensive episodes during the maintenance phase of the study, although there was a significantly higher number of hypotensive episodes in the propofol group during propofol loading.¹⁰⁵ In addition, despite the mild to moderate degree of hypotension that accompanies the use of this agent, ICU patients sedated with propofol appear to have no compromise in oxygen transport.¹⁰¹ Furthermore, in a study by Stephan and colleagues,⁸⁶ patients treated with propofol were found to have a parallel and equal decrease in myocardial oxygen supply and demand, implying that this agent may be safe in the setting of coronary artery disease.

Despite the fact that propofol is not noted to possess analgesic properties, ICU patients sedated with propofol were noted to have a lower supplemental narcotic requirement than patients sedated with midazolam.^{99,105} Several studies including patients sedated for prolonged periods show a significantly more rapid awakening time and time to extubation with propofol than with midazolam.^{82,95} In a study by Carrasco and colleagues,⁸² the time to extubation in ICU patients treated with propofol was 2 hours as opposed to 37 hours in patients sedated with midazolam for more than 7 days. This experience has not been universal, and in two studies comparing propofol with midazolam in postoperative CABG patients, there was no significant difference in time to extubation.^{102,105} It is notable that in these studies, the duration of sedation was relatively short, perhaps preventing the fatty tissue uptake of midazolam, which seems to result in the pharmacodynamic changes responsible for prolonged sedation with this agent (discussed previously).

The absolute mechanism by which patients awaken so rapidly after prolonged propofol infusions is not clear because several studies have shown a dramatic increase in $t_{1/2\beta}$ when these agents are infused for long periods.^{98,100} Even so, Bailie and colleagues¹⁰⁰ showed an impressive decrease in plasma propofol level of 50% in the first 10 minutes after termination of propofol infusions in critically ill patients sedated for a mean of 86 hours.

Propofol infusions for mechanically ventilated patients provide a good option in the area of critical care and sedation. In terms of applicability to the cardiology patient, the published experience is limited. Experience in the medical-surgical and postoperative CABG patient population suggests that this therapy is safe and efficacious. As described previously, the literature suggests that propofol's main advantage over standard sedative agents is rapid awakening, but this improvement in time to awakening may only be significant in patients treated with prolonged infusions. In addition, there is a general consensus

in the literature that the minute-to-minute control of sedation is improved with propofol compared with standard sedative agents.⁹⁴ The available literature supports the use of sedative doses of propofol in the CICU for mechanical ventilation only.

Dexmedetomidine

History and Structure

Dexmedetomidine is the active dextro-isomer of medetomidine and is a highly selective α_2 -adrenergic receptor agonist. The α_2 -adrenergic agonist class of drugs can be divided into three groups: imidazolines, phenylethylamines, and oxalozepines. Clonidine, a more commonly used α_2 -agonist, and dexmedetomidine are both imidazole compounds. They exhibit a high ratio of specificity for the α_2 - versus the α_1 -receptor. Dexmedetomidine has eight times the potency as clonidine at the α_2 -receptor, and therefore is considered a full agonist at the α_2 -receptor.¹⁰⁶ As an α_2 -adrenergic agonist, dexmedetomidine exhibits sedative, anxiolytic, and analgesic properties.¹⁰⁷ It was granted FDA approval in December of 1999 for use as a short-term sedative (<24 hours) in ICU patients.

Site of Action and Receptor Physiology

Dexmedetomidine works at α_2 -receptors both peripherally and centrally. The sedative and anxiolytic effects of the drug are mediated through stimulation of central α_2 -receptors. Activation of these receptors attenuates central nervous system excitation, especially in the locus coeruleus.¹⁰⁸ Stimulation of central α_2 -receptors also leads to a decrease in sympathetic outflow and augmentation of cardiac vagal activity.¹⁰⁹ In addition, α_2 -receptors modulate pain pathways within the spinal cord. Activation of the α_{2c} -receptor subtype produces an analgesic effect by accentuating the action of opioids.³ Finally, α_2 -receptors are located on blood vessels and sympathetic terminals where they mediate vasoconstriction and inhibit norepinephrine release, respectively.¹⁰⁹

Pharmacokinetics, Pharmacodynamics, and Metabolism

Dexmedetomidine has an onset of action of approximately 15 minutes with peak concentrations reached within 1 hour following continuous infusion. It exhibits a rapid distribution phase with a $t_{1/2\alpha}$ of approximately 6 minutes and a $t_{1/2\beta}$ of approximately 2 hours. The drug is highly protein bound and has a large volume of distribution.¹¹⁰

Dexmedetomidine is highly metabolized by the liver. It undergoes glucuronidation and cytochrome P450 mediated metabolism. Therefore, patients with severe hepatic insufficiency may require lower doses of dexmedetomidine.¹¹⁰ The by-products of dexmedetomidine metabolism are excreted by the kidneys.¹¹¹

Cardiovascular and Hemodynamic Effects

The manufacturer's recommended dose of dexmedetomidine is 1 $\mu\text{g}/\text{kg}$ loading infusion over 10 minutes, followed by a continuous intravenous infusion of 0.2 to 0.7 $\mu\text{g}/\text{kg}/\text{hr}$.¹⁰⁸ A bolus of dexmedetomidine (1 $\mu\text{g}/\text{kg}$ over 10 minutes) may result in a transient increase in blood pressure and a reflex decrease in heart rate, especially in young patients.¹¹² This response is likely related to direct vasoconstriction of peripheral vessels. Animal studies show that the pressor response to bolus doses of α_2 -agonists is enhanced after autonomic denervation.¹¹⁰ In other words, when sympathetic inhibition from the central effects of α_2 -agonists are absent, the peripheral effects predominate, and

vasoconstriction leading to high blood pressure occurs.^{109,110} Alternatively, patients may experience profound hypotension and bradycardia with the bolus dose.^{112a} Most intensivists simply start a continuous infusion of dexmedetomidine between 0.2 and 0.7 $\mu\text{g}/\text{kg}/\text{hr}$ since omitting the bolus dose may avoid undesirable hemodynamic effects without compromising sedation.^{112b} During a continuous infusion of dexmedetomidine (0.2 to 0.7 $\mu\text{g}/\text{kg}/\text{hr}$), patients typically experience a slight decrease in blood pressure, heart rate, and cardiac output.¹⁰⁹ Sympatholysis from dexmedetomidine is involved in decreasing the heart rate as evident by the fact that patients taking β -blockers do not experience heart rate slowing.¹⁰⁹

Side Effects, Complications, and Toxicity

Giving a bolus dose of dexmedetomidine before initiation of a continuous infusion may cause hypertension or hypotension and bradycardia as noted above. Patients may experience hypotension and bradycardia during the continuous infusion of dexmedetomidine as well. This hypotension may be more severe in patients who are hypovolemic. Significant bradycardia and sinus arrest may occur in patients with high vagal tone or during rapid intravenous or bolus administration. Dexmedetomidine should be avoided in patients with advanced heart block and ventricular dysfunction because bradycardia and hypotension may be more pronounced.¹¹¹ Doses of the drug should be reduced in patients with hepatic impairment because the drug is highly metabolized by the liver. As noted above, the metabolites are excreted in the urine, and although the effects of the metabolites have not been studied, cautious dosing with renal failure may be prudent because these metabolites may accumulate. Mild respiratory depression is seen with bolus dosing of dexmedetomidine. This likely occurs as a result of sedation and is not due to any direct respiratory effects of the drug.¹⁰⁹

Clinical Indications

Dexmedetomidine is FDA approved for use as a sedative in the intensive care unit for less than 24 hours duration. Studies in intensive care patients have shown that compared with propofol, dexmedetomidine produces similar levels of sedation and time to extubation with less opioid requirements.¹⁰⁸ One study by Herr and colleagues examined dexmedetomidine versus propofol-based sedation regimens in post-coronary artery bypass graft patients. The results showed that dexmedetomidine provided safe and effective postoperative sedation in this patient population and reduced the need for analgesics, β -blockers, antiemetics, epinephrine, and diuretics.^{112c} Since dexmedetomidine provides sedation without decreasing respiratory drive, it can be used as a sedative during weaning from mechanical ventilation and throughout the extubation period. This can be particularly useful in anxious patients who otherwise might require large doses of propofol or benzodiazepines to tolerate the endotracheal tube during spontaneous breathing trials. In addition, dexmedetomidine may be beneficial in patients who have a high tolerance to opioids. Finally, current studies are evaluating whether dexmedetomidine is associated with less delirium than other types of sedatives.

In the cardiac care unit, many patients may have pre-existent bradycardia, cardiac conduction problems, or reduced ventricular ejection fractions. Patients may also be hypotensive or hypovolemic for a variety of reasons. Caution should be used in choosing dexmedetomidine as a sedative in these patient

populations. The risk of the side effects may outweigh the benefits in some patients.

Antipsychotic Agents

The occurrence of delirium in the intensive care unit is associated with adverse outcomes including lengthened ICU and hospital stay and increased 1-year mortality.^{113,114} Antipsychotic administration is broadly accepted as a treatment for delirium not associated with hypoglycemia, hypoxemia, or other treatable causes. The hope is that severity and duration of symptoms will be decreased.^{115,116} Two commonly used antipsychotic agents used to treat delirium in the critical care setting include haloperidol and olanzapine.

Haloperidol

Haloperidol is a member of the butyrophenone class of neuroleptic major tranquilizers. It has a moderately rapid rate of onset, with a $t_{1/2\alpha}$ of 3 to 19 minutes and a $t_{1/2\beta}$ of 10 to 19 hours.¹⁴ It is a more potent neuroleptic compared with the phenothiazines, with less severe side effects. Haloperidol is reputed to have fewer extrapyramidal, anticholinergic, and α -blocking effects than the other commonly used major tranquilizers.¹¹⁸ In addition, respiratory depression is rare with this agent, as is hypotension.¹⁴ Initially developed as an oral neuroleptic agent, haloperidol has gained favor as an intravenous agent for the acute treatment of psychosis and delirium in the critically ill medical patient.¹¹⁹ The intravenous route of administration seems to decrease the incidence of extrapyramidal side effects compared with the usual oral route of administration.¹²⁰ Intermittent bolus administration with rapid bolus escalation is recommended and commonly used to treat acute delirium.¹⁴ Standard doses range from 2 to 10 mg administered every 10 to 15 minutes until the desired effect is obtained. If around the clock dosing is desired the patient may be started on a divided intravenous dose based on the loading dose.¹⁴

Although haloperidol is an effective agent for the treatment of delirium it is not without serious side effects that may adversely affect CICU patients. A prolonged Q-T interval, torsades de pointes, ventricular arrhythmias, and cardiac arrest have been reported in patients treated with intravenous haloperidol.^{121,122} Daily electrocardiograms are warranted to follow the Q-T interval in all patients receiving haloperidol for the treatment of acute delirium. In addition to the cardiovascular effects, haloperidol may cause extrapyramidal effects, such as akathisia and oropharyngeal dysfunction.^{116,123} Neuroleptic malignant syndrome and dystonic reactions may also occur.^{118,124} In spite of these side effects, haloperidol has been investigated as a safe and efficacious treatment of agitation and delirium associated with the intra-aortic balloon pump.¹²⁵

Olanzapine

Olanzapine is a second-generation antipsychotic agent that belongs to the thienobenzodiazepine class. It is a selective monoaminergic antagonist with a high affinity for multiple receptors including serotonin 5HT₂/2C and 5HT₆, dopamine D₁-4, histamine H₁, and adrenergic α_1 -receptors. The mechanism of action of olanzapine is largely unknown.¹²⁶ It is available in oral and intramuscular forms, but is more commonly given by mouth in the intensive care setting. The oral form of Olanzapine is well absorbed with good bioavailability. It reaches

peak concentrations in approximately 6 hours and its $t_{1/2\beta}$ is approximately 21 to 54 hours. The drug undergoes direct glucuronidation and cytochrome P450 mediated oxidation. Renal dysfunction does not likely impact pharmacokinetics.¹²⁶ If a patient is able to take medications by mouth it is a good alternative to haloperidol for the treatment of ICU delirium, and in fact may be better tolerated with fewer side effects. In one study of olanzapine versus haloperidol, the group taking olanzapine had no extrapyramidal side effects.¹¹⁶ The drug is typically administered orally in doses that range from 5 to 10 mg daily.¹²⁶

Side effects of olanzapine include orthostatic hypotension that is likely the result of antagonism of adrenergic α_1 -receptors. Q-T prolongation has been reported with atypical antipsychotics such as olanzapine, however, the occurrence rate is lower than that seen with haloperidol.¹²⁷ Some studies indicate that olanzapine should be avoided in patients with dementia-related psychosis as there may be an increased risk of stroke and death compared to placebo.^{126,128} A recent prospective study, however, reported that neither the use of atypical antipsychotics nor the use of conventional neuroleptics increased mortality among elderly patients with dementia.¹²⁹ Nonetheless, olanzapine is not approved for the treatment of patients with dementia-related psychosis and should be avoided in this patient population.¹²⁶ Other side effects include hyperglycemia, neuroleptic malignant syndrome, and hyperlipidemia.

Pharmacologic Interactions in the CICU

Shoshana Zevin

CHAPTER

42

Vasodilators
Angiotensin-Converting Enzyme Inhibitors and
Angiotensin Receptor Blockers

Inotropic Drugs
Antiarrhythmic Drugs

CONCOMITANT ADMINISTRATION of several drugs is common in the treatment of cardiovascular diseases. Often, combinations of drugs are necessary and result in increased efficacy of therapy, but with a large number of medications there is also an increased concern about drug interactions. Although the number of potential interactions is great, many are inconsequential. Conversely, drug interactions can have a significant adverse effect or even be lethal.^{1,2}

Many drug interactions can be prevented by recognizing the drugs and the patients at risk. Situations with a high likelihood for clinically significant adverse drug interactions include the following¹⁻⁴:

1. A large number of drugs. The risk is significantly higher when more than 10 drugs are concurrently administered.
2. Drugs with a steep dose-response relation, so that even small changes in the drug level lead to profound changes in its action.
3. Drugs with a narrow therapeutic index.
4. Concomitant administration of drugs known as liver enzyme inducers or inhibitors (e.g., rifampin and cimetidine).
5. Elderly patients.
6. Critically ill patients.

It is important to be aware of the possibility of drug interactions in the CICU because many of these patients receive high-risk drugs, are elderly, and may have circulatory failure or be critically ill. It is also important to inquire about the use of herbal supplements and medicines, as many of these products can interact with drugs and cause adverse events. Drug interactions may mimic worsening or progression of the underlying disease, with manifestations such as arrhythmia or heart failure.

Mechanisms of interactions may be pharmacokinetic, affecting drug absorption, bioavailability, metabolism, or renal excretion; or pharmacodynamic, occurring at the sites of action in the heart such as sinoatrial and atrioventricular nodes, the intraventricular conduction system, and the smooth muscle.⁴

This chapter discusses interactions of drugs commonly used in CICU, with emphasis on interactions with other cardiovascular drugs.

Vasodilators

Nitrates

The chief interactions of nitrates are pharmacodynamic. Nitrates (e.g., nitroglycerin, isosorbide dinitrate, isosorbide mononitrate) are widely used both in patients with angina

and in those with congestive heart failure. A limitation in nitrate therapy is the development of tolerance, which is time-dependent.⁵ Many theories are proposed to explain this phenomenon⁶⁻⁸ including nitrate resistance,⁹ pseudotolerance (i.e., activation of counter-regulatory responses, such as secretion of catecholamines, angiotensin II, and endothelin)¹⁰ and “true” tolerance resulting from impaired bioconversion to nitric oxide (NO)^{11,12} and increased generation of superoxide.⁸

There are several reports of agents that limit or reverse nitrate tolerance when coadministered with nitroglycerin to isosorbide dinitrate. These include *N*-acetylcysteine, ACE inhibitors,^{13,14} angiotensin receptor blockers (ARBs),¹⁵ carvedilol,¹⁶ hydralazine,¹⁷ ascorbic acid,¹⁸ folic acid,¹⁹ and L-arginine.²⁰ However, there are not enough data to make definite recommendations on drug combinations to prevent nitrate tolerance.

The combination of nitrates with hydralazine has been long known to be beneficial in congestive heart failure and is still used in patients who are intolerant of ACE inhibitors and in African-American patients who have reduced capacity for endogenous production of nitric oxide.²¹ These drugs may interact at the site of smooth muscle, involving inhibition of pyridoxal-dependent enzymes by hydralazine and resulting in an increased availability of sulfhydryl groups and prevention of nitrate tolerance by decreasing superoxide production and scavenging of reactive oxygen species.^{17,22}

A clinically significant interaction occurs between nitrates and phosphodiesterase type 5 (PDE5) inhibitors, such as sildenafil and tadalafil, commonly used to treat erectile dysfunction.²³⁻²⁵ Inhibition of PDE5 results in increased cGMP levels, which are generated from endogenously derived NO. Nitrates exert their effect via biotransformation to NO and generation of cGMP. Coadministration of nitrates and PDE5 inhibitors causes significant reduction of blood pressure via a synergistic increase in cGMP levels, resulting in symptomatic hypotension and even death.²³⁻²⁵ PDE5 inhibitors are contraindicated for patients treated with nitrates. Conversely, nitrates should not be started within 24 hours of using sildenafil and 48 hours of using tadalafil.²⁶

Another pharmacodynamic interaction occurs when nitrates are used with β -blockers, calcium channel blockers, or both as part of an intensive antianginal regimen, resulting in hypotension with reduced coronary flow. The result may be worsening of angina.²⁷

Table 42-1. Drug Interactions with Angiotensin-Converting Enzyme Inhibitors (ACEI)

Interacting Drug	Effect	Mechanism	Comments
Potassium supplements or potassium-sparing diuretics	Hyperkalemia	Inhibition of aldosterone release	Avoid combinations, monitor potassium levels
Angiotensin receptor blockers	Hyperkalemia Hypotension Renal failure	Dual inhibition of RAS	Monitor potassium levels, blood pressure, and renal function
Diuretics	Hypotension Renal failure	Inhibition of angiotensin II-mediated response to hypovolemia	Reduce dose or temporarily discontinue the diuretic before starting ACE inhibitor
NSAIDs	Inhibition of hypotensive effect of ACEI	Inhibition of kinin-mediated prostaglandin synthesis	Monitor blood pressure
Lithium	Lithium toxicity	Reduction of Na concentration in the proximal tubules by ACEI, causing increased lithium reabsorption	Reduce lithium dose by 50%, monitor lithium blood levels
Sulfonylurea	Hypoglycemia	Increased sensitivity to insulin	Monitor blood glucose

Abbreviations: NSAIDs, nonsteroidal anti-inflammatory drugs; RAS, renin-angiotensin system.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors (Table 42-1) are widely used for the treatment of heart failure and hypertension, and to prevent remodeling after myocardial infarction.

Interactions involving ACE inhibitors are primarily pharmacodynamic and are based on their mechanism of action. The principal mechanism of action is lowering of angiotensin II levels, resulting in vasodilatation and suppression of aldosterone release. ACE inhibitors also inhibit the degradation of bradykinin and increase prostaglandin synthesis, both of which may contribute to vasodilation.

The main interaction of concern is between ACE inhibitors and potassium supplements or potassium-sparing diuretics. These combinations can result in rapid development of hyperkalemia, especially in the presence of diminished renal function.

There is a beneficial effect in the synergism between ACE inhibitors and diuretics (e.g., thiazides and furosemide) in the treatment of hypertension and heart failure, but in a sodium-depleted patient or one with high renin levels, the combination can result in hypotension and worsening of renal failure. In such patients, the physician should start with a lower than normal dose of ACE inhibitor, temporarily lower the dose of diuretic, or discontinue the diuretic before administration of an ACE inhibitor.²⁸ There is no evidence of a significant pharmacokinetic interaction between ACE inhibitors and diuretics.²⁹ A synergistic effect on blood pressure reduction was also observed between various ACE inhibitors and calcium antagonists without pharmacokinetic interactions.²⁸

No significant interactions were found between ACE inhibitors and β -blockers or digoxin.^{28,29}

Among the interactions with noncardiovascular drugs, the most notable is with nonsteroidal anti-inflammatory drugs (NSAIDs) because of these drugs' opposing effects on prostaglandin synthesis. The result is an attenuation of the

antihypertensive effects of ACE inhibitors, predisposition to renal failure, or both.^{30,31} There are conflicting reports on the interactions between ACE inhibitors and low-dose aspirin.^{32,33} However, a retrospective analysis did not demonstrate an adverse effect of aspirin on the survival of patients with left ventricular systolic dysfunction treated with ACE inhibitors.³⁴

There are reports of lithium toxicity when patients on chronic lithium therapy were started on ACE inhibitors. Because renal excretion of lithium is dependent on glomerular filtration and on sodium concentration in the proximal tubule, the possible mechanism of interaction may be the reduction of both by ACE inhibitors, especially in volume-depleted patients.^{28,29}

A life-threatening anaphylactoid reaction has been described in a patient treated with ACE inhibitors while on hemodialysis with a polyacrylonitrile membrane (AN69). The possible mechanism of this interaction is activation of the kinin-kallikrein system by the surface of the AN69 membrane, resulting in an increased production of bradykinin, the breakdown of which is inhibited by ACE inhibitors.²⁸ No adverse reactions were reported with other dialysis membranes.

ACE inhibitors increase insulin sensitivity, and there have been several reports of hypoglycemia when captopril or enalapril was given to patients receiving glibenclamide, although others did not observe this effect.³⁵⁻³⁷ It seems prudent to monitor for possible hypoglycemia when ACE inhibitors are given to patients who are already receiving oral antihypoglycemic agents.

Angiotensin receptor blockers (ARBs) have low potential for interaction with other drugs. Among ARBs, only losartan and irbesartan undergo significant metabolism by cytochrome P-450 enzymes (CYP 2C9 and CYP 3A4). Rifampin significantly reduces the AUC and the half-life of losartan and of its active metabolite, and dose increase of losartan may be indicated during concomitant administration.³⁸ However, no clinically significant interactions were found between losartan and erythromycin, digoxin, or warfarin, and between irbesartan and digoxin, nifedipine, or hydrochlorothiazide.³⁹ There was a report of a significant interaction between valsartan and lithium resulting in lithium toxicity.⁴⁰

Attenuation of the hypertensive effect of ARBs may result from concomitant administration of NSAIDs, via mechanisms similar to the interaction with ACE inhibitors.³⁹

Combination of ACE inhibitors and ARBs provides a dual and more effective blockade of the renin-angiotensin system (RAS). The combination was shown to be more effective in patients with diabetic and nondiabetic nephropathy and in patients with congestive heart failure.^{41,42} However, there are more adverse effects of hypotension, hyperkalemia, and renal dysfunction in patients on combination therapy.⁴² There are conflicting data on the use of dual RAS blockade with β -blockers in patients with CHF. Val-HeFT trial suggested an increased mortality in patients treated with triple therapy compared with an ACE inhibitor and β -blocker alone, while the CHARM and VALIANT trials did not find any increase in mortality in patients on triple therapy.⁴³⁻⁴⁵ The combination therapy of ACE inhibitor and ARB seems prudent in patients with CHF with highly activated RAS despite full-dose ACE inhibition, and in diabetic patients with nephropathy.⁴¹

Inotropic Drugs

Dopamine and Dobutamine

Vasoactive amines are used in the CICU to treat heart failure and shock. Both drugs are metabolized in the liver: dopamine by catechol-*O*-methyltransferase and monoamine oxidase; dobutamine by catechol-*O*-methyltransferase. Dopamine is inactivated in alkaline pH and therefore should not be administered in the same infusion as bicarbonate.⁴⁶

Although there are not many reports in the literature about drug interactions involving vasoactive amines, such interactions could be expected in patients treated with monoamine oxidase inhibitors, requiring lowering the dose of dopamine. The dose of vasoactive amines should be adjusted in patients treated with tricyclic antidepressants because of the possibility of an increased pressor effect.

Changes in blood pressure and in blood flow to the liver will affect the metabolism of high-extraction drugs, such as lidocaine and lipophilic β -blockers (e.g., propranolol, metoprolol). As a result, doses of inotropic drugs that increase cardiac output will also increase liver blood flow and accelerate the clearance of lidocaine, requiring an increased dose of lidocaine. Conversely, when dopamine is used in high doses, resulting predominantly in α -activation and vasoconstriction, the liver blood flow decreases, and lidocaine clearance would be expected to do the same.

Low-dose dopamine prevented norepinephrine-induced decreases in renal plasma flow in healthy volunteers.⁴⁷ However, it is not clear whether the same effect is found in critical-care patients. A multicenter study of low-dose dopamine use in critical care patients did not find any improvement in renal outcomes, and there were more adverse effects in patients on dopamine.^{48,49}

There is a report of interaction between dobutamine and low-dose carvedilol resulting in severe hypotension.⁵⁰ The proposed mechanism is a fall in systemic vascular resistance due to excessive β_2 -receptor activation caused by a selective β_1 -receptor blockade by low-dose carvedilol. This interaction may be expected with other selective β_1 -blockers.

Digoxin

Digoxin is a drug with a narrow therapeutic range and is subject to many drug interactions, both pharmacokinetic and pharmacodynamic (Table 42-2).

Interactions Affecting Absorption and Bioavailability

Digoxin tablets are absorbed slowly; therefore, agents that increase gastrointestinal motility (e.g., metoclopramide) may decrease its absorption, whereas agents that slow gastrointestinal transit (e.g., propantheline, other anticholinergic agents) may increase its absorption.⁵¹ Elixir preparations are usually not subject to these interactions because their absorption is more rapid.

Treatment with high-dose chemotherapeutic agents resulting in intestinal mucosal injury can reduce digoxin absorption from tablets by as much as 50% but does not significantly affect absorption from elixir.⁵²

In about 10% of patients, digoxin that is not absorbed in the upper gastrointestinal tract or that is excreted in the bile is reductively metabolized by the anaerobic bacteria *Eubacterium Lentum*, which is part of the normal flora of the colon. Such metabolism can account for about 40% of digoxin elimination. These patients may be recognized by the characteristic of needing higher than usual doses of digoxin to achieve therapeutic levels. In this group of patients, treatment with broad-spectrum antibiotics (e.g., erythromycin, tetracycline) can result in significantly increased bioavailability and digoxin toxicity.⁵³

Cholesterol-binding resins (e.g., cholestyramine, colestipol) bind digoxin in the gut and may reduce its absorption by 20% to 30%. This effect can be avoided by giving digoxin at least 1 hour before the resins.⁵⁴

Sucralfate has been reported to decrease the absorption of digoxin.⁵⁵ No significant interaction has been found between digoxin and antacids.⁵⁶

Intestinal P-glycoprotein (P-gp) plays an important role in bioavailability of digoxin.⁵⁷ Rifampin increases P-gp content in the intestine and decreases digoxin bioavailability, resulting in significantly lower digoxin AUC after oral administration.⁵⁸ On the other hand, drugs that inhibit intestinal P-gp increase digoxin bioavailability and AUC. Dipyridamole was shown to increase digoxin bioavailability in vitro and in vivo; however, the effect on AUC was slight and clinically insignificant.⁵⁹ Carvedilol significantly decreased oral clearance of digoxin in children, resulting in digoxin toxicity in some cases.⁶⁰ However, in adults carvedilol caused only a modest increase in digoxin bioavailability and AUC.⁶¹

St. John's wort (*Hypericum perforatum*) is an herbal medicine frequently used for treatment of depression. *Hypericum* induces intestinal P-gp, resulting in a 1.4-fold increased expression of duodenal P-gp in humans.⁶² Coadministration of St. John's wort and digoxin caused a 25% decrease in AUC and a 33% reduction in trough and C_{max} concentrations of digoxin.⁶³

Interactions Affecting Elimination

Digoxin is eliminated primarily by renal excretion via the ATP-dependent efflux pump P-glycoprotein (P-gp).^{57,64-66} Basic drugs, among them amiodarone, clarithromycin, itraconazole, quinine, quinidine, verapamil, spironolactone, cyclosporine A, propafenone, and ritonavir decrease the renal clearance of digoxin by inhibiting P-gp in the kidney.⁶⁷⁻⁷² Carvedilol caused significant increases in digoxin AUC and C_{max} in men, but not in women.⁷³ The explanation may be that men have a higher P-gp activity compared to women, and thus are more sensitive to the effects of inhibiting drugs.

Because the combination of digoxin with drugs that inhibit its elimination results in increased toxicity, the physician should

Table 42-2. Drug Interactions with Digoxin

Interacting Drug	Serum Digoxin Levels	Mechanism	Comments
Cholestyramine, colestipol	D	Decreased absorption	Wait 1 hr after digoxin administration
Metoclopramide	D	Decreased absorption due to increased GI motility	Monitor digoxin levels; substitute elixir for tablets
Erythromycin	I (only in small percentage of patients)	Increased bioavailability due to decreased gut metabolism	Monitor digoxin levels, adjust dose
Anticancer drugs	D	Decreased absorption due to mucosal injury	Monitor digoxin levels; substitute elixir for tablets
Sucralfate	D	Decreased absorption	Do not administer within 1 hr of digoxin
Amiodarone	I	Decreased clearance (P-gp inhibition)	Decrease digoxin dose, monitor levels
Cyclosporine	I	Decreased clearance of digoxin (P-gp inhibition)	Monitor digoxin levels, decrease dose
Diuretics	I	Decreased renal clearance in hypovolemia; increased toxicity due to hypokalemia/hypomagnesemia	Monitor serum potassium and magnesium levels; monitor digoxin levels
Itraconazole	I	Decreased clearance (P-gp inhibition)	Decrease digoxin dose, monitor levels
Propafenone	I	Decreased renal clearance	Monitor digoxin levels, adjust dose
Quinine, quinidine	I	Decreased renal clearance (P-gp inhibition)	Decrease digoxin dose, monitor blood levels
Spironolactone	I	Decreased renal clearance (P-gp inhibition)	Monitor levels
Verapamil	I	Decreased renal excretion (P-gp inhibition)	Decrease digoxin dose, monitor levels
Rifampin	D	Increased bioavailability (intestinal P-gp induction)	Monitor levels

Abbreviations: D, decrease; GI, gastrointestinal; I, increase; P-gp, P glycoprotein.

reduce the digoxin dose by 50% when starting another drug such as quinidine or amiodarone. Because of the long half-life of digoxin, even after dose reduction there is still a potential for toxicity during the first week after adding another drug to the regimen, and patients must be monitored closely during this period.

Pharmacodynamic Interactions

Digitalis effect and toxicity are enhanced in the presence of hypokalemia and hypomagnesemia, and toxicity may be present even with digoxin blood levels within the therapeutic range. Because digoxin is often used with diuretics, which can cause electrolyte abnormalities, it is important to monitor and correct deficiencies, even though potassium and magnesium blood levels do not always accurately reflect body stores.⁷⁴ Concomitant administration of digoxin and sympathomimetic or vagolytic drugs may mask digitalis toxicity because of opposing effects on cardiac conduction. This effect is used therapeutically when digoxin is administered at the beginning of quinidine therapy to prevent rapid atrioventricular node conduction as a result of the vagolytic effect of quinidine.

Coadministration of digoxin with sympatholytic drugs (e.g., β -blockers) or calcium antagonists (e.g., verapamil, diltiazem) may result in additive atrioventricular block or bradyarrhythmia.

Antiarrhythmic Drugs

Drug interactions with antiarrhythmic drugs are presented in Table 42-3. A detailed review was published by Trujillo and Nolan.⁷⁵

Class 1A

Quinidine

Quinidine is a drug with many adverse side effects, and it interacts with many other drugs.

Pharmacokinetic Interactions

Quinidine is primarily metabolized in the liver, and only about 20% is excreted in urine. Thus it is subject to interactions with drugs that either induce or inhibit liver enzymes. Among the enzyme inducers, phenobarbital, phenytoin, and rifampin accelerate the metabolism of quinidine, resulting in decreased blood levels. Therefore, when any of these drugs is added, the quinidine dose should be increased, and when these drugs are stopped, the quinidine dose should be decreased. The dose adjustment may be as great as threefold.⁷⁶

There have been conflicting reports about the effect of nifedipine on quinidine blood levels.⁷⁷ However, quinidine

Table 42-3. Drug Interactions with Antiarrhythmic Drugs

Drug	Interacting Drug	Effect	Mechanism	Comments
Quinidine (Q)	Rifampin	Decrease in Q levels	Induction of Q metabolism	Increase Q dose, monitor Q levels
	Phenytoin Phenobarbital Cimetidine	Increase in Q levels	Inhibition of Q metabolism	Decrease Q dose, monitor Q levels
	Amiodarone Verapamil Antacids	Increase in Q levels	Alkalinization of urine, reduced Q tubular secretion	Monitor Q levels, change can be minor
	Procainamide	Proarrhythmic effect	Additive Q–T prolongation	Use combination with caution; monitor Q–T and potassium levels
	Disopyramide Amiodarone Sotalol Succinylcholine	Torsades de pointes		
		Prolonged neuro-muscular blockade	Inhibition of neuromuscular transmission (muscarinic receptors)	
Procainamide (P)	Cimetidine Trimethoprim Levofloxacin	Increased P levels	Reduced tubular secretion of P	Reduce P dose, monitor P levels
Disopyramide (Di)	Rifampin	Decreased Di levels	Acceleration of Di metabolism	Increase Di dose or avoid combination (increased anticholinergic effects with Di metabolite)
	Phenytoin Macrolides	Increased Di levels	P-450 inhibition	Decrease Di dose or avoid combination
Lidocaine (L)	Cimetidine Amiodarone Fluvoxamine Phenobarbital β -blockers	Increased L levels Decreased L levels Increased L levels	Inhibition of L metabolism Acceleration of L metabolism Decrease in L clearance due to reduction in hepatic blood flow	Reduce L infusion rate Increase L dose Reduce L infusion rate
Mexiletine (M)	Quinidine	Increased M levels	Inhibition of M metabolism	Reduce M dose or avoid combination
	Rifampin Phenytoin	Decreased M levels	Acceleration of M metabolism	Increase M dose
Flecainide (F)	Cimetidine Amiodarone Quinine Antacids	Increased F levels Increased F levels	Inhibition of F metabolism Alkalinization of urine, decrease in tubular secretion	Decrease F dose Minor effect
Encainide (E)	Quinidine	Increased E levels; diminished efficacy due to reduced formation of active metabolite	Inhibition of E metabolism	Avoid combination
	Cimetidine	Increased E levels; enhanced activity due to inhibition of active metabolite clearance	Inhibition of E metabolism	Avoid combination

Continued

Table 42-3. Drug Interactions with Antiarrhythmic Drugs—*cont'd*

Drug	Interacting Drug	Effect	Mechanism	Comments
Propafenone (Pr)	Quinidine	Increased Pr levels and β -blockade	Inhibition of Pr metabolism	Decrease Pr dose or avoid combination
Amiodarone (A)	Digoxin	Increased levels of the interacting drugs	Inhibition of the drug's metabolism by A	Monitor serum A levels, adjust dosages
	Flecainide			
	Lidocaine			
	Procainamide			
	Quinidine			
	Simvastatin			
	Cyclosporine			
	Phenytoin			
	Warfarin			
	Class 1A and 1C drugs	Proarrhythmic effect, torsades de pointes	Additive Q-T prolongation	Avoid combination or monitor Q-T
	β -blockers Ca channel blockers	Hypotension, bradycardia, AV	Additive depression of conduction	Monitor blood pressure and pulse rate; avoid combination in conduction disorders and heart failure
Adenosine (Ad)	Theophylline (T)	Antagonizes Ad effect	Competition for Ad receptors	Ad ineffective for patients on T
	Dipyridamole	Increased Ad levels and effect	Inhibition of Ad reuptake	Decrease Ad dose by 50%-75%

pharmacokinetics do not appear to be significantly changed by nifedipine or felodipine.⁷⁷

Cimetidine, verapamil, and amiodarone inhibit quinidine metabolism and necessitate downward dose adjustment.⁷⁸⁻⁸⁰

Even though renal excretion accounts for only 20% of quinidine clearance, clearance is influenced by urine pH, and alkalinization of urine (e.g., with intensive antacid therapy) may result in a moderate increase in quinidine levels.⁸¹

Pharmacodynamic Interactions

The combination of quinidine with other class 1A drugs (e.g., disopyramide, procainamide) or with class 3 drugs (e.g., amiodarone, sotalol) can result in Q-T prolongation and increased risk of torsades de pointes.^{82,83}

Moxifloxacin, a methoxyquinolone antibiotic, prolongs Q-T interval, and must be used with caution with class 1A or class 3 drugs.⁸⁴ Hypokalemia, hypomagnesemia, or both, common with diuretic treatment, can increase Q-T prolongation and the risk of torsades de pointes from quinidine or other drugs.⁸⁵

A proarrhythmic effect of combining amiloride and quinidine together has been described, probably resulting from a synergistic increase in sodium channel blockade.⁸⁶

Quinidine has also been reported to potentiate the anticoagulant effects of warfarin by direct inhibition of clotting factor synthesis in the liver.^{81,87} Quinidine inhibits neuromuscular transmission and prolongs the duration of anesthesia when used with curare or succinylcholine.⁸⁸

Procainamide

Procainamide is both metabolized and excreted renally, and its active metabolite, *N*-acetyl procainamide (NAPA), is cleared primarily by renal excretion. The major mechanism is tubular

secretion with little reabsorption; therefore, urine pH changes do not cause significant changes in blood procainamide concentration. Conversely, other basic drugs that are secreted by renal tubules (e.g., cimetidine, ranitidine, trimethoprim) significantly inhibit procainamide secretion.^{89,90} Levofloxacin, but not ciprofloxacin, was found to significantly inhibit renal clearance of procainamide and of NAPA.⁹¹

Additive effects of combined treatment with other class 1A or class 3 drugs, or other drugs that cause Q-T prolongation, are the same as for quinidine.

Disopyramide

Disopyramide is metabolized by liver enzymes. Enzyme inducers (e.g., rifampin, phenytoin, barbiturates) enhance the metabolism of disopyramide and may cause subtherapeutic blood levels.⁹² Enzyme inhibitors such as cimetidine are expected to decrease disopyramide clearance and to increase blood levels. Macrolide antibiotics, including erythromycin, clarithromycin, and azithromycin, inhibit P450 enzymes and there are reports of disopyramide toxicity during concomitant administration.⁹³⁻⁹⁵

Class 1B

Lidocaine

Lidocaine is extensively metabolized by the liver, with a high extraction ratio; therefore, its clearance is dependent on hepatic blood flow. Lidocaine is usually administered as a bolus followed by continuous intravenous infusion. The distribution of a bolus to the tissues is slowed in patients with severe heart failure and shock and may result in high blood levels and toxicity.⁹⁶ To avoid this, a bolus dose of lidocaine in these situations should be given slowly.

Drugs that decrease hepatic blood flow (e.g., β -blockers) decrease lidocaine clearance, whereas drugs that increase

hepatic blood flow (e.g., dopamine and dobutamine) can be expected to increase clearance.⁹⁷

Lidocaine clearance changes with liver enzyme inducers and inhibitors; it decreases with cimetidine and increases with phenobarbital.⁹⁸ Amiodarone has been reported to reduce lidocaine clearance, resulting in high lidocaine plasma levels and seizures.⁹⁹ Fluvoxamine, a CYP 1A2 inhibitor, significantly reduced lidocaine clearance.¹⁰⁰ An interaction with mexiletine, resulting in increase in plasma lidocaine levels and toxicity, was reported.¹⁰¹ The purported mechanism is displacement of lidocaine from tissue binding sites. It is recommended that the rate of lidocaine infusion be adjusted by 25% to 50% in the presence of potential drug interactions.

Increased cardiotoxicity resulting in sinoatrial block has been reported with concomitant use of lidocaine and quinidine or procainamide.^{81,102}

Mexiletine

Mexiletine is extensively metabolized by the liver, mainly by cytochrome P-450 isozyme 2D6, the activity of which is genetically determined, and in part by isozyme 1A2. Mexiletine metabolism is inhibited by quinidine.¹⁰³ Fluvoxamine, a CYP 1A2 inhibitor, caused significant increases in mexiletine AUC.¹⁰⁴ The enzyme inducers rifampin and phenytoin have been shown to enhance its metabolism.¹⁰⁵

Class 1C

Flecainide

Flecainide is eliminated by renal excretion and hepatic metabolism. Changes in urine pH are expected to affect its clearance; alkalization of urine will result in higher plasma concentrations. Cimetidine, quinine, and amiodarone have been reported to inhibit the clearance and increase plasma concentrations of flecainide.^{106,107}

Encainide

Encainide is extensively metabolized by the liver with significant first-pass effect, and its metabolism is genetically determined. Its metabolites are active and are responsible for the majority of its pharmacologic activity.¹⁰⁸ Quinidine inhibits encainide metabolism, resulting in diminished pharmacologic activity.¹⁰⁹ Cimetidine inhibits the metabolism of the active metabolites of encainide even more than it inhibits encainide metabolism, resulting in enhanced pharmacologic activity.¹¹⁰

Propafenone

Propafenone is metabolized by cytochrome P-450 isozyme 2D6; thus its metabolism is subject to genetic polymorphism of 2D6; about 10% of whites are poor metabolizers of this drug. When propafenone is administered to extensive metabolizers, quinidine, a potent inhibitor of 2D6 enzyme, inhibits its clearance, resulting in higher blood levels and a significant increase in pharmacologic effect.^{111,112} Conversely, rifampin, a P-450 inducer, increases propafenone clearance.¹¹³ Propafenone has been reported to inhibit the metabolism of theophylline.¹¹⁴

Class 3

Amiodarone

Amiodarone has a number of significant pharmacokinetic and pharmacodynamic drug interactions.

Pharmacokinetic Interactions

Amiodarone is an inhibitor of certain cytochrome P-450 enzymes. Amiodarone potentiates the effect of warfarin and causes enhanced anticoagulation.^{115,116} Because the half-life of amiodarone is very long, this effect may take up to several weeks to reach maximum intensity. Conversely, after amiodarone is discontinued, its effect on warfarin metabolism can persist for several months. Amiodarone also elevates the blood levels of digoxin, quinidine, procainamide, flecainide, lidocaine, metoprolol, simvastatin, cyclosporine, and phenytoin.^{99,117-120} It is recommended that dosages of warfarin and digoxin should be decreased by half when amiodarone is added.⁷⁵

Pharmacodynamic Interactions

The combination of amiodarone with class 1A or 1C drugs can result in enhanced antiarrhythmic efficacy. However, when combined with class 1A drugs such as quinidine, amiodarone can result in marked Q-T prolongation and an increased risk of torsades de pointes.⁷⁴ Another pharmacodynamic interaction with calcium antagonists or β -blockers may result in sinoatrial node depression, with excessive bradycardia or sinus arrest.¹²¹ This effect may persist for weeks after discontinuing amiodarone. However, the combination of amiodarone and β -blockers is usually safe, and may be beneficial in post-MI patients.¹²²

Sotalol

The administration of aluminum and magnesium hydroxide decreased sotalol absorption.¹²³ Separation of the drugs by 2 hours avoided the interaction. Sotalol is excreted primarily unchanged by the kidneys. The same pharmacodynamic effects for the combination with class 1A drugs would be expected for sotalol as with amiodarone. Hypokalemia can aggravate the risk of torsades de pointes with this combination.¹²⁴ Torsades de pointes was reported after the combination of sotalol and terfenadine.¹²⁵ The combination of sotalol with other β -blockers may produce bradycardia, atrioventricular block, or exacerbation of heart failure.¹²⁶

Class 4

Adenosine

Adenosine is used for acute treatment of supraventricular tachycardia. Dipyridamole inhibits adenosine reuptake, causing increased blood concentrations. Patients on dipyridamole should receive one fourth the standard dose of adenosine. Theophylline competes with adenosine for the same receptors and thus inhibits its action.¹²⁷

Calcium Channel Blockers

The most commonly used calcium channel blockers (Table 42-4) (e.g., verapamil, diltiazem, nifedipine) are extensively metabolized by the liver; therefore, their metabolism is dependent on hepatic blood flow. Because of their extensive hepatic metabolism, they undergo significant first-pass metabolism in the liver, with a low level of bioavailability.¹²⁸ Verapamil and diltiazem also inhibit some P-450 enzymes, thus affecting the metabolism of other drugs.

Pharmacokinetic Interactions

Cytochrome P-450 enzyme inducers (e.g., rifampin, phenytoin, phenobarbital) decrease the bioavailability and increase the clearance of verapamil and diltiazem. St. John's wort also

Table 42-4. Drug Interactions with Calcium Channel Blockers

Drug	Interacting Drug	Effect	Mechanism	Comment
Verapamil Diltiazem	β -blockers	Bradycardia, sinus arrest, heart block, heart failure	Additive effect on myocardial contractility and conduction	Avoid combination in elderly patients and in those with heart failure or conduction abnormalities
	Cimetidine	Increased bioavailability	Inhibition of metabolism	Decrease dose of Ca blockers
Felodipine Nitrendipine	Grapefruit juice	Increased bioavailability	Inhibition of metabolism	Monitor blood pressure and side effects
Verapamil (V) Diltiazem (D)	Rifampin	Decreased levels	P-450 induction; decreased bioavailability and increased clearance	Increase V and D dose
Verapamil (V)	Clarithromycin	Increased V levels	Inhibition of metabolism	Decrease V dose
Verapamil	Digoxin (D)	Increased D levels, heart block, asystole in D toxicity	Inhibition of P-gp, additive depression of conduction	Decrease D dose, monitor serum levels, avoid Ca blockers in digitalis toxicity
Verapamil	Prazosin (Pz)	Increased Pz levels, excessive hypotension	Inhibition of metabolism, additive α blockade	Monitor blood pressure
Verapamil Diltiazem	Simvastatin (S) Atorvastatin (A)	Increased S and A levels Increased risk of myotoxicity	CYP 3A4 inhibition	Avoid high S and A doses; use another statin
	Theophylline (T)	Increased T levels	Inhibition of T metabolism	Decrease T dose, monitor T levels
Verapamil	Quinidine	Hypotension (after verapamil IV)	Additive α -blockade	Use verapamil IV cautiously
	Clonidine	Complete AV block, hypotension	Additive myocardial depression	Use combination cautiously
	Halothane	Excessive bradycardia	Additive myocardial depression	Avoid combination if possible
	Cyclosporine (Cy)	Increased Cy levels	Inhibition of Cy metabolism	Decrease Cy dose, monitor serum levels
Verapamil	Phenytoin (Ph)	Increased Ph and C levels	Inhibition of Ph and C metabolism	Decrease anticonvulsant dose, monitor levels
	Midazolam (Md)	Increased Md levels and effect	Inhibition of Md metabolism	Reduce Md dose
	Disopyramide	Heart failure	Additive negative inotropic effect	Avoid combination
Diltiazem	Sirolimus (Sir) Tacrolimus (Tac)	Increased Sir and Tac levels	Inhibition of metabolism	Decrease dose, monitor levels
Nifedipine	Magnesium sulfate	Neuromuscular blockade	Additive effect on depletion of intracellular calcium	
	Quinidine (Q)	Decreased Q levels	Increased clearance of Q(?); effect found in men with left ventricular failure	Monitor Q levels

significantly decreases verapamil bioavailability through induction of first-pass metabolism in the gut.¹²⁹ Conversely, the enzyme inhibitor cimetidine increases the bioavailability and decreases the clearance of calcium antagonists.¹³⁰⁻¹³² Macrolide antibiotics clarithromycin and telithromycin also inhibit CYP 3A4, and their combination with verapamil resulted in significant verapamil toxicity.^{133,134} Felodipine metabolism was inhibited by itraconazole and erythromycin resulting in significant increases in plasma concentrations and AUC.^{135,136}

Grapefruit juice, which inhibits some P-450 enzymes, has been found to increase the bioavailability of some dihydropyridine calcium antagonists. The most significant interaction was with felodipine and nitrendipine, whereas nifedipine bioavailability was

not significantly affected.¹³⁷ Verapamil increases digoxin concentration by inhibiting its renal excretion through P-glycoprotein.¹³⁸ Diltiazem has been reported to increase digoxin concentration, but this effect is not always present, and digoxin levels are affected to a lesser degree than with verapamil.¹³¹ Nifedipine does not have a significant effect on digoxin concentration.¹³⁹

Verapamil and diltiazem are inhibitors of CYP 3A4, and thus are expected to inhibit the clearance of drugs metabolized by this enzyme. Verapamil and diltiazem significantly increase peak plasma levels and AUC of simvastatin and atorvastatin,¹⁴⁰⁻¹⁴² and there are reports of rhabdomyolysis with these combinations.^{143,144} Verapamil and diltiazem have been reported to increase cyclosporine plasma levels, thus necessitating reduction of cyclosporine

doses.^{145,146} The same interaction was observed between diltiazem and sirolimus¹⁴⁷ and diltiazem and tacrolimus.^{148,149} Verapamil has also been reported to increase blood levels of prazosin. This pharmacokinetic interaction, along with a possible pharmacodynamic interaction, may result in hypotension.¹⁵⁰ Verapamil inhibits theophylline metabolism.¹⁵¹ Verapamil and diltiazem significantly decrease the metabolism of midazolam, potentially causing excessive sedation; they also inhibit the metabolism of the anticonvulsants carbamazepine and phenytoin.^{152,153}

Because verapamil is highly bound to plasma proteins, its displacement can result in transient toxicity. Complete atrioventricular block has been precipitated by ceftriaxone and clindamycin, which are also highly bound drugs, in a patient receiving verapamil.¹⁵⁴

Pharmacodynamic Interactions

Many calcium antagonists depress cardiac contractility and conduction and thus can cause sinus bradycardia or arrest, atrioventricular block, asystole, hypotension, and heart failure.¹⁵⁵ There is a greater risk of these events when calcium channel blockers are coadministered with other drugs that can have similar effects on the heart, such as β -blockers. Verapamil and diltiazem have the greatest effect on conduction and contractility and thus the most reported interactions with β -blockers, but nifedipine has also been implicated in such interactions.^{131,155-158} The combination of calcium antagonists and β -blockers can be desirable and necessary to control angina, but patients should be closely monitored. The probability of adverse interactions is increased in the elderly and when the patient has underlying heart failure or conduction disorders. Intravenous verapamil should be avoided in patients treated with β -blockers because asystole has been reported as a complication of such therapy.¹⁵⁸ Development of heart failure is also a risk when administering verapamil with other negative inotropic agents, such as disopyramide. Hypotension with verapamil and quinidine has been described, possibly as a result of additive α -adrenergic blocking effects.¹⁵⁹ An interaction between verapamil and clonidine that resulted in severe hypotension and atrioventricular block has been reported.¹⁶⁰

Verapamil is contraindicated in patients with digitalis toxicity because of additive depression of the sinoatrial and atrioventricular nodes.¹⁶¹

An interaction between nifedipine and intravenous magnesium sulfate was reported in a woman with preeclampsia, resulting in neuromuscular blockade in the presence of normal magnesium blood levels. The possible mechanism is depletion of intracellular calcium by the additive actions of the calcium antagonist and magnesium.¹⁶²

Interactions between calcium channel blockers and anesthetic agents have been described, notably a pronounced bradycardia when halothane was given to a patient on verapamil.¹³¹

Calcium can negate some of the effects of calcium antagonists and has been used to treat their overdose or adverse effects. Calcium reverses the negative inotropic effect and partly reverses atrioventricular conduction depression caused by calcium channel blockers but does not offset sinus node depression or vasodilation.^{155,163}

β -blockers

β -blockers (Table 42-5) can be divided into two groups based on their disposition: the lipophilic drugs (e.g., propranolol, metoprolol, timolol) and the more hydrophilic drugs (e.g., atenolol,

nadolol, pindolol). The lipophilic drugs are extensively metabolized by the liver and are subject to a significant first-pass metabolism. The hydrophilic drugs have little first-pass metabolism, although absorption is less complete. The hydrophilic β -blockers are mostly excreted unchanged by the kidneys.

Pharmacokinetic Interactions

Absorption of all β -blockers is reduced by concomitant administration of antacids or cholesterol-binding resins. For the drugs with high first-pass metabolism (e.g., propranolol, metoprolol), rifampin, phenytoin, and phenobarbital decrease bioavailability and increase clearance, resulting in low blood concentrations. Cimetidine has the opposite effect.¹⁶⁴⁻¹⁶⁷

Hydralazine has an effect on propranolol and metoprolol disposition whereby it increases the bioavailability of these β -blockers by increasing hepatic blood flow, saturating the metabolizing enzymes. By the same token, by increasing hepatic blood flow, hydralazine increases propranolol clearance, but the increase in bioavailability exceeds the increase in clearance; therefore the net result is an increase in propranolol blood levels.¹⁶⁸ Metoprolol is metabolized by the cytochrome P-450 isozyme 2D6, and its metabolism is genetically determined. Quinidine inhibits metoprolol clearance in extensive metabolizers.¹⁶⁹ There is some evidence that desethylamiodarone, a metabolite of amiodarone, can increase metoprolol serum concentration by inhibiting CYP 2D6.¹⁷⁰ β -blockers themselves, by decreasing hepatic blood flow, reduce clearance of other extensively metabolized drugs, such as lidocaine. Carvedilol and propranolol significantly inhibit P-glycoprotein, and can lead to an increase in serum concentrations of drugs such as digoxin and cyclosporine.^{73,171} Doses of both drugs should be adjusted if combined with carvedilol.

Pharmacodynamic Interactions

Because the major effects of β -blockers are depression of cardiac contractility and conduction, their combination with drugs exerting similar effects may result in excessive bradycardia, sinus arrest, atrioventricular block, heart failure, and hypotension. Especially implicated is a combination of β -blockers with verapamil, but adverse effects with diltiazem and nifedipine have also been reported, especially in patients with heart failure or conduction disorders.^{157,158} The combination of β -blockers and disopyramide, which has a significant negative inotropic effect, may precipitate heart failure.

The interaction between β -blockers and epinephrine can be very serious. Nonselective β -blockers, and also selective ones in high doses, also block β_2 -receptors, which mediate arterial vasodilation. Administration of epinephrine to a patient receiving nonselective β -blockers can result in unopposed action on α -receptors and cause a serious increase in blood pressure that could be catastrophic.¹⁷²

Chronic treatment with β -blockers has also been shown to increase sensitivity to pressor effects of norepinephrine and angiotensin about twofold; the mechanism is unclear.¹⁷³

Antithrombotic and Anticoagulant Drugs

Aspirin

Aspirin is a mainstay of antithrombotic therapy in patients with ischemic heart disease. Most aspirin interactions are pharmacodynamic. The most significant interaction is with warfarin, resulting in excessive bleeding by producing additive effects

Table 42-5. Drug Interactions with β -blockers

Drug	Interacting Drug	Effect	Mechanism	Comments
All β -blockers	Antacids Verapamil	Decreased concentrations Bradycardia, AV block, sinus arrest, hypotension, heart failure	Reduced absorption Additive effect on myocardial contractility and conduction	Separate dosing by 1 hr Avoid combination in elderly and in patients with heart failure or conduction disturbance
	Diltiazem Amiodarone Epinephrine (adrenalin)	Severe hypertension	Unopposed effect on α -receptors	Avoid epinephrine with patients on β -blockers
Propranolol (Pp)	Rifampin	Reduced bioavailability	Accelerated metabolism	Increase the doses of Pp and Me
Metoprolol (Me)	Phenytoin Phenobarbital Cimetidine Hydralazine	Increased bioavailability Increased bioavailability and clearance; usually, increase in Pr levels	Inhibition of metabolism Increased hepatic blood flow, accelerated metabolism, and saturation of first-pass metabolism	Decrease the dose Adjust Pr dose to achieve β -blockade
Metoprolol (Me)	Quinidine	Increased levels	Inhibition of metabolic clearance	Decrease the dose of Me
Carvedilol	Digoxin (D) Cyclosporine (Cy)	Increased D and Cy levels	Inhibition of P-gp	Decrease D and Cy dose, monitor levels

through their different effects on hemostasis. This additive effect is diminished when both drugs are used in low doses.¹⁷⁴

Concomitant use of low-dose aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) may increase gastrointestinal bleeding; and use of aspirin with selective COX-2 inhibitors may abolish their gastroprotective effect.¹⁷⁵ In addition, NSAIDs, and in particular ibuprofen, may interfere with the antithrombotic effects of low-dose aspirin, especially when the ibuprofen dose is given before aspirin or with chronic use.^{176,177} However, short-term use of over-the-counter ibuprofen did not result in a clinically meaningful loss of cardioprotection.¹⁷⁸

Thienopyridines

Ticlopidine

Ticlopidine has a different antithrombotic action than aspirin; ticlopidine's mechanism is inhibition of ADP-dependent platelet aggregation. It is cleared primarily through hepatic metabolism. Ticlopidine has been shown to inhibit some P-450 enzymes. It reduces theophylline clearance.^{179,180} Contrary to expectations, ticlopidine was reported to significantly decrease plasma cyclosporine levels; the mechanism responsible for this action is unknown.¹⁸¹

Clopidogrel

Clopidogrel has largely replaced ticlopidine because of lower incidence of neutropenia. Clopidogrel is a prodrug, and is metabolized to an active drug by CYP 3A4. Concerns have been raised about potential interaction causing decreased efficacy of clopidogrel with some statins that inhibit CYP 3A4, such as atorvastatin and simvastatin. Indeed, there are several reports of the reduced antiplatelet effect of clopidogrel with atorvastatin in vitro.^{182,183} However, other studies did not find this effect,¹⁸⁴ and

no adverse effect on cardiovascular outcomes was found when clopidogrel was administered with CYP 3A4-inhibiting statins compared with statins with no effect on CYP 3A4.¹⁸⁵⁻¹⁸⁷

Addition of clopidogrel to aspirin has a synergistic effect on platelet inhibition, and in some patients was shown to overcome aspirin resistance assessed by aggregometry, flow cytometry, and platelet resistance index.¹⁸⁸

Warfarin

Warfarin (Tables 42-6 and 42-7) is subject to many drug interactions, both pharmacokinetic and pharmacodynamic. As many as 80 interactions have been described; most of these have been known for many years. The consequences of warfarin interactions can be catastrophic (e.g., bleeding, thrombosis). Most consequences can be avoided by checking the concomitant medications and adjusting the warfarin dose accordingly, especially when starting or discontinuing another drug. Warfarin metabolism is stereo-selective. The more potent S isomer is metabolized by CYP 2C9, whereas the less potent R isomer is metabolized by CYP 1A2 and CYP 3A4. CYP 2C9 is subject to genetic polymorphism, and *2 and *3 alleles are associated with poor warfarin metabolism.¹⁸⁹ CYP 2C9 polymorphism contributes to the variability in warfarin dosage also in the presence of drug-drug interactions.¹⁹⁰

Pharmacokinetic Interactions

Enhancing the Anticoagulant Effect Drugs that enhance the anticoagulant effect of warfarin (see Table 42-6) do so by inhibiting warfarin metabolism. Among drugs that inhibit warfarin metabolism are anti-infectives (metronidazole, macrolides, trimethoprim-sulfamethoxazole, fluoroquinolones, and azole antifungals), cardiovascular drugs (amiodarone, diltiazem,

Table 42-6. Drug Interactions with Warfarin: Increased Anticoagulation

Interacting Drug	Mechanism	Comment
Allopurinol	Inhibition of warfarin metabolism	Reduce warfarin dose, monitor PT
Amiodarone		
Propafenone		
Diltiazem		
Cimetidine		
Ranitidine		
Omeprazole		
Quinolones		
Macrolides		
Co-trimoxazole		
Metronidazole		
Azole antifungals		
Lovastatin		
Gemfibrozil		
Fenofibrate		
Fluvoxamine		
Sertraline		
Phenylbutazone		
Sulfinpyrazone		
Broad-spectrum antibiotics	Reduction in vitamin K availability	Primarily in malnourished patients
Acetaminophen	Inhibition of vitamin K-dependent carboxylase	Variable effect
Quinidine	Inhibition of clotting-factor synthesis	Adjust warfarin dose, monitor PT
NSAIDs	Depression of platelet function	Avoid combination; monitor
Clopidogrel		
SSRIs		
Cefamandole		
Moxalactam		

Abbreviations: NSAIDs, nonsteroidal anti-inflammatory drugs; PT, prothrombin time; SSRIs, selective serotonin reuptake inhibitors.

propafenone), lipid-lowering drugs (fenofibrate, gemfibrozil, lovastatin), antidepressants (selective serotonin inhibitors, such as fluvoxamine and sertraline), GI drugs (cimetidine, ranitidine, omeprazole), and other drugs such as allopurinol, anabolic steroids, and tamoxifen.^{191,192} The time course of the interactions is difficult to predict because it depends on the half-lives of the interacting drug and warfarin and the vitamin K–dependent clotting factors II, VII, IX, and X. For most drugs, the interactions start within 2 to 3 days after administration and reach their maximal effect at 1 to 2 weeks.

Inhibiting the Anticoagulant Effect Drugs such as cholestyramine and colestipol inhibit the anticoagulant effect of warfarin by decreasing its absorption (see Table 42-7). Most of the drugs that antagonize the anticoagulant response do so by accelerating warfarin metabolism. Among these drugs are rifampin, phenytoin, barbiturates, and carbamazepine.^{191,192}

Table 42-7. Drug Interactions with Warfarin: Decreased Anticoagulation

Interacting Drug	Mechanism	Comments
Barbiturates	Accelerated metabolism of warfarin	Increase warfarin dose, monitor PT
Carbamazepine		
Griseofulvin		
Phenytoin		
Nafcillin		
Rifampin		
Cholestyramine	Decreased absorption of warfarin	Allow at least 1 hr after warfarin administration
Colestipol		
Vitamin K	Antagonizes warfarin action	Avoid combination

Abbreviation: PT, prothrombin time.

Nafcillin and dicloxacillin also accelerate warfarin metabolism, and high doses of warfarin may be required to achieve prothrombin time prolongation in the presence of these drugs.¹⁹³

Pharmacodynamic Interactions

Warfarin acts by inhibiting the synthesis of vitamin K–dependent clotting factors. Most of the vitamin K is obtained from food, with a small amount synthesized by intestinal bacteria. Treatment with antibiotics may reduce the amount of vitamin K produced by intestinal flora and thus cause an enhanced sensitivity to warfarin. However, the degree of INR change following this interaction is highly variable.¹⁹¹ Acetaminophen was reported to potentiate warfarin effect by inhibiting vitamin K–dependent carboxylase. There is a significant inter-individual variation in the magnitude of this effect.¹⁹⁴ Drugs that depress the synthesis of clotting factors (e.g., quinidine, salicylate in high doses) also enhance the anticoagulant effect of warfarin.⁸⁷

The most significant interactions are those resulting from the additive effects of other drugs affecting hemostasis by a different mechanism and thus creating an increased risk of bleeding. Such drugs include aspirin, NSAIDs, clopidogrel, some third generation cephalosporins, which inhibit platelet function, and heparin, which affects other clotting factors.^{195,196} Selective serotonin reuptake inhibitors may inhibit platelet aggregation by depleting platelet serotonin levels, and cause additive risk of bleeding with warfarin.¹⁹⁷ Drugs that injure gastrointestinal mucosa, such as NSAIDs and to lesser degree COX-2 inhibitors, also increase the risk of gastrointestinal hemorrhage.^{195,198}

Some herbal preparations, such as garlic, ginger, ginseng, ginkgo biloba, and the Chinese herb danshen, have been shown to have antiplatelet activity and may increase the risk of bleeding when used concomitantly with warfarin.¹⁹⁹

Drugs that antagonize the effects of warfarin are vitamin K analogues and foods, and enteral formulas containing high amounts of vitamin K. Oral contraceptives inhibit the anticoagulant effect by increasing the synthesis of clotting factors VII and X.

Table 42-8. Drug Interactions with Lipid-Lowering Drugs

Drug	Interacting Drug	Effect	Comments
Simvastatin Lovastatin Atorvastatin	Macrolides Fluconazole Amiodarone Diltiazem Verapamil	Rhabdomyolysis via increased statin levels (CYP 3A4 inhibition)	Avoid combination if possible; otherwise, monitor CPK
Simvastatin Lovastatin	Gemfibrozil	Rhabdomyolysis via increased statin levels (CYP 2C8 and OATP1B1 inhibition)	Avoid combination if possible; otherwise, monitor CPK
HMG-CoA reductase inhibitors	Cyclosporine Clarithromycin Ritonavir Saquinavir Indinavir	Rhabdomyolysis via increased statin plasma levels (OATP1B1 inhibition)	Avoid combination if possible; otherwise, monitor CPK; decrease dose when combined with cyclosporine
HMG-CoA reductase inhibitors	Fibrates	Rhabdomyolysis	Avoid combination if possible; otherwise, monitor CPK
Clofibrate Gemfibrozil	Warfarin	Increased anticoagulation (inhibition of warfarin metabolism)	Monitor PT, adjust warfarin dose
Probucol	Class 1A antiarrhythmics	Additive Q–T prolongation; risk of torsades de pointes	Avoid combination
Cholestyramine Colestipol	Digoxin Ezetimibe Thiazide diuretics Warfarin Sulfonylurea Thyroid hormones	Binding in the gut and decreased absorption of the interacting drugs	Separate administration of bile acid sequestrants by 2–3 hr

Abbreviations: CPK, creatine phosphokinase; PT, prothrombin time.

Heparin and Low Molecular Weight Heparins (LMWHs)

The significant interactions of heparin and LMWHs are with other drugs that affect hemostasis, such as aspirin in high doses, NSAIDs, and warfarin. Concomitant use of glycoprotein IIB/IIIA antagonists, particularly in elderly patients, is also associated with increased risk of major bleeding.²⁰⁰ There have been reports of interactions with intravenous nitroglycerin, in which the anticoagulant effect of heparin is reduced and therefore higher heparin doses are required, but subsequent studies did not support this observation.^{201–203}

Lipid-Lowering Drugs

Drug interactions with lipid-lowering drugs are displayed in Table 42-8. The significant interactions with hydroxymethylglutaryl-coenzyme A reductase inhibitors (e.g., lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin, and rosuvastatin) are pharmacokinetic, leading to high statin concentrations in the peripheral blood and muscle tissue, and pharmacodynamic, leading to additive or synergistic muscle toxicity.

Concomitant use of simvastatin, lovastatin, and atorvastatin with CYP 3A4 inhibitors, such as erythromycin, clarithromycin, fluconazole, verapamil, diltiazem, and amiodarone, results in significantly increased AUC of statins, and particularly when high doses of statins are used, in myotoxicity and rhabdomyolysis.^{204,205} CYP 3A4 inhibitors have no appreciable effect on plasma levels of pravastatin and rosuvastatin, which are not metabolized by CYP 3A4.²⁰⁵ Cytochrome P-450 inducers, such

as rifampin and carbamazepine, can significantly reduce the AUC of simvastatin and atorvastatin.

The uptake of statins into the liver is mediated by organic anion transporter OATP1B1. This mechanism is particularly significant for hydrophilic statins, such as pravastatin and rosuvastatin. Inhibitors of OATP1B1 include cyclosporine, clarithromycin, and protease inhibitors ritonavir, saquinavir, and indinavir. Coadministration of these drugs with statins results in increased AUC of statins and increased risk of rhabdomyolysis.²⁰⁵

Concomitant use of statins and fibrates results in increased risk of myopathy and rhabdomyolysis because of their additive risk. The risk of interaction with gemfibrozil is the greatest because, in addition to the pharmacodynamic interaction, gemfibrozil also inhibits CYP 2C8, which metabolizes the active form of simvastatin and lovastatin, and OATP1B1.²⁰⁵ Gemfibrozil also increases plasma levels of other CYP 2C8 substrates, particularly the glucose-lowering drugs repaglinide, rosiglitazone, and pioglitazone.²⁰⁵

Clofibrate and gemfibrozil increase the anticoagulant effect of warfarin by inhibiting its hepatic metabolism.

Cholesterol-binding resins (e.g., cholestyramine, colestipol) bind to acidic drugs such as digoxin, warfarin, thiazide diuretics, thyroid hormones, and sulfonylurea in the gut, thereby interfering with their absorption.²⁰⁶ Cholestyramine also decreases the bioavailability of ezetimibe.²⁰⁵ Probucol can prolong the Q–T interval and thus create an additive risk for torsades de pointes when administered with class 1A or class 3 drugs.²⁰⁷

Diuretics

Most of the drug interactions with diuretics are pharmacodynamic. There is a synergistic effect when a loop diuretic is administered with a thiazide, and this combination is used in refractory edematous states (e.g., severe heart failure), in which loop diuretic efficacy is limited because of enhanced sodium reabsorption in the distal tubules. Because this combination may result in massive fluid and electrolyte loss, the thiazide should be started at low doses.²⁰⁸ Care should be exercised when an ACE inhibitor is added to a diuretic because the inhibition of angiotensin II response may result in profound hypotension and renal failure. Reduction in the diuretic dose or temporary withdrawal of the diuretic is prudent before starting an ACE inhibitor.^{28,29} NSAIDs and COX-2 selective inhibitors raise blood pressure and significantly increase the incidence of congestive heart failure, and thus can be expected to diminish the response to loop and thiazide diuretics.^{209,210} There are reports of indomethacin inhibiting the antihypertensive actions of the diuretics, although other NSAIDs, specifically diclofenac and sulindac, did not have this effect.²¹¹

Diuretics reduce the renal excretion of lithium because sodium depletion causes enhanced tubular reabsorption of lithium. Lithium doses should therefore be reduced by 25% when adding diuretics, and plasma levels should be monitored. There is a risk of additive ototoxicity when loop diuretics are used with aminoglycosides, especially with high doses of the diuretic and in patients with renal failure.

Concomitant use of potassium-sparing diuretic with ACE inhibitors or angiotensin receptor blockers can result in severe hyperkalemia, particularly in patients with spironolactone doses higher than 25 mg/day, the elderly, and patients with impaired renal function and diabetes mellitus.²¹²

CHAPTER

43

**Evaluation of Patients with Chest Pain
Pulmonary Embolism
Aortic Diseases**

**Pericardial Effusion
Infective Endocarditis**

ECHOCARDIOGRAPHY PROVIDES critical diagnostic information in the care of patients in the CICU. It is an easy, safe, portable, and readily available tool for thoroughly evaluating patients who are hemodynamically unstable and require intensive monitoring. It provides information on cardiac structure, function, and hemodynamics. Echocardiography can diagnose, detect complications, evaluate reperfusion therapy, and can assist in risk stratification in patients having myocardial infarction.

Advances in echo technology and the ability to digitally store data enable acquisition of accurate information that can easily be displayed and compared with prior studies for serial comparison. Echocardiography has increasing utility in guiding management of a wide spectrum of cardiovascular

disorders. It has been shown to influence therapeutic decision making in critically ill patients and provide supplemental information beyond that obtained by pulmonary artery catheterization.^{1,2}

This section is divided into the following categories:

- Evaluation of patients with chest pain
- Echocardiography in patients with acute coronary syndrome
- Evaluation of left ventricular (LV) function
- Exclusion and evaluation of LV aneurysm
- Exclusion of apical clot
- Exclusion of right ventricular (RV) involvement
- Ischemic mitral regurgitation (MR)
- Left ventricular outflow tract (LVOT) obstruction

- Mechanical complications
- Guidance of placement and monitoring of assist devices
- Assessment of the aorta
- Evaluation of patients with suspected or documented pulmonary embolism
- Evaluation of pericardial effusion and tamponade physiology
- Evaluation of patients with suspected or documented infective endocarditis

Evaluation of Patients with Chest Pain

Each year 6 million patients in the United States come to the emergency room with chest pain.³ The sensitivity of electrocardiography in diagnosing acute myocardial infarction (MI) is relatively low.⁴ Detection of regional wall motion abnormalities by echocardiography is a very sensitive method for diagnosing an acute MI. If no regional wall motion abnormalities are present during chest pain, ischemic risk is very low.^{5,6,7} Although not approved by the U.S. Food and Drug Administration for this indication, numerous studies have demonstrated the incremental value of perfusion echo in identifying the presence of ischemia. Kaul and colleagues⁶ compared contrast echocardiography with a modified Thrombolysis In Myocardial Infarction (mTIMI) score for triage of nearly 1000 patients having chest pain and nondiagnostic ECG before troponin levels became available. Both regional myocardial function and perfusion were analyzed by rest contrast echocardiography and related to early (in the first 24 hours), intermediate (at 30 days), and late (1 year) events. Only 0.4% of patients with normal regional function had a primary event consistent with an excellent negative predictive value of contrast echo. Contrast echocardiography was able to classify patients with an intermediate mTIMI score into low and high risk for acute coronary syndrome (ACS). When the troponin level was not available, the mTIMI score failed to identify approximately 4% of patients with ACS, consistent with previous data. The regional function provided incremental prognostic information beyond the mTIMI score for predicting intermediate and late events. Myocardial perfusion provided additional prognostic information beyond the mTIMI score and regional function in patient with abnormal regional function. The complete TIMI score did not provide incremental prognostic benefit when compared with the combination of mTIMI, regional function, and myocardial perfusion in the prediction of early and intermediate events. Therefore, in patients with chest pain and nondiagnostic ECG, rapid identification of regional function and myocardial perfusion help to risk stratify patients even before troponin levels are known.

Echo can be used to differentiate ischemic chest pain from other mimicking abnormalities, such as aortic dissection, pulmonary embolism, and pericardial effusion, which will be described later in the chapter.

Echocardiography in Patients with Acute Coronary Syndrome

Once the diagnosis of acute coronary syndrome is made, echocardiographic evaluation of the location and extent of regional wall motion abnormalities can be used to assess the results of reperfusion therapy, infarct expansion, extension, or remodeling.

Evaluation of Left Ventricular Function

Accurate assessment of left ventricular systolic function and ejection fraction are critical in patients with myocardial infarction (MI) since further interventions, such as placement of an AICD or BiV pacemaker, require a certain ejection fraction (EF) as an indication. In addition, LV ejection fraction provides important prognostic information in patients with ST elevation myocardial infarction (STEMI). LV function has been shown to be an important determinant of mortality and subsequent development of congestive heart failure, and development of ventricular arrhythmias and sudden cardiac death.⁸⁻¹¹ Figure 43-1 demonstrates the recommended method for calculation of EF by the American Society of Echocardiography.

In patients in whom accurate quantification of systolic function cannot be obtained with 2D echo, new techniques such as 3D echo can be used. Multiple studies have confirmed the accuracy and feasibility of a 3D echocardiogram for assessment of LV volumes and function,¹²⁻¹⁵ and demonstrated good correlation between these parameters and those obtained by MRI.¹⁶⁻¹⁸ Because a data set comprises the entire LV volume, the greatest advantage of 3D echo over 2D echo is that there is no need for any assumption on the shape of the ventricle, which is required for volume calculation obtained from two planes only. As a result volume calculations using 3D echo are more accurate. This is especially true in patients in whom the geometry and shape of the LV is distorted secondary to MI and the presence of wall motion abnormalities and or an aneurysm. In these patients, direct measurements of full volume acquired by 3D will result in a more accurate analysis of structure and function than by making erroneous assumption using 2D data. Advances in technology now enable 3D data acquisition to be performed at the bedside. (Fig. 43-2 demonstrates 3D reconstruction of the LV). If image quality is limited, acquisition can be combined with infusion of contrast to improve the delineation of the endocardial border.

LV Aneurysm

Aneurysm is defined as a discontinuity in the left ventricular contour that is present during both systole and diastole. It is formed when normal myocardium is replaced by necrotic myocardium and fibrous scar tissue, and is therefore a potential complication of transmural infarction. Mechanically, the aneurysm is a reservoir of blood that is not ejected, thus reducing the overall stroke volume, which could lead to the development of heart failure. Other potential consequences of the presence of an aneurysm are the development of a clot due to stagnation of blood and intractable arrhythmias due to the presence of scar tissue. Heart failure is a common indication for surgical resection of the aneurysm. Patients with ejection fraction of 35% or more generated by contractility of the basal portion of the ventricle, as measured by the basal fractional shortening, derive more benefit from aneurysm resection.¹⁹ Echocardiography plays a major role defining the size and location of an aneurysm and excluding the presence of a clot. It is instrumental in distinguishing it from a pseudoaneurysm by demonstrating the presence of a wide neck communicating with the ventricular cavity. Use of contrast echocardiography can clearly delineate the aneurysm better (Fig. 43-3). Three-dimensional echocardiography has a role in accurate determination of EF in these patients with abnormal geometry as outlined in detail previously.

Figure 43-1. Ejection fraction calculation using biplane method of disks. **A**, Diastolic (*left*) and systolic (*right*) frames obtained from apical four-chamber view. **B**, Diastolic (*left*) and systolic (*right*) frames obtained from apical two-chamber view.

Apical Clot

Left ventricular thrombus usually occurs in anteroapical infarction although it can infrequently be seen in inferior myocardial infarction as well (Fig. 43-4). A thrombus can be mobile, pedunculated, or laminar in nature. It occurs in areas of extensive regional wall motion abnormalities, where stagnation of flow is expected, or within an aneurysm. Although the majority of clots form at least 72 hours after the onset of MI, it can occasionally

be seen much earlier and emphasis should therefore be made to exclude their presence on any echo performed in a post-MI patient. Identification of a thrombus is important because these patients require anticoagulation therapy for at least 6 months to reduce risk of embolic events. Two-dimensional echo can be repeated to assess resolution of a thrombus. The use of echo contrast has significantly increased the sensitivity of echo for detection of small clots, which appear as filling defects.²⁰ Figure 43-5.

Figure 43-2. Left ventricular volume generated by three-dimensional echocardiography.

Figure 43-3. Contrast-enhanced left ventricular cavity showing the presence of an apical aneurysm.

Exclusion of Right Ventricular (RV) Involvement

The incidence of right ventricular infarction in association with left ventricular myocardial infarction ranges from 14% to 84% and is dependent on the population studied and the pathologic criteria.²¹ Right ventricular (RV) infarction usually occurs in association with inferior wall infarcts, less commonly with anterior wall infarcts, and rarely in isolation. The clinical triad characteristic of RV infarcts is: hypotension, clear lungs, and elevated jugular venous pressure. The Kussmaul sign (an increase in jugular venous pressure with inspiration) is a highly sensitive and specific clinical finding for the diagnosis

Figure 43-4. Large apical clot (arrow).

of RV infarction. These patients have normal LV filling pressures, but elevated right atrial and ventricular filling pressures. ST elevation seen on right-sided ECG leads (V_3R , V_4R , and V_5R) is very suggestive of RV involvement. Echocardiography identifies depression of right ventricular systolic function with

Figure 43-5. Small apical clot seen as a filling defect (arrow) with the use of contrast medium.

Figure 43-6. Three-dimensional reconstructions of the right ventricle.

segmental wall motion abnormalities, and dilation of the right ventricle. Abnormal interventricular septal motion is also seen due to increased right ventricular end-diastolic pressure. The parasternal short axis view has the highest sensitivity (82%) with specificity ranging between 62% to 93% for hemodynamically significant right ventricular infarction.²² Interatrial septal bowing toward the left atrium, indicative of an increased right atrial-left atrial pressure gradient, has been shown to be an important prognostic marker in right ventricular infarction. This finding is associated with hypotension, heart block, and increased mortality.²³ Recently 3D echocardiographic assessment of RV volumes in healthy adults has been shown to be reproducible, accurate, and closely correlated with the assessment of RV volumes using cardiac MRI.²⁴ Given the complex structure of the RV, 3D echo may prove to be the preferred method for accurate assessment of RV structure and function, especially in patients with dilated RV and reduced function [Figure 43-6](#). The treatment of right ventricular infarction includes aggressive maintenance of RV preload, reduction of RV afterload, inotropic support, and early reperfusion.

Ischemic Mitral Regurgitation (MR)

Myocardial infarctions (MIs) often trigger a remodeling process that leads to gross ventricular distortion, contractile dysfunction of normally perfused myocardium, symptomatic congestive heart failure (CHF), and premature death.²⁵ Depending on size, location, and transmural extent of the infarct, the remodeling process may be associated with the development of ischemic mitral regurgitation (IMR).²⁶ Mild degrees of mitral regurgitation after acute MI portend a substantially increased risk of cardiovascular mortality within 5 years, even in patients who do not initially have signs of overt CHF.²⁷ Echocardiographic features

include severe segmental hypokinesis/akinesis predominantly of the inferior wall, tethering of the mitral valve leaflets, and inadequate coaptation of the valve leaflets associated with mitral regurgitation²⁸ [Figure 43-7](#). It is critical to exclude the presence of a significant degree of ischemic MR by performing a transthoracic echocardiogram (TTE), followed by a transesophageal echocardiogram (TEE) as needed, particularly in those who are candidates for surgical revascularization since it has been shown that CABG alone does not reduce the severity of MR.²⁹ Alternative surgical and percutaneous approaches to these patients using repair and placement of devices in an attempt to restore the original shape of the annulus are now being explored.²⁹⁻³³

Innovative 3D reconstruction software have been developed recently that allow accurate evaluation of the mitral annulus. The utility of this 3D data in guiding interventions still need to be determined.³⁴

LVOT Obstruction

Recent case reports have described dynamic left ventricular outflow tract obstruction in the setting of anteroapical infarction ([Fig. 43-8](#)). In this instance, the basal portions of the myocardium are hyperdynamic compensate for the reduced stroke volume, causing systolic anterior motion of the mitral valve. Both these features can easily be recognized on TTE. This entity should be suspected in a patient having hypotension refractory to inotropes and an intra-aortic balloon pump. Since the LVOT obstruction is dynamic and caused by the hyperdynamic contractility of the basal segments, inotropic medications would worsen the hypotension and should be avoided. Similar mechanism of LVOT obstruction can also be seen in patients with left ventricular apical ballooning syndrome, also known as Takotsubo cardiomyopathy^{35,36} ([Fig. 43-9](#)).

Figure 43-7. Tethering of the mitral leaflets.

Mechanical Complications

Echocardiography is invaluable in the diagnosis of complications of acute myocardial infarction such as free wall rupture, left ventricular pseudoaneurysm, ventricular septal rupture, and acute mitral regurgitation.

Free Wall Rupture

Rupture of the free wall accounts for 10% of in-hospital deaths due to STEMI.³⁷ Free wall rupture occurs more commonly in patients who have received fibrinolytics, especially in patients who present after a long delay from the symptom onset. In the era before reperfusion, the incidence was as high as 6% of patients with STEMI.³⁸ The incidence has sharply decreased after the widespread use of primary percutaneous intervention for acute myocardial infarction, accounting for less than 1%.^{20,39} A patient can have either an acute rupture, which usually results in immediate death, or a subacute rupture, which is associated with nonspecific symptoms, including nausea, hypotension, and pericardial type of discomfort. A quarter of these patients have pericardial effusion with blood in the pericardial space (hemopericardium). Early recognition of this complication is critical because stabilization with an intra-aortic balloon pump and prompt surgical repair determines survival. Whenever suspected, an echocardiogram at the bedside should be performed immediately. The presence of pericardial effusion can be evaluated with 2D imaging, and flow into the pericardial space should be confirmed by color Doppler.³⁸

Occasionally, incomplete free wall rupture is sealed by organizing a thrombus, hematoma, and adjacent pericardial tissue, thus preventing the development of hemopericardium (Fig. 43-10). This leads to the formation of a pseudoaneurysm, which can still communicate with the left ventricular cavity. This is

Figure 43-8. A and B, Pulsed wave Doppler at the level of the left ventricular outflow tract showing normal gradients at rest (A) and increased gradients during Valsalva maneuver (B).

distinguished echocardiographically from a true aneurysm by a narrow neck. Color flow into the pseudoaneurysm can be visualized by echocardiography and confirms the communication with the left ventricle. Unlike a true aneurysm, the wall of the pseudoaneurysm is very thin because it is composed of pericardium not myocardium and lacks all the elements of the ventricular wall. Characteristic features of a pseudoaneurysm as described by Roelandt and colleagues⁴⁰ are: (1) Saccular or globular echolucent extracardiac space; (2) discontinuity of the endocardial border at the site of the pseudoaneurysm suggestive of a communication between the left ventricle and the echo free space by a narrow neck; and (3) systolic expansion of the echo free space and displacement of the cardiac chambers.

Figure 43-9. Apical ballooning cardiomyopathy enhanced with the use of contrast medium.

Ventricular Septal Rupture

This is a less frequent complication than free wall rupture. In the era before reperfusion therapy, septal rupture (VSD) complicated 1% to 3% of acute myocardial infarctions.^{37,41-43} Similar to other mechanical complications, the incidence has decreased to 0.2% in the reperfusion era as demonstrated in a retrospective review of 41,021 patients in the GUSTO-I trial.⁴⁴ It usually occurs after transmural infarctions. Biventricular failure usually occurs within hours to days. The presentation depends on the site and size of the rupture. Mortality is high; 25% of affected patients die within 24 hours and 65% die within 2 weeks without prompt surgical repair. Echocardiography is highly sensitive for the diagnosis and characterization of the type of ventricular septal rupture⁴⁵⁻⁵⁰ and in differentiating it from acute mitral regurgitation, which shares similar clinical characteristics.^{46,49,50,52} Using color flow imaging, a high-velocity mosaic jet can be seen entering the right ventricular cavity in the short axis and the apical views. Direct visualization of the defect by two dimensional imaging can be seen in 50% of the patients. Contrast imaging using agitated saline helps to identify the septal rupture in 80% of the patients. This can be seen as a negative contrast effect in the right ventricle since high-velocity flow is exiting the left ventricle into the right ventricular cavity. Addition of color flow and pulsed wave Doppler imaging increases the sensitivity to 96%⁴⁸ (Fig. 43-11). Using continuous wave Doppler, the right ventricular systolic pressure and the pulmonary artery pressure can be determined directly by interrogating the VSD jet.

Acute Mitral Regurgitation Secondary to Rupture of the Papillary Muscle

Another rare complication of AMI is a ruptured papillary muscle, which occurs in 1% of patients with MI. This complication, unless treated surgically, carries high mortality, accounting

Figure 43-10. Free wall rupture and clots adjacent to the left ventricular apex (arrows).

Figure 43-11. Ventricular septal defect shown by color flow across the interventricular septum.

for up to 5% of postinfarction deaths—with 50% dying within 24 hours and 90% within 1 week.⁵³ Papillary muscle rupture involves the posteromedial papillary muscle in 75% of cases and the anterolateral papillary muscle in 25% of cases. The reduced occurrence in the anterolateral papillary muscle is a result of its dual blood supply from left anterior descending and left circumflex coronary arteries. The physical examination is highly unreliable. Due to rapid equalization of pressures between the left ventricle and atrium, a murmur may not be heard. When a new holosystolic murmur is heard in a post-MI patient, an

Figure 43-12. Eccentric mitral regurgitation.

Figure 43-13. Ruptured papillary muscle, seen as a mobile tissue density in the left ventricular cavity (arrow).

emergent echocardiogram is indicated to exclude the presence of ventricular septal rupture or acute mitral regurgitation (MR). Using transthoracic echocardiography, the following features can be seen: an eccentric jet of mitral regurgitation (Fig. 43-12), a flail mitral leaflet, and a ruptured or partially ruptured papillary muscle seen as a mobile echodensity in the left ventricular cavity prolapsing back into the left atrium (Fig. 43-13). These features can be better appreciated using transesophageal echocardiography (TEE), so when a papillary muscle rupture is suspected and not confirmed on TTE, a TEE should be performed.

Figure 43-14. Left ventricular assist device cannula (arrow) as it can be seen with transesophageal echocardiography.

When the diagnosis is made using TTE, TEE should still be performed (preferably in the operating room) to better define the anatomy for the surgeon. In 65% of the patients described by Moursi and colleagues,⁵⁴ the papillary muscle head was seen in the left atrium. In 18 of 20 patients who did not have prolapse of the ruptured papillary muscle head into the left atrium, TEE was useful in making the diagnosis by demonstrating an erratic large amplitude motion of the papillary muscle in the left ventricle, as confirmed by surgery.

Multiple Complications

Although rare, more than one complication can be found in post-MI patients. A combination of left ventricular free wall and papillary muscle rupture has been described. Also a combination of ventricular septal rupture and papillary muscle rupture may occur in the same patient. Rapid identification of both these complications in critically ill patients who need urgent cardiac surgery is possible with transthoracic and transesophageal echocardiography.⁵⁵

Guidance of Placement and Monitoring of Assist Devices

Implantable ventricular assist devices are now approved to be used as a bridge to transplantation in transplant eligible patients with congestive heart failure. TEE is invaluable in the preoperative, intraoperative, and postoperative management of these devices. Assessment of right ventricular function and exclusion of patent foramen ovale, aortic regurgitation, aortic atheroma, and mural thrombus are important in the preoperative assessment. Intraoperatively, the function of the left ventricular and right ventricular assist device and the position of the inlet and outlet cannula position should be assessed echocardiographically (Fig. 43-14). Postoperatively, low and high pump flow states, interrogation of grafts, and patency of the cannulae can be assessed via TEE. Finally, explant of the left ventricular /right ventricular assist device is guided by TEE to prevent microperforation and air entrapment.⁵⁶

Figure 43-15. Clot seen in the right pulmonary artery (arrow).

Pulmonary Embolism

Pulmonary embolism can be a potentially life-threatening disorder. Administration of thrombolytic therapy is reserved for patients who are hemodynamically unstable; however, according to recent studies,⁵⁷ echocardiographic evidence of right ventricular strain is considered an indication for thrombolytic therapy even in patients who are hemodynamically stable.

Large clots in the pulmonary artery and the proximal branches can be visualized using TTE and TEE (Fig. 43-15), and these modalities can be performed at the bedside in patients who are hemodynamically unstable and cannot be transported to the radiology department for a confirmatory test. TEE has 70% sensitivity and 81% specificity for detection of pulmonary embolism.^{58,59} In addition, TTE enables assessment of right ventricular function, which carries prognostic information in these patients. The presence of McConnell sign—wall motion abnormality of the free wall of the right ventricle with preservation of the apex, largely due to tethering by the left ventricle—is 77% sensitive and highly specific (94%) for the diagnosis of pulmonary embolism.⁵⁸ Echocardiographic features of elevated pulmonary artery pressures, such as inferior vena cava plethora and interventricular septal flattening, can be assessed using transthoracic echocardiogram. In addition, systolic, diastolic, and mean pulmonary artery pressures can be measured noninvasively using this modality. This information can be used for diagnosing PE, guiding therapy, and following up these patients serially.

Figure 43-16. Dissection flap extending through the aortic valve resulting in severe aortic regurgitation.

Aortic Diseases

Aortic dissection is a life-threatening disorder that requires prompt treatment to reduce morbidity and mortality. These patients are critically ill, requiring invasive and intensive monitoring. An ideal imaging modality is one that is portable, readily available, and characterizes the dissection. TEE fulfills all of these criteria and also provides vital information, such as the presence of aortic valve involvement with resultant aortic regurgitation (Fig. 43-16), pericardial effusion, and LV function. TEE also helps to identify other disorders in the same spectrum, such as aortic aneurysm and intramural hematoma. Since the aortic lumen is not affected by the presence of intramural hematoma, other diagnostic modalities that image the lumen and not the wall of the aorta (computerized tomography, aortogram) frequently fail to diagnose this life-threatening pathology, which is associated with the same mortality rate as aortic dissection. TEE can also identify the presence of mobile aortic atheromas.

The sensitivity of TTE for imaging of the aorta is low because only the aortic root and a portion of the ascending aorta can be visualized; however, a proximal dissection, especially in cases in which the aortic valve is involved, can be visualized using a TTE. TEE overcomes many of the limitations of TTE and is able to image the aortic root, ascending aorta, arch, and the descending thoracic aorta. The distal portion of the ascending aorta is difficult to image because of interceding bronchus. A recent meta-analysis by Shiga and colleagues⁶⁰ reviewed all published studies of the diagnosis of aortic dissection by TEE, helical CT, and MRI and showed that all three modalities yield equally reliable diagnostic values. The sensitivities of TEE, helical CT, and MRI for diagnosing aortic dissection were 99%, 100%, and 98%, respectively, with specificities of 95%, 98%, and 98%.

In addition to demonstrating the extent of the dissection, TEE can provide additional important information for the surgeon, including the presence of entry and exit sites, extravasation of blood into the thoracic cavity and pericardial space, and assessment of LV function and aortic valve involvement, which were mentioned earlier. Conventional helical CT can identify the dissection flap but cannot elucidate the entry and exit points and can provide very limited information on LV function and the aortic valve.

Pericardial Effusion

Echocardiogram is a rapid means of identifying the size, location, and hemodynamic effects of pericardial effusions. The echocardiographic findings that are consistent with the presence of

Figure 43-17. Large pericardial effusion (PE) and collapsed right ventricle (RV).

Figure 43-18. Significant respiratory variation in transmittal inflow velocities.

a hemodynamically significant effusion and tamponade physiology include the swinging motion of the heart, right ventricular diastolic collapse (Fig. 43-17), right atrial collapse, respiratory variation in mitral and tricuspid inflow velocities (Fig. 43-18), and plethora of the inferior vena cava (IVC). Early diastolic collapse of the right ventricle is a specific but not sensitive finding. Late systolic collapse of the right atrium is a more sensitive but not specific finding. Measuring the duration of right atrial collapse increases the diagnostic yield of this finding. The presence of inversion of the right atrium during more than one third of the duration of systole has 94% sensitivity and 100% specificity for the diagnosis of tamponade. The respiratory variation can be nonspecific and is seen in atrial fibrillation and lung diseases, such as chronic obstructive pulmonary disease and asthma. Plethora of the IVC, which is defined as dilated IVC that exhibits less than 50% respiratory change in its diameter, has a sensitivity of 97% and specificity of 40% for the presence of tamponade. The lack of a single marker with high sensitivity and specificity mandates a comprehensive echo examination with close attention to all the findings outlined above.

In some centers, TTE is also used to guide pericardiocentesis. After placement of a drain into the pericardial space, serial monitoring of size of the effusion using an echocardiogram is invaluable for optimal management.

Infective Endocarditis

This diagnosis carries a high mortality and morbidity rate. Frequently, patients are critically ill and early diagnosis and treatment may result in a favorable outcome. Echocardiography plays a critical role in the diagnosis and characterization of the endocarditis along with the functional consequences and presence of potential complications. TTE has a sensitivity of 60% to 70% for diagnosing endocarditis on a native valve. The sensitivity is much higher at 95% with the use of TEE.⁶¹⁻⁶³ The identification of vegetations is made by visualizing a mobile, irregularly shaped echodensity usually attached to the free edge of the valve leaflet (Fig. 43-19). TEE is instrumental in identification of potential

Figure 43-19. Large vegetation (arrow) attached to the atrial surface of the mitral valve, as seen on transesophageal echocardiography.

Figure 43-20. Large vegetation (arrow) attached to the mitral valve annulus, as seen from the left atrium using three-dimensional transesophageal echocardiography.

complications, such as valve perforation, periannular abscesses, and fistula formation, which are indications for valve replacement. In addition, it can be used for evaluation of the effect of the endocarditis on valvular function, and both mechanical obstruction to flow across the valve and regurgitation can be thoroughly evaluated using a combination of TTE and TEE. TEE is the mainstay for the assessment of prosthetic heart valves due to multiple artifacts seen on transthoracic images. A recent study demonstrated the potential role of transthoracic 3D echocardiography in evaluation of prosthetic valves in patients with suspected endocarditis.⁶⁴ A transesophageal 3D probe was recently added to the armamentarium of diagnostic tools available and may be instrumental for earlier and more precise diagnosis of endocarditis and its potential complications (Fig. 43-20).

Vascular Access in the Intensive Care Unit

Christopher J. Gallagher, Shaji Poovathor

CHAPTER 44

Peripheral Intravenous Line

Radial Arterial Line

Brachial Arterial Line

Femoral Arterial Line

Femoral Central Venous Line

Internal Jugular Central Venous Line

External Jugular Central Venous Line

Subclavian Central Venous Line

Pulmonary Artery Catheter Placement

Peripheral Intravenous Line

Almost every patient in the intensive care unit needs intravenous access.¹⁻³ If fluids or drugs need to be delivered, if the patient cannot be managed entirely on a PO regimen, if the need to resuscitate may arise, access to the vascular system is required. Most often patients need more invasive access, but peripheral intravenous access still has its utility.

Equipment

The equipment for peripheral venous line placement includes the following: (1) intravenous catheter (always have extras); if volume access is required, a 14-gauge catheter is ideal but often impractical, and a 16-gauge may be a better choice; (2) alcohol wipes; (3) tourniquets; (4) TB or 3-mL syringe with 1% lidocaine plain; (5) 25-gauge needle, preferably a short one; (6) intravenous bag and tubing to connect to catheter, as well as a short section of tubing with flush in it; and (7) steri-drape and tape to secure the line.

Technique

Site of insertion matters, since some places are easier to place lines into than others. The back of the hand is usually handy to review an important point. Look for a Y-shaped vein and aim for the confluence. When you place the line in the hand, think of where the end of the catheter goes. If the end of the catheter is where the wrist bends, you can get a positional line. Antecubital is a favorable site but the patients have to keep their arm straight, so only use this if nothing else looks good. There are big veins in the forearm, but they are mostly L-type veins. Sometimes the anterior aspect of the wrist is the only vein you can see. In obese patients this is sometimes the only option.

Steps for inserting a peripheral intravenous line are shown in [Figure 44-1](#). Always wear gloves. Place the tourniquet, but do not tie it in a knot. Get the vein to pop up by asking the patient to pump the fist, lightly tapping the vein, or hanging the arm down. Other ways to get the vein to stick up include putting warm blankets on the arm or using the blood pressure cuff: inflate the cuff above systolic pressure; wait a minute, then let the cuff down between systolic and diastolic so the blood can go in but can't get out.

Look for a vein that has an inverted Y and aim for the middle of the Y. Apply a little bit of local anesthetic. (Local anesthesia is not

necessary if the first attempt at placing the line is successful, but it is very helpful in cases of repeated attempts.) Use the non-dominant hand to pull the skin taut as a drum. Use the dominant hand to stick the catheter through the skin and into the vein. When the first flash of blood appears in the hub of the needle, advance another millimeter or two to get the catheter into a vein, not just the tip of the needle. Without letting go of the skin, use the dominant hand to advance the catheter all the way into the vein. Keep the needle in. With the non-dominant hand, compress the vein just above the catheter. With the dominant hand, undo the tourniquet. With the dominant hand, pull out the needle and discard it. Connect the intravenous tubing and secure it to the catheter. Place a steri-drape and ensure the line stays in place. Open the line and make sure it runs. Watch for infiltration. If everything works well, remember to slow down the IV.

Clinical Pearls

Most resistance to flow occurs in the long tubing line. A 16-gauge runs as well as a 14-gauge. If there is any doubt about the vein, it is better to use the 16-gauge. The veins that look like an L rather than a Y are harder to hold down and will more likely "roll" away from you. If peripheral veins look impossible, put in a central line. It is a lot less painful than multiple peripheral attempts, after which one may end up placing a central line anyway. Some patients are difficult to get lines into, such as chemotherapy patients, intravenous drug abusers, morbidly obese patients, and those with a history of difficult lines. Only experienced staff should be inserting those lines, and adequate time should be allowed for line placement. A common mistake is to stop when you get a flash of blood in the hub; you might only have the tip of the needle in the vein. The catheter itself is a few millimeters away and you have to insert the catheter into the vein too. If you let go of the skin once you get the blood flash, the skin retracts back, and the underlying vein also pops back, and then the catheter tip is no longer in the vein. Always secure the IV right away as the patient will move later. Intravenous lines tend to infiltrate, especially when they are covered up by sheets or blankets, so they must be inspected frequently.

Complications

Some of the known complications of intravenous line placement are phlebitis, infection, and extravasation. Contributing factors for phlebitis are size of the catheter itself, site of insertion and

Figure 44-1. Peripheral intravenous line placement. **A**, Lay out all the equipment in an organized way. **B**, Look for a good vein, ideally one shaped like an inverted Y. **C**, Make sure the tourniquet can be undone with one hand. **D**, Try to get the vein to stand out. **E**, Apply alcohol wipe and administer lidocaine. **F**, Pull the skin taut and keep it taut. **G**, Approach at a shallow angle to get the needle and catheter tip in. **H**, Without letting go of the taut skin, advance the catheter. **I**, Undo the tourniquet. **J**, Hold down above the catheter.

skill of the practitioner, and duration. Infection may be aggravated by contaminated infusions, poor technique, and inadequate preparation of the skin. Age, duration, site of insertion, and type of cannula may make patients susceptible to extravasation.

Radial Arterial Line

Indications and Contraindications

The radial artery is the most common location for placing an arterial line.⁴⁻⁸ It is indicated for close blood pressure measurement, where small changes in blood pressure will make a big difference, as well as frequent blood gas sampling. Radial arterial line is contraindicated in patients who underwent radial artery harvesting for a bypass, arterial insufficiency of the hand, and infection at the site. Interestingly, Raynaud's

phenomenon is not a contraindication for placement of a radial arterial line.

Equipment

The equipment for radial arterial line placement includes the following: (1) a board to hold the wrist in extension; (2) tape; (3) 1% lidocaine in a small syringe with a small (25-gauge) needle; (4) cannula (either specially designed Arrow 20-gauge cannula, or a regular cannula) and (5) transducer and pressure tubing.

Technique

Steps for inserting a radial arterial line are shown in [Figure 44-2](#). First, explain the procedure and obtain consent. Set up the equipment so there is pressure tubing ready to connect

Figure 44-2. Radial arterial line placement. **A**, To approach the radial artery one needs to go over the thenar eminence. **B**, Extending the wrist allows a straight shot to the radial artery. **C**, Approach at a shallow angle to get the needle in, then slide up a little more to get the catheter in as well. **D**, Make sure the blood keeps flowing as you advance. **E**, Slide the catheter in, then hold down above the line so the blood does not squirt out. **F**, It is recommended to use the Luer-Lok to avoid disconnecting the line.

as soon as the line is in, as the blood will be pumping out at arterial pressure. Zero the transducer and make sure the pressure tubing is pressurized. Using the patient's non-dominant hand, extend the wrist and flatten out the hypothenar eminence so there is a straight shot into the radial artery. Going up and over the thenar eminence is much more difficult. Prep and apply a little local anesthetic. In the through-and-through technique, poke all the way into and through the artery, then pull back until the blood flows (signifying the catheter's re-entry into the artery) and then advance the catheter up into the artery. A variant of this technique involves a wire: go through the artery, pull the needle out, then pull back until there is pulsatile flow, slide a wire in, then advance the catheter over the wire. In the go-in-the-first-time technique, do not go all the way through. When blood flow is seen, advance a little (making sure the catheter is in the artery, not just the needle tip), then advance the catheter. There are proponents and detractors of both techniques, so use the one that works best for you. Keep in mind that the blood should keep flowing and the catheter should slide easily with either technique. Hold the artery to keep the blood from spilling when you pull out the needle. Connect the pressure tubing to the catheter via Luer Lok (a non-Luer may fall out). Check the tracing to ensure that there is an arterial waveform. Once the line is in, do not keep the wrist in extreme extension to avoid stretching the median nerve.

If the first attempt is missed, apply pressure and try another spot. Avoid working through a hematoma. Infection is less likely in the high flow of an arterial system than a low-flow venous system, but it can still happen. Ischemia is one of the most feared complications, but it is an unusual event. Allen's test is not a good screening test. Be careful of pushing air into the arterial circulation to avoid embolization. When flushing the line, flush for just a second, wait, then flush again. A prolonged flush can push air all the way into the cerebral circulation.

Clinical Pearls

The radial artery is very skinny and placing a line in it requires extremely fine motor control of the muscles of the hand. Standing and bending over while performing the procedure decreases the success rate; sitting down will increase the success rate. It is best to come at the artery in a shallow angle, along the same axis that the artery is describing. If the trace looks damped, there might be a loose connection or an air bubble in the system. After placing the line, if the hand looks ischemic, call a vascular specialist and make sure one is available in case surgical intervention is needed. You may opt to inject nitroglycerin or papaverin down the line, then pull the line out; as you pull, aspirate in case there is a clot on the end.

Complications

One of the complications that may occur with radial arterial line placement is arterial occlusion. The frequency of this complication correlates with the type and size of cannula, with 20-gauge Teflon having the lowest complication rate. Post-cannulation aneurysms are rare and related to abnormal state of the vessel wall, multiple attempts at cannulation, and hematoma or infection at the cannulation site. Other complications include infection (rare), hematoma, and sclerosis (narrowing of the artery with repeated punctures).

Brachial Arterial Line

Indications and Contraindications

The indications for placing a brachial arterial line^{9,10} are the same as for other arterial lines, i.e., when close blood pressure monitoring and frequent blood gases are needed. In reality, most often a brachial line is chosen after the femoral artery is not an option due to aorto-occlusive disease or history of femoral vascular surgery. Contraindications for placing a brachial arterial line include vascular disease in the arm and infection at the intended site.

Equipment

The equipment for brachial arterial line placement includes the following: (1) a 20-gauge, 12-cm line kit (it is not recommended to place a short line in the brachial artery, because it can come out as the patient moves around); (2) sterile prep, drapes, and gloves; (3) an arm board.

Technique

Steps for inserting a brachial arterial line are shown in [Figure 44-3](#). Explain the procedure and get consent. Position the patient's arm flat on the arm board. Palpate the brachial artery, just medial to the midline in the antecubital fossa. Make a mark on the skin with a marker. Prep, drape, and administer local anesthetic. We recommend the Seldinger technique for line placement. Use the hollow needle to nick the vessel. Disconnect, observe for good blood flow, and then advance wire up the hollow needle. Remove the needle, advance the catheter up the wire, remove the wire, hook up and sew in the line. Ensure all the connections are tight, the trace is good, and that one can draw back easily.

Complications

Complications of brachial arterial line placement include local damage to the artery itself, arterial spasms, as well as accidental intra-arterial injection of drugs. As with any other invasive lines,

chances of infections exist but are rare for arterial lines and will be minimized by using strict aseptic technique. Daily risk of infection for a peripheral arterial catheter is 1.9% per day compared to 3.3% per day for central lines. Arterial sclerosis is also a potential complication, as repeated punctures at the same site may scar the artery and lead to lumen narrowing. This can be overcome by choosing another site of the same artery or choosing a different artery.

Femoral Arterial Line

Indications and Contraindications

Similar to radial arterial line, femoral arterial line¹¹⁻¹³ is indicated for close blood pressure measurement, where small changes in blood pressure can make a big difference, as well as frequent blood gas sampling. Also, in some cases one can anticipate the need for an intra-aortic balloon pump later on, so having a line already in the femoral artery will allow quick access. Femoral arterial line is contraindicated in patients with recent femoral surgery (aorto-iliac procedure, femoral-femoral or femoral-popliteal bypass), infection at the site, those who already have a venous line in the femoral region (can get an arteriovenous malformation), and patients with an occluded aorta (the blood pressure measurement will not be accurate).

Figure 44-3. Brachial arterial line placement. **A**, Equipment kit for brachial arterial line placement. **B**, Never put a short line in the brachial artery as it will kink when the arm bends. **C**, Feel the brachial pulse just medially to the biceps tendon. **D**, Administer local anesthesia. **E**, Use the standard Seldinger technique to arrive at the artery. **F**, Advance the wire, making sure it progresses easily. **G**, The wire is in place. **H**, Slide the catheter up, check the location again, connect the tubing, and sew in place.

Equipment

The equipment for femoral arterial line placement includes the following: (1) as for any arterial line, have pressurized tubing ready to connect, as well as a monitor to look at the arterial trace; (2) a long catheter with a soft tip (rather than a sharp tip that could erode through the back of the femoral artery and cause a retroperitoneal bleed); (3) a 16-gauge 16-cm single-lumen central line kit (anything smaller or shorter tends to kink); (4) sterile prep and gloves; (5) if the patient is obese, it is very helpful to have someone assist in pulling back the pannus to facilitate access to the artery.

Technique

Steps for inserting a femoral arterial line are shown in [Figure 44-4](#). Explain the procedure and obtain consent. If the operator is right-handed, the right femoral artery is easier to approach. The left femoral artery is easier to approach for a left-handed person. Prep and drape in sterile fashion and have an assistant nearby. Apply local anesthetic liberally as the femoral artery is very deep and it can be uncomfortable. The mnemonic NAVEL is useful to remember for anatomic structures from lateral to medial (Nerve, Artery, Vein, Empty space, Lymphatics). It is recommended to use a

long needle without a finder. Stick below the inguinal crease and go for the pulse. Use ultrasound guidance to find the vessel if it is available. When blood flow is seen, ensure it is arterial and not venous. Pass the wire through the needle without forcing it; it should pass easily. When the wire is in, remove it. Make a small nick in the skin, pass the catheter, again check that there is good flow, sew in place, and put a good dressing on.

Clinical Pearls

Ultrasound guidance offers great help in placing femoral arterial lines. Inexperienced operators as well as anyone with ready access to it should use it. The femoral pulse can seem very wide and seem easy to hit. In reality what one is feeling is a transmitted pulse. If there is pulsatile blood and it is dark, make sure the patient is well oxygenated. The vessel can be quite deep so at first you may have to go straight in; once in, try to flatten the approach a bit so the wire can be passed. Putting a pillow under the patient's knees can alter the plane of the vessels and make it easier. The femoral artery is deep and one can get frustrated during repeated tries. A missed attempt should never lead to mangling. If it looks like a struggle, always stop and ask for help or get an ultrasound.

Figure 44-4. Femoral arterial line placement. **A**, Shown is a good kit for femoral arterial line. The needle is soft-tipped so it does not erode and cause retroperitoneal bleeding. **B**, Palpate the femoral pulse and remember the mnemonic NAVEL for anatomic structures going lateral-to-medial (Nerve, Artery, Vein, Empty space, Lymphatics). **C**, Apply local anesthetic generously. **D**, Using the big hollow needle, advance until bright blood is observed. **E**, Once the needle is in, proceed with the Seldinger technique, making sure the wire goes in easily. **F**, A small nick is enough for the 16-gauge catheter to go in easily. **G**, Dilate with caution to avoid a major bleed. **H**, Slide the catheter up, check the location again, connect the tubing, sew in place, and apply dressing.

Complications

Hemorrhage can happen if there is a disconnect (Luer Loks are less likely to disconnect than other types). A hole in the back of the femoral artery can cause a retroperitoneal bleed, so if any unexplained hypotension, tachycardia, or a hematocrit drop is seen, this complication should be suspected. The femoral area may be more prone to infections compared to radial artery area; however, as long as strict aseptic technique is used during insertion and during maintenance, infection should not be a problem.

Nerve damage is another potential complication due to the proximity of the femoral nerve just lateral to the femoral artery. One must always be careful not to damage the nerve, especially in repeated attempts.

One should always watch for signs of vascular insufficiency or emboli. A healthy femoral artery in a young person is extremely unlikely to develop insufficiency from a femoral line, but most femoral arterial lines are not placed in young, healthy people. Sclerosis is rare for large arteries such as the femoral. Other obvious complications include hematoma and local damage to the artery.

Femoral Central Venous Line

Volume access on the venous side usually makes us think of a neck or subclavian line. One should not forget the femoral vein, however, as it is big, relatively easy to hit, does not get infected any more than the central lines in the upper body, and this approach makes one of the ultimate complications, pneumothorax, extremely unlikely.

Indications and Contraindications

Femoral central venous line¹⁴⁻¹⁶ is indicated in patients who need volume access (emergent or otherwise), inotropic access, CVP monitoring, pulmonary artery catheter monitoring, hypertonic fluids, if access from above is interrupted (such as in superior vena cava syndrome), transvenous pacing (in the catheterization laboratory the pacing wire is often passed from below), and temporary hemodialysis. Also, a need for a regular intravenous line can be served by a femoral line. Femoral central venous line is contraindicated in patients who already have a femoral arterial line on the same side (it can later lead to an arteriovenous malformation), infected site, penetrating abdominal trauma, and those in whom access from below is blocked (such as tumor in the inferior vena cava from a renal cell carcinoma). Prior groin surgery is a relative contraindication.

Equipment

The equipment for femoral central venous line placement includes the following: (1) central line kit; (2) an introducer (if big volume or a Swan placement is needed later); (3) sterile prep and drape equipment; and (4) an assistant to pull the abdomen back in case of pannus that needs to be pulled out of the way.

Technique

Steps for inserting a femoral central venous line are shown in Figure 44-5. Explain the procedure and obtain consent. Prep, drape, and set up the kit where it can be reached easily. Never place it on the patient. Pull any pannus back to allow a straight shot into the vessel. The anatomic landmarks can be recalled by using the mnemonic NAVEL (Nerve, Artery, Vein, Empty space, Lymphatics), so one should go in just medial to the artery. Use of

ultrasound is absolutely recommended if there is ready access to it. Apply local anesthetic generously. Use the long hollow needle in the kit without the finder. Once blood flow is observed, make sure it is venous rather than arterial. Advance the wire through the needle, remove the needle, nick the skin, dilate, then advance the catheter. If an introducer is being used, make sure the nick is big enough to slide the catheter in. Make sure you can aspirate easily, then flush and secure the line.

Clinical Pearls

The femoral artery is very deep, so it is important to realize when to use ultrasound guidance or ask for help. A right-handed operator should aim for the right femoral vein due to the easier mechanics.

Internal Jugular Central Venous Line

Indications and Contraindications

Internal jugular central venous line¹⁷⁻²⁷ is the most common central line placed in the ICU. It is indicated in the following situations: (1) same as any venous line, this central line can be “just an IV” when peripheral access is difficult; (2) same as any central line, this can be a mainstay of support; (3) volume access; (4) monitoring central pressures; (5) providing access for cardiosupportive drugs; (6) hypertonic solutions such as TPN; (7) transvenous pacemaking; (8) if a central line is needed but the subclavian line is not the preferred option (the risk of a bleed from a subclavian line and the risk of pneumothorax are higher with subclavian lines); (9) for the easiest approach to floating a pulmonary artery catheter; (10) temporary hemodialysis.

Contraindications for placement of the internal jugular central line are as follows: (1) previous carotid surgery; (2) carotid occlusive disease; (3) superior vena cava syndrome; (4) neck trauma; (5) coagulopathy. As is the case with a lot of other lines, it often happens that the very patient who most needs the line in is the very patient who has a relative contraindication. For example, the person who needs a big volume line in is the very person with a coagulopathy, so one needs to carefully weigh the risks versus. benefits.

Clinically Relevant Anatomy

The internal jugular vein originates at the jugular foramen and ends up behind the sternoclavicular joint where it joins the subclavian vein. It lies right alongside the carotid artery and the vagus nerve within the carotid sheath. The vein is initially posterior to, then lateral and then anterolateral to the carotid artery during its descent in the neck (it literally wraps around the carotid artery). It is the most superficial in the upper part of the neck. At the level of the thyroid cartilage the vein lies deep to the sternocleidomastoid muscle. As it passes toward the thorax, it emerges from behind the muscle and comes to lie at the apex of the triangle between the sternal and clavicular insertions of the muscle.

At the inferior portion of the vein there is a bicuspid valve that directs flow toward the heart. On the left side of the neck the internal jugular vein lies anterior to the thoracic duct. Because of this, the right side is preferred to avoid the risk of thoracic duct injury. On the right side, the vein is typically straight all the way. On the left, in contrast, the vessel takes a right turn once in the thorax; thus, the dilator can tear through the vessel and cause a hemothorax, which is yet another reason to choose the right side.

Figure 44-5. Femoral central venous line placement. **A**, The mnemonic NAVEL is very useful for reviewing the anatomic landmarks (Nerve, Artery, Vein, Empty space, Lymphatics). **B**, Apply local anesthesia generously. **C**, Using the hollow needle, advance until dark venous blood is observed. **D**, Hold the needle steady, wire it up, and proceed using the standard Seldinger technique. **E**, Nick the skin, dilate, and pass the line. **F**, Aspirate, flush, sew in place, and apply dressing.

Technique

Steps for internal jugular central venous line placement are shown in [Figure 44-6](#). Obtain consent and explain procedure. Review the history and physical examination to make sure there are no contraindications (such as infection at the site). It is important to make the first attempt the best attempt, e.g., by using ultrasound before the start. Put the patient in Trendelenburg position and administer fluids (if the patient can tolerate them) to make the vein as prominent as possible. Turn the patient's head about 45 degrees. Turning the neck all the way over will compress and flatten the vessel. It is useful to mark the landmarks on the skin before starting the procedure. If the patient can tolerate it, provide sedation. Use strictly aseptic technique. Palpate the carotid and go right next to it. Do not press down on the carotid as it will flatten the internal jugular vein. Also, pressing hard on the carotid artery may cause a vagal reaction. In case of doubt or difficulty, use ultrasound guidance. Administer 1% plain lidocaine. Use a finder, such as a 22-gauge needle on a 3-mL syringe. Go at an angle of 30 degrees to the skin. Insert at the medial border of the sternocleidomastoid between the 2 heads of the muscle toward the ipsilateral nipple. After the internal jugular vein is located, the finder needle is kept in place,

and a larger 18-gauge short bevel needle mounted on a 5-mL syringe is applied just adjacent to the needle finder, with gentle aspiration in the same needle finder track. Go right next to the finder and have the needle entering at the same angle to the skin. With gentle negative pressure advance slowly until dark venous blood appears. Hold the hub firmly as you detach the 18 g from the syringe and observe venous blood flow. Advance the wire into the hollow needle. Slide the 18 g catheter over the wire, remove the wire, and either transduce or hook up a small length of intravenous tubing; observe the blood flow again to ensure that the location is the vein and not the carotid artery. Replace the wire through the catheter, make a nick in the skin, and advance the line over the wire. Watch for dysrhythmias at all times as the wire may “tickle” the heart. If a dysrhythmia occurs, the wire should be pulled back. Make sure the depth is right: 16 cm to the atriocaval junction from the right side, and 19 cm to the atriocaval junction from the left side. Flush all the ports, secure the catheter in place with sutures, apply a sterile dressing, and obtain a chest x-ray to make sure the line is in the right place and there is no pneumothorax. The catheter should lie in the superior vena cava, at the level of T4-T5 below the clavicle.

Figure 44-6. Internal jugular central venous line placement. **A**, Get lined up and then palpate the sternal notch (lower finger) and mastoid process (upper finger) to identify the sternocleidomastoid muscle. **B**, Without any imaging guidance, go in at about the halfway point. **C**, Palpate the carotid artery but do not press down on it to avoid compressing and flattening the internal jugular vein, making it hard to hit. **D**, Use local anesthetic judiciously. **E**, It is crucial to be close to the carotid artery but aiming away from it (at the ipsilateral nipple). If this is performed under ultrasound guidance, carotid artery and internal jugular vein are adjacent to each other. **F**, Proceed until dark venous blood is observed, usually 1-2 cm deep. **G**, Once the finder is in, place the needle right on top of the finder to exactly reproduce the approach angle. **H**, If the blood is bright and squirts out in pulsatile fashion, the attempt has missed and hit the artery. **I**, Assuming that did not happen, advance the wire, keeping an eye out for ectopy. **J**, Once the wire is in, again check that it is in the right place. Slide the 18-gauge catheter down the wire, pull the wire out, and connect the catheter to the extension tubing. **K**, Hold the tubing up, make sure that the blood goes up to CVP height and not to arterial height (it would climb all the way to the top and squirt out). This is a quick and effective way of ensuring the correct location. Proceed with the standard Seldinger technique. **L**, Nick, dilate, flush, sew, and dress. **M**, If a cordis is being placed, the dilator and cordis should be placed as a unit. **N**, Aspirate and flush, without leaving anything open to air, which could lead to an air embolus.

Clinical Pearls

There are several different approaches described (posterior, anterior), but the most important landmark is the carotid artery. The internal jugular vein lies next to it, so feel the carotid artery and go a little off to the side of it. Stay high enough to avoid a pneumothorax. Before starting the procedure always be familiar with central venous catheter types, gauges, length and number of lumens. Make sure you open the right kit. Take the time to set up a good working environment. If you miss, be methodical. Pull straight back, change direction a little, and try again. Don't get fixated on one place. If you just cannot get it, go to the other side.

If the first attempt is unsuccessful, use ultrasound guidance. It is beneficial as it requires fewer needle passes, there are fewer arterial punctures, and fewer failures. On ultrasound, the jugular vein is easily compressed with the Doppler probe; it exhibits the lack of pulsation and enlargement with a Valsalva maneuver.

Complications

It is important to know how to manage pitfalls and complications associated with internal jugular central venous line placement. The most critical complications can arise from inadvertently sticking the carotid artery. Major bleeds can lead to hematoma in the neck and airway compromise. This can also lead to cerebrovascular insufficiency or pseudoaneurysm formation. In case of a carotid artery stick, leave the catheter in place and consult a vascular surgeon. If the patient is at risk of a big bleed, consider intubating to protect the airway prior to removing the sheath. If you remove directly (after having consulted the surgeon and having airway equipment/expertise nearby), apply firm pressure for at least 15 minutes, all the time monitoring for neurologic, airway, or hemodynamic problems.

Other misses can involve the vertebral artery, or even the lung if one goes too deep and inferior, causing a pneumothorax. If the catheter or needle are left in place and open to air, the patient can get a venous air embolism. The pitfalls can involve any of a number of nerves in the neck—vagus, phrenic, hypoglossal, stellate ganglion. Advancing the wire can sometimes cause dysrhythmias. Left bundle branch block can convert to complete heart block as the wire “shorts out” the right bundle branch. In the intubated patient, going too medially can hit the trachea and pop the endotracheal tube cuff. Hitting the thoracic duct can cause a chylothorax. Also, there are the generic complications associated with any line placement, such as infection or misplacement.

External Jugular Central Venous Line

Indications and Contraindications

The external jugular central venous line is included here for complete coverage, but it is rarely performed because it is not an effective procedure. If you choose to place a line in the neck, internal jugular vein is the preferred approach. The indications and contraindications are the same as for other central lines, so we will focus on the technique itself.

Technique

Steps for external jugular central venous line placement (Fig. 44-7) are the same as those shown in Figure 44-6. Place the patient in Trendelenburg position, which reduces the incidence of venous air embolism and makes the external jugular vein more engorged with blood. Turn the patient's head away from

Figure 44-7. External jugular central venous line placement. Steps are equivalent to those described in Figure 44-6.

the site of insertion. Prep the area with chlorhexidine and set up a sterile work environment including gown, gloves, mask, and cap. Administer 1% lidocaine. Too much lidocaine can compress the vessel. With one hand, pull the skin taut and poke through it quickly. The external jugular vein, even when large and prominent, tends to slide away. Stick the catheter through the skin and insert it into the vein. If the flash of blood in the hub can't be seen, connect the catheter to a 3-mL syringe and aspirate as you go (you may be in and not get flow back unless you pull back on the plunger). If the line is intended to be used as a regular IV, keep in mind that it can come out easily when the patient turns the head. If it is intended to be a true central line, it may be difficult to get past the clavicle. It sometimes helps to bend the catheter a little (exaggerated in the figure) to slide into the external jugular vein.

Complications

Complications of this technique are the same as for other central lines. There is decreased success with obesity, short neck, and placements of triple-lumen catheter and pulmonary artery lines.

Subclavian Central Venous Line

Indications and Contraindications

Subclavian central venous line²⁸⁻³⁰ can be useful for the following reasons: (1) the only anatomical landmark is the clavicle—there is no need to palpate the carotid pulse, which can sometimes be difficult (short neck, obese patient, subcutaneous emphysema, neck collar); (2) it does not require turning the neck, which in some patients can be dangerous (C-spine injury) or impossible (severe arthritis); (3) patients tend to tolerate subclavian lines better than internal jugular lines.

Subclavian central venous line is not recommended in the following situations: (1) superior vena cava syndrome/thrombosis; (2) infection at the site of entry; (3) injury to the clavicle that might distort anatomy; (4) coagulopathy; (5) COPD—there is a higher risk of pneumothorax with a subclavian line versus an internal jugular line; and (6) high PEEP.

Technique

Steps for subclavian central venous line placement are shown in Figure 44-8. If the goal is to place a PA catheter or pacing wires, the left subclavian vein is preferable to the right because it is

Figure 44-8. Subclavian central venous line placement. **A**, The needle should target the sternal notch, but always angle away from the lungs. If the needle needs to be depressed, press down on top with three fingers so the whole needle goes down flat as a single unit rather than just pointing the tip down. **B**, The needle is in the clavicle and the upper fingers are pressing the needle down as a unit so it goes down but is still inclined away from the lung. **C**, Once the needle is in, the subclavian area has a distinct advantage over the internal jugular vein area, as the needle is held between the clavicle and the first rib and is better secured. **D**, Wire, nick, dilator, and flush. Do not go too medially to avoid getting stuck between the first rib and the clavicle. **E**, Aspirate, flush, sew, and dress.

a more natural angle for placing the PA catheter. If a chest tube is already in, the subclavian line should be placed on the same side. Because the first rib is very close to the clavicle, going too medially might get the wire in, but the line will not be able to pass between the first rib and the clavicle.

Set up the work space including good lighting, a dedicated table for the kit, and a bed that can get into the Trendelenburg position. Set up a sterile work environment, including prep and drape, gown, mask, and hat. Take care of patient explanation and consent. Put a roll down the middle of the patient's back to throw the shoulders back and get a straight shot into the subclavian vein rather than going up and over the shoulder, because lines are not good at turning corners. Ventilated patients should be put on 100% oxygen, lower tidal volumes, and decreased PEEP (if feasible) to make a pneumothorax less likely. Have an assistant pull the shoulder down (5 cm caudal from the neutral position) and put the patient in Trendelenburg position. Make sure the vein is as prominent as possible. Inject 1% lidocaine plain to form a little wheal at the injection site. Using the long hollow needle in the kit, go about 1 cm

below the mid-clavicular point of the lower border of the clavicle. Ultrasound guidance is difficult due to the proximity of the lungs and the bones. Aim for the suprasternal notch and pass below the clavicle. If the clavicle is touched, “walk” off it by pushing down on the needle with your fingers. Stay parallel to the plane of the ground in order to keep the needle directed away from the lungs at all times. Usually the vein is found beneath the inner third of the clavicle, near the clavicular head of the sternocleidomastoid. Sometimes it will be missed going in but found coming back, thus both going in and coming out should be done slowly. Always check to make sure the blood being aspirated is venous. Disconnect the needle from the hub of the syringe and make sure there are no arterial pulsations. Place the wire through the needle, then withdraw the needle while keeping an eye out for ectopy. Nick the skin and advance the dilator over the guidewire using the Seldinger technique. The dilator can get caught between the first rib and clavicle and cause problems. Place the line, flush the lines, sew in place, check the chest x-ray for misplacement or pneumothorax, and place a dressing.

Complications

The biggest concern is hitting the subclavian artery and not being able to stop the bleeding. This may require emergent surgery and is not an easy repair. To avoid pneumothorax, the needle should be kept inclined up and away from the lung at all times. If the lung is dropped and there is not enough time for a chest tube, place a 14-gauge catheter in the second intercostal space on the affected side to achieve emergent decompression of a tension pneumothorax. Infection rates for subclavian central lines are lower compared to those of internal jugular lines and patient comfort is also better with subclavian lines if they are awake and alert.

Pulmonary Artery Catheter Placement

Indications and Contraindications

There is an ongoing debate about the utility of the flow-directed pulmonary artery catheter. The following section reviews how to float such a catheter once venous access is obtained.

Pulmonary artery catheter³¹⁻³⁴ can be useful for the following reasons: (1) obtaining a host of filling pressures (central venous pressure from the proximal port; pulmonary artery systolic and diastolic pressures from the distal port; pulmonary capillary wedge pressure from the distal port); (2) obtaining a host of additional hemodynamic values (cardiac output; continuous cardiac output if the catheter is so equipped; mixed venous oxygenation, either by drawing a sample from the distal port, or by direct measurement in a catheter so equipped; continuous mixed venous oxygenation in a catheter with this function built in; from these measurements, deriving systemic vascular resistance); (3) drawing blood samples from different areas (an unexplained “step up” in oxygenation could indicate the presence of an intracardiac shunt); (4) monitoring the effect of inotropic support by following the trends of pressures, cardiac output, systemic vascular resistance; (5) monitoring volume status in patients in whom central venous pressure alone is not sufficient; (6) management of the critically ill patient, especially one whose urine output defies traditional remedies or one whose hemodynamics defy routine maneuvers; and (7) temporary pacing (some pulmonary artery catheters have built-in pacing capability, while the Paceport Swan catheter allows passing a wire into the right ventricle for temporary pacing).

Pulmonary artery catheter is not recommended in the following situations: (1) post-pneumonectomy patients (due to the risk of occlusion of the one remaining pulmonary artery); (2) clots or infected masses in the right heart (as they may get dislodged); (3) pulmonary hypertension (this situation presents the classic dilemma: one could argue we need this information in this critically ill patient, but the very presence of pulmonary hypertension means this patient is at higher risk for a pulmonary artery rupture); (4) left bundle branch block (due to the risk of blocking the right bundle and converting this to a complete block); (5) superior vena cava syndrome.

Equipment

The equipment for pulmonary artery catheter placement consists of the following: (1) introducer in place (most often the introducer will be in the right internal jugular vein; the pulmonary artery catheter can be floated from any other location since it is flow-directed); (2) pulmonary artery catheter sleeve to keep the catheter from getting contaminated; (3) pulmonary artery

catheter, which comes in different types (continuous mixed venous oxygen saturation, continuous cardiac output, pacing catheters, paceport catheters); (4) transducers connected to the catheter (two transducers are needed to see the distal and proximal ports); (5) sterile set-up; (6) EKG monitor and someone watching, as dysrhythmias are common as the catheter traverses the heart; (7) fluoroscopy may be needed on rare occasions to help pass the catheter; and (8) pacing capability (e.g., external Zoll pads) if the patient has a left bundle branch block.

Technique

Steps for pulmonary artery catheter placement are shown in [Figure 44-9](#). First, clear the area to avoid contaminating the catheter. Pre-flush the catheter so there is no air in the lines. Take care of patient explanation and consent. Prepare a sterile field, gown, hat, and mask. Ensure that transducers are zeroed and leveled. Pull the catheter through the sheath, making sure the sheath is oriented in the correct direction with the locking mechanism toward the patient. Once the catheter is through the diaphragm of the sheath, check the balloon and make sure that it didn't rupture. Put the catheter into the introducer and advance it to 20 cm to put the balloon-tipped end out of the introducer and near or in the right atrium. Watch the monitor for a CVP trace. Inflate the balloon with the special syringe from the catheter kit (do not use more than 1.5 mL) and maintain constant communication with the person inflating and deflating the balloon. When the trace goes from central venous to right ventricular, there will be a change in the waveform. Continue advancing the catheter. If another change in the trace is seen, the catheter should be in the pulmonary artery. Advance until a wedge trace is seen. If the catheter is advanced to 50 cm and there is no wedge trace but there is a good pulmonary artery trace, stop there. Overzealous pursuit of a wedge trace may lead to pulmonary artery rupture. Let the balloon down. If there is a wedge trace, once the balloon is let down the trace should revert to a pulmonary artery trace. If it does not, the catheter is too far out and should be pulled back a few centimeters. If the catheter is pulled too far back, the trace will revert to a right ventricle trace. In this case, the catheter will need to be re-advanced until it is in the pulmonary artery again. Slide the sheath over the catheter and click it in place.

Complications

Pulmonary artery rupture is the ultimate complication and manifests as massive bleeding of bright red arterial blood into the trachea. If that happens, get a thoracic surgeon right away, isolate the lung if possible, and keep the balloon up to try to tamponade the bleeding. If the catheter is tied in a knot, send the patient to special procedures so they can remove it out under fluoroscopic guidance. In cases of ectopy with dangerous runs of ventricular tachycardia, it is recommended to forego the pulmonary artery catheter.

Clinical Pearls

If the catheter does not go into the pulmonary artery, reposition the patient head up and tilted to the right. That favors a balloon floating up and out the pulmonary artery outflow tract. If the patient is on a ventilator, consider turning off the ventilator for a short while to increase venous return and favor forward flow. Inspect the catheter by pulling it out and making sure the balloon still inflates and the catheter is curling the right way (sometimes it points around the wrong way and goes down the arm).

Figure 44-9. Pulmonary artery catheter placement. **A**, Exercise caution when taking the catheter out of the kit to avoid contaminating it. **B**, Put the sheath on. **C**, Make sure the balloon inflates correctly. It can rip as it goes through the sheath. **D**, Advance to 20 cm, then inflate the balloon and advance. Maintain communication with the person inflating the balloon at all times. **E**, Once it is in the right place, snap on the sheath.

Open the IVs to fill up the heart a little more. Try to advance the catheter very slowly, as this allows the catheter to “catch a wave”. If all else fails get a new catheter; a new, stiffer catheter may float out more easily. Alternatively, try advancing the catheter using fluoroscopic or TEE guidance.

Invasive Hemodynamic Monitoring in the Cardiac Intensive Care Unit

Robin Mathews, David L. Brown

CHAPTER 45

Systemic Arterial Blood Pressure Cardiac Output and Mixed Venous O₂ Consumption

Indications for Pulmonary Artery Catheterization

HEMODYNAMICS is derived hydrodynamics, the physics of the motion and action of water. The dimensions of hydrodynamics include: flow, pressure, static resistance, dynamic impedance, reflectance and compliance, branching effects, viscosity, fluid friction, turbulence, and other physical characteristics.¹ The goals of hemodynamic assessment and manipulation in the critically ill patient are to ensure adequate organ blood flow and oxygen supply.² Noninvasive parameters to measure organ perfusion include systolic and diastolic blood pressure, body temperature, heart rate, and respiratory frequency.³ Though established clinical signs of organ perfusion should be used for monitoring, these sometimes have limited value as accurate indicators of cardiovascular function.⁴ Important pathophysiology may remain obscured if judged solely on clinical signs.² The evolution of modern technology has allowed for quantitative biologic measurements. The principles of hemodynamic monitoring have allowed basic physiologic measurement to be applied in a meaningful manner in the management of cardiovascular aspects of critical illness.⁵ The development of bedside intravascular catheterization procedures has permitted extension of the application of the physiologic principles established early in the century to the population of critically ill patients.⁵

Systemic Arterial Blood Pressure

The continuous measurement of arterial pressure is essential in hemodynamic monitoring. Arterial pressure is the input pressure for organ perfusion.⁶ It is usually monitored noninvasively with a sphygmomanometer. In the Cardiac Intensive Care Unit (CICU), however, a more invasive technique with insertion of an indwelling arterial catheter into either the arm (brachial or radial sites) or groin (femoral arterial site) is often used to provide more precise monitoring. The advantages of arterial catheterization over noninvasive means are continuous monitoring of arterial pressure and its waveform, and serving as a site for repetitive blood sampling.⁶

The arterial pressure is a function of both vasomotor tone and cardiac output. Local metabolic demands determine local vasomotor tone that in turn determines blood flow distribution.⁶ The perfusion pressure and local vascular resistance determine organ perfusion of all capillary beds. Flow is proportional to local metabolic demand if there is no hemodynamic instability to cause increased sympathetic tone.⁶ Cardiac output primarily determines arterial pressure in the setting of varying degrees of

local blood flow and because it is proportional to local metabolic demand, there is no normal value in an unstable, metabolically active patient.⁶ The literature currently suggests maintaining previously nonhypertensive patients at a mean arterial blood pressure (MAP) of 65 mm Hg.^{6,7} Based upon a clinical trial that examined the effects of resuscitative efforts with fluid and vasopressors in circulatory shock patients to varying MAP targets ranging from 60 to 90 mm Hg. No increased organ blood flow could be determined above a MAP of 65 mm Hg.⁸ Thus, there is no proven benefit in forcing either cardiac output or arterial tone to higher levels above this threshold.

Table 45-1 displays indications for arterial catheterization. The transducers used for blood pressure measurement are connected to the circulation via fluid-filled tubing. The accuracy of the system is optimized when the catheters and tubing are stiff, the total length of tubing is not excessive, the number of stopcocks is limited, and residual air bubbles are eliminated.² The “zeroing” of the transducer at the appropriate level in relation to the patient (i.e., midthorax) must be correct to prevent errors caused by hydrostatic pressure of the fluid column.^{2,9} In most cases, the choice of location for insertion of the catheter is the radial artery because the femoral artery approach is more often associated with displacement during patient movement and hemorrhage that is more difficult to control.¹ Although arterial catheterization is an invasive procedure with inherent risks, most complications are not severe (temporary vascular occlusion 20% and hematoma 14%) with permanent ischemic damage, sepsis, and pseudoaneurysm formation occurring in less than 1% of cases.¹⁰

Right Heart and Pulmonary Artery Catheterization: A Historical Perspective

The data that is the basis of our current understanding of cardiac function was obtained nearly 100 years ago. Claude Bernard performed the initial cardiac catheterization in 1844 entering both the right and left ventricles of a horse.⁹ The physiologic and anatomic data obtained over the ensuing years lead to the development of important concepts, such as pressure manometry and cardiac output measurement. In 1929, Werner Forssmann successfully performed a right heart catheterization on himself. In 1947 Lewis Dexter passed a catheter to the distal pulmonary artery and measured pulmonary capillary wedge pressure and oxygen saturation for the first time. Subsequent work from his laboratory noted pulmonary capillary wedge pressure to be a

reliable estimate of left atrial pressure.¹¹ In 1956 Dickinson Richards and Andre Cournard along with Forssmann were awarded the Nobel Prize in Medicine for their work describing cardiovascular physiology using the pulmonary artery catheter (PAC).⁹

Right heart catheterization permitted measurements of cardiac output and right heart and pulmonary pressures that make it possible to calculate other derived hemodynamic parameters, such as cardiac work indices and systemic and pulmonary vascular resistance.² Initially, the procedure was exclusively performed in the cardiac catheterization laboratory primarily to diagnose congenital and valvular heart lesions.¹² However, the increasing numbers of admissions to CICUs for hemodynamic instability as a result of ischemic heart disease prompted an expanded role for invasive hemodynamic monitoring. The 1960s ushered in the establishment of Coronary Care Units (CCU) to manage cardiac arrhythmias in the setting of acute myocardial infarction.^{1,13} It was noted that profound hemodynamic changes might be the primary factor in arrhythmic deaths.¹ However, practical limitations in transporting critically ill patients to a cardiac catheterization suite and the increased risk of induction of cardiac arrhythmias limited the application of invasive hemodynamic monitoring.¹

In 1970, motivated by a lack of understanding of the disease process in those patients admitted with ischemia, Swan developed a balloon-tipped, flow-guided catheter that for the first time established a reliable way to perform bedside catheterization in

specialized cardiac care units.¹⁴ The initial catheter was a double lumen extruded polyvinylchloride catheter with an outside diameter of 1.6 mm and a length of 110 cm.⁵ There was a minor lumen of 0.4 mm in diameter and a major lumen of 1 mm in diameter. The minor lumen was used to inflate the balloon to a volume of about 0.8 mL. Their initial study involved 100 patients in whom successful bedside hemodynamic monitoring was performed.¹⁴ They concluded it was possible to safely catheterize the pulmonary artery (PA) at the bedside without fluoroscopy in a high proportion of patients. The information gained proved to be important in understanding the altered pathophysiology of a given illness and thereby altered management in these patients.⁵

It is following this landmark report that widespread use of PACs began. The relative ease in hemodynamic monitoring transformed the care of cardiac pump failure in the CCU. It allowed recognition of hemodynamic subsets in myocardial infarction, such as right ventricular infarction, and provided additional prognostic insight and allowed for the selection and monitoring of pharmacologic therapy.¹⁵

As stated earlier, the PAC allows for determination of various fundamental hemodynamic parameters, including measurement of cardiac output by the thermodilution (TD) right atrial (RA), right ventricular (RV), PA, and pulmonary capillary pressures; and sampling of blood from the PA, the RV, and RA. Pulmonary vascular and systemic resistance and right and left ventricular stroke work could then be derived. Further developments include continuous measurement of PA blood oxygen saturation¹⁶ and near continuous or instantaneous cardiac output.¹⁷

The Catheter

The catheter most commonly used is a 7.5 French thermodilution catheter. It is a 3-lumen radiopaque catheter, 110 cm long and made of polyvinylchloride. The outside is marked with black rings every 10 cm from the tip that allow determination without fluoroscopy of the appropriate catheter length at which to inflate the distal balloon. The distal lumen terminates at the tip of the catheter, whereas the RA lumen terminates 30 cm proximal to the tip. There is a venous infusion lumen 1 cm proximal to the RA lumen. A thermistor bead located 3 to 5 cm from the tip is connected to an external thermistor connector by a wire. The external thermistor is in turn linked to a computer that allows for determination of cardiac output by the thermodilution method.^{14,15,18} A latex balloon with a maximum inflating capacity of 1.0 to 1.5 mL is positioned at the tip. Upon inflation, the balloon engulfs the catheter tip reducing the transmitted force and hence limiting irritation and injury of endocardium and reducing the frequency of arrhythmia.¹⁴ The inflated balloon facilitates flow-directed advancement of the catheter through the right heart into the pulmonary artery. Once inflated in a distal branch of the pulmonary artery, the balloon occludes the vessel and allows for measurement of pulmonary capillary pressure. Most catheters are heparin-coated to reduce thrombogenicity. In addition, electrodes implanted in some catheters allow for pacing and electrocardiographic recording. The inclusion of fiberoptics allows measurement of oxygen saturation in the PA. The catheter can serve multiple functions including: measurement of CO by TD, PA temperature, intracardiac pressures (RA, RV, PA, PCW), and PA occluded pressure. Blood sampling can be done through the active lumens of the catheter.

Probable indications for arterial catheterization

Guide to management of potent vasodilator drug infusions to prevent systemic hypotension

Guide to management of potent vasopressor drug infusions to maintain a target MAP

As a port for the rapid and repetitive sampling of arterial blood in patients in whom multiple arterial blood samples are indicated

As a monitor of cardiovascular deterioration in patients at risk for cardiovascular instability

Useful applications of arterial pressure monitoring in the diagnosis of cardiovascular insufficiency

Differentiating cardiac tamponade (pulsus paradoxus) from respiration-induced swings in systolic arterial pressure; tamponade reduces the pulse pressure but keeps diastolic pressure constant. Respiration reduces systolic and diastolic pressure equally, such that pulse pressure is constant.

Differentiating hypovolemia from cardiac dysfunction as the cause of hemodynamic instability. Systolic arterial pressure decreases more following a positive pressure breath as compared with an apneic baseline during hypovolemia. Systolic arterial pressure increases more during positive pressure inspiration when LV contractility is reduced.

Equipment and Signal Calibration

Properly functioning electronic monitoring equipment is essential. The fluid-filled PAC is connected via a semirigid pressure tubing to pressure transducers. These transducers consist of a fluid-filled dome, a diaphragm, and a strain gauge Wheatstone bridge arrangement.¹⁸ An electric current directly proportional to the fluid motion is amplified and transmitted to the oscilloscope equipment for display. Other factors that influence accurate reproduction of a biologic signal include frequency response, natural frequency, damping, and catheter whip artifact.

The system must have a frequency response of flat to 15 to 20 Hz to be adequate for human studies. Pressure waveforms are not reliable in patients with excessively rapid heart rates of greater than 180 beats/min. The length of the pressure tubing determines the natural frequency of fluid-filled systems. Excessively long tubing will drop the natural frequency to below physiologic range, causing an overamplification of signal resulting in falsely elevating pressure readings. The recommended length of pressure tubing is 3 to 4 feet.¹⁸ Damping is the opposite effect with a loss of physiologic signal, which most often

results from air trapped in the circuit. Because air, unlike fluid, is compressible, less motion is transmitted to the diaphragm per unit of pressure. Damping of the PA pressure signal may make it difficult to discern from the wedge pressure. Catheter whip artifact results from motion imparted to the catheter with each cardiac contraction. High-frequency filters can eliminate this artifact.¹⁸

Accurately measuring pressure signals requires proper calibration of the monitoring system. With a patient supine, the pressure transducer is aligned with the fourth intercostal space midway between the front and the back of the chest.¹⁸ This site serves as the standard zero reference point. The calibration of the monitor involves the introduction of a known pressure signal. This can be done either internally or externally. Zero reference and calibration should be checked each day of hemodynamic monitoring.¹⁸ Table 45-2 lists the required equipment for PAC insertion. Prepackaged kits with the above materials are available.

Catheter Insertion

Catheter equipment should be inspected and calibrated. All lumens should be flushed with normal saline and be free of air. Insertion site selection can vary between internal jugular, subclavian, and femoral veins (Table 45-3). Although the site of insertion is at the discretion of the operator, the right internal jugular vein is preferable because of the straight course to the superior vena cava. Meticulous preparation of the chosen site with aseptic technique is crucial. The operator and any assistants should be in sterile gown, gloves, facemasks and caps. Any other personnel in the room should also have masks and caps.

The patient should be properly prepped, draped, and in the Trendelenburg position. The site is then accessed percutaneously through a modified Seldinger technique. After local anesthesia, an 18-gauge, 7.6-cm Cook needle with attached syringe is inserted bevel up at approximately 45 degrees between the heads of the sternocleidomastoid muscles toward the ipsilateral nipple, while palpating the ipsilateral carotid artery. After free flowing venous blood is obtained, the syringe is disconnected from the needle and a 40 cm long J-tipped guide wire is inserted into the needle and passed gently into the vein. The guide wire should pass without any resistance. The guide wire should never be advanced if any resistance is encountered. The needle is then removed and the skin puncture is enlarged with a scalpel blade. The dilator sheath system is then advanced over the guide wire into the vein with a gentle rotating movement. Once the sheath is properly positioned, the wire and dilator should be removed and the sheath sutured in place.

Table 45-2. Equipment Required for Swan-Ganz Catheter Insertion

Appropriate Swan-Ganz catheter
Dilator-sheath-side arm assembly
Three-way stopcocks
Pressure tubing
Transducers
18-gauge, thin-walled Cook needle
Sterile gowns, drapes, gloves
1% lidocaine
Heparinized saline
J-tipped guidewire
Towel clips, syringes, suture material
Electrocardiography and pressure-monitoring equipment
Intravenous line
Atropine
Defibrillator unit

Table 45-3. Comparison of Venous Access Routes

Vein	Advantages	Disadvantages
Internal jugular	Rapidly accessible Does not interfere with CPR Provides a straight route to the heart Less restrictive to patient movement	Air embolism, carotid artery puncture, and tracheal injury may occur Pneumothorax (more common in the left than the right internal jugular vein) Thoracic duct injury (left internal jugular vein only)
Subclavian	Rapidly accessible Allows free neck and arm movement Easier to keep sterile	Air embolism, more frequent pneumothorax and hemothorax; subclavian artery puncture; injury to nerve bundle may occur
Femoral	Rapidly accessible Does not interfere with CPR	Sepsis, in situ thrombosis, and pulmonary embolism may occur usually requires fluoroscopy

Figure 45-1. Normal hemodynamic pressures. (Adapted from Swan HC: *The pulmonary artery catheter*. *Dis Mon* 1991;37:518.)

The PAC should be inspected for bends and kinks and the balloon tested with air inflation underwater to evaluate for leaks. The catheter should then be connected with pressure tubing to calibrated pressure transducers. Finally, a plastic sleeve is placed over the catheter to preserve the sterile length of the catheter outside of the body for possible future manipulation.

The catheter is then inserted and advanced approximately 10 cm before the balloon is inflated with 1 to 1.5 mL of air. In most patients the catheter will reach the RA within 10 to 15 cm from the internal jugular or subclavian vein. Once in the RA, the catheter should be quickly advanced under continuous pressure and electrographic monitoring across the tricuspid valve, through the RV, PA, and into the pulmonary wedge position. The catheter should reach the PA approximately 50 to 55 cm from the internal jugular vein. One should suspect catheter coiling if significantly greater lengths are required. Figure 45-1 illustrates typical pressure waveforms.

The deflated catheter should recoil slightly into the proximal PA. With inflation, the catheter should then float to a wedge position. The goal is passive occlusion of a distal vessel impeding blood flow to that area. The balloon should be slowly inflated while pulmonary artery pressure is continuously monitored. Wedge tracings obtained at substantially less than the full inflation volume indicates distal migration of the catheter. With the balloon deflated, it should be repositioned with slow withdrawal of 1 to 2 cm at a time. Poor wedging can be due to patient movement, mechanical ventilation, positive end-expiratory pressure (PEEP), and eccentric balloon inflation.¹⁸ Catheter position should be checked routinely by overpenetrated chest x-rays.¹⁸ To minimize the risk of endothelial damage to the PA, PA rupture, or pulmonary infarction, wedge time should be kept to a maximum of about 8 to 15 seconds.¹⁸ End-expiration diastolic pulmonary pressures should approximate mean wedge pressure in the absence of increased pulmonary arteriolar resistance, such as with pulmonary hypertension or pulmonary embolus.¹⁸

The pressure recorded through a wedged end-hole catheter is that of the next vascular system, which in most circumstances reflects the left atrium (LA) or left ventricular (LV) end-diastolic

pressure. This assumes that the vascular system distal to the catheter tip provides a direct connection to the LA without any anatomic or functional interruption. The ideal placement of the catheter is the lower lung zone. In zone 3, the most dependent portion, both pulmonary artery and venous pressures exceed alveolar pressure thereby maintaining an open vascular system from the catheter tip to the LA.¹⁸ In the upper lung, or zone 1, alveolar pressure exceeds pulmonary artery and venous pressures, keeping the capillaries closed and therefore disrupting the system preventing accurate measurement of LA pressures. The arterial pressures in the central lung, or zone 2, should exceed alveolar pressure, but low pulmonary venous pressure may prevent retrograde transmission of pressures to assessment of the LA. Fortunately, most of the lung in the supine position is in zone 3 and flow-guided catheters will usually enter this zone. A lateral chest x-ray can confirm position of the catheter tip below the LA.

Pulmonary Artery Occluded and Wedge Pressure

Pulmonary capillary pressure is a phase-delayed, amplitude-damped version of LA pressure. During diastole with a nonstenotic mitral valve, the pulmonary venous system, LA, and LV is a continuous circuit and the pulmonary capillary pressure is then reflective of the LV diastolic pressure.¹⁵ The level of pulmonary capillary wedge pressure is important for two reasons. First it provides the measure of hydrostatic pressure that is responsible for forcing fluid out of the pulmonary vascular space. Additionally, the capillary pressure is directly related to diastolic fiber stretch according to Starling's principle, which states that the strength of contraction is proportional to myocardial fiber length/left ventricular volume.¹⁵ When applied to construct a cardiac function curve, it is often termed left ventricular filling pressure.

The pulmonary artery occluded pressure (PAOP) is obtained after inflating the distal balloon of the PAC in a large branch of the PA (about 10 mm in size). A static column of fluid is created between the site of occlusion and where the venous flow resumes as other venous branches connect down stream.⁷

As downstream pulmonary flow decreases, the PA pressure decreases to a minimal value reflecting that pressure.⁶ The compliance of the vasculature relative to the catheter causes a slight dampening of the pressure signal. Therefore PAOP pressures are lower than PA diastolic pressure with dampened waveforms.⁶ The wedge pressure is obtained when a catheter tip engages a small PA vessel (less than 2 mm) as opposed to an occlusion pressure obtained from balloon inflation in a medium to large vessel. The anatomic territory affected by the wedge is smaller than that affected by the occlusion pressure therefore subjecting each to varying forces that generate a pressure. The term occluded pressure is preferred to wedge.¹

The natural oscillation in intrathoracic pressure associated with respiration directly affects intraluminal pulmonary vascular pressure. During spontaneous breathing, end-expiration occurs at the highest vascular pressure values. This is the opposite of mechanical positive pressure ventilation where end-expiration occurs at the lowest pulmonary vascular pressures.⁶ To minimize this artifact, recorded pressures should be made at end-expiration. Even in the setting of end-expiration, with a direct intact fluid column from the catheter tip to the venous system, PAOP measures can still be overestimated if pleural pressures are elevated at end-expiration. Factors such as hyperinflation, air trapping, and PEEP in relation to lung and chest wall compliance increases pleural pressure to varying degrees.⁶ Normal pulmonary vascular resistance (PVR) ranges from 150 to 250 sec/cm⁵. If pulmonary hypertension is associated with increased PVR, then causes are primarily within the lung, such as pulmonary embolism, pulmonary fibrosis, essential pulmonary hypertension, and pulmonary veno-occlusive disease. Normal PVR in the setting of pulmonary hypertension is more indicative of LV failure.

Cardiac Output and Mixed Venous O₂ Consumption

Though cardiac output (CO) can be measured by several techniques, the two most commonly used are the indicator thermodilution technique and the Fick oxygen technique. Both are based on the theoretical principle devised by Adolf Fick in 1870, which states that the total uptake or release of any substance by an organ is the product of blood flow to the organ and the arterio-venous (AV) concentration difference of the substance.²⁰ The clinical marker commonly used is oxygen and the difference between arterial and venous oxygen content is the uptake of oxygen as it flows through the lungs.²⁰

The Indicator Dilution Method

Stewart was the first to use this method to determine cardiac output in 1897.²¹ There have been a number of indicators used in the past, but the most commonly used today is the “cold” indicator in the thermodilution (TD) method. This technique applies this principle to the change in the temperature of blood caused by introduction of a known quantity of heat upstream from a point of temperature measurement.²⁰ Typically cold saline is injected into the right atrium. This results in cooling of the blood that is measured downstream by a thermistor to produce a thermodilution curve. The area under the curve represents the integral of the instantaneous mixing temperature at the sensing point²⁰ (Fig. 45-2). Cardiac output is automatically computed from these measurements using a small microprocessor device.

Figure 45-2. Sample thermodilution curve shows the change in instantaneous mixed temperature at the sensing point (thermistor) versus time. (Adapted from Ehlers KC, Mylrea KC, Waterston CK, et al: *Cardiac output measurements: a review of current techniques and research.* *Ann Biomed Eng* 1986;14:219-239.)

Accurate calculation of CO by TD assumes that the injectate mixes completely with the blood and its concentration can be measured correctly. Though Felger described the TD method in 1954, it gained wide clinical use only after Swan and Ganz developed a multilumen PAC with a distal thermistor.²⁰

The validity of results depends on the precision of the technique. The injection technique should be smooth and rapid to avoid dispersion of the injectate. Multiple measures should be taken and averaged to avoid ventilatory cycle specific patterns.⁶ The presence of significant tricuspid regurgitation can introduce error into the calculation and overestimate the cardiac output. In a patient with a left-to-right intracardiac shunt, measurement of the right ventricular CO would not reflect LV function. CO measurements via the TD method show good correlation with the Fick method for CO in the range of 3 to 6 L/min.^{22,23} In the case of low flow states, loss of indicator may occur because of warming of the blood by the walls of cardiac chambers. Grondelle and colleagues noted TD measurement overestimated CO consistently in patients with CO less than 3.5 L/min (with the greatest discrepancy in patients with CO <2.5 L/min).^{22,24} A modification of the standard TD method now allows for continuous CO monitoring. The flow-guided catheter was modified with placement of a blood-warming filament on the catheter at the region of the catheter injectate port. The catheter filament delivers heat to the flowing blood with a random on/off sequence that is continuously repeated with approximate total heating time of about 50%. Cardiac output is derived from the reconstructed washout curve using an equation analogous to the Stewart-Hamilton equation used for solution-based flow measurements.¹⁷ This advancement simplifies the assessment of CO at the bedside, eliminating the need for accurate repeated injection of solution.

Fick Method

In the Fick method of CO measurement, pulmonary blood flow is determined by measuring the AV difference of oxygen across the lungs and the rate of uptake by blood across the lungs.

If there are no intracardiac shunts, pulmonary and systemic blood flow should be equal and the CO equals oxygen consumption divided by AV oxygen difference.⁹

$$\text{CO (vol/time)} = \frac{\text{O}_2 \text{ consumption (mass/time)}}{[\text{arterial} - \text{venous O}_2 \text{ content}] (\text{mass/vol})}$$

The oxygen consumption $\dot{V}\text{O}_2$ can be either directly measured or calculated. Direct measurement is preformed with exhaled breath analysis using a spirometer, such as the metabolic rate meter (MRM) or the Deltatrac II.⁹ In a steady state, oxygen consumption can be determined by having the patient breathe pure O₂ from the spirometer with a CO₂ absorber and measuring O₂ uptake directly by the net gas flux.²⁰ Normal oxygen consumption in a resting individual is approximately 250 mL O₂/min. Calculation of the $\dot{V}\text{O}_2$ can be done with rearranging the Fick equation:

$\dot{V}\text{O}_2$ (mL O₂/min) = CO × (Cao₂ – CVO₂), where Cao₂ is the arterial oxygen content and CVO₂ is the mixed venous blood content. Normal Cao₂ and CVO₂ are 20 mL O₂/dL and 15 mL O₂/dL, respectively.

Oxygen consumption can also be estimated using from a nomogram based on age, sex, height, and weight. The AV difference is calculated by obtaining blood from a peripheral artery and the pulmonary artery for a mixed venous sample. The oxygen saturation is then multiplied by theoretical oxygen carrying capacity to yield the oxygen content of the sample (Fig. 45-3).

Mixed venous oxygen saturation (SVO₂) reflects the relationship between oxygen consumption ($\dot{V}\text{O}_2$) and oxygen delivery (DO₂).

$$\text{SVO}_2 = \frac{\text{oxygen delivered (SaO}_2 \times \text{Hb} \times \text{CO})}{\text{oxygen consumed } (\dot{V}\text{O}_2)}$$

It should be measured from blood drawn from the distal tip of the PAC to allow for adequate mixing of superior vena cava, inferior vena cava, and coronary sinus samples. The normal range of SVO₂ is 60% to 80%. If the SVO₂ is normal, one can assume that tissue perfusion is adequate, whereas high or

low values reflect an imbalance between oxygen supply and demand. A low SVO₂ reflects either decreased oxygen delivery (i.e., decreased Hb, SaO₂, or cardiac output) or increased oxygen demand. Conversely, high SVO₂ reflects increased oxygen delivery or decreased oxygen demand such as in the case of sepsis.

Complications

As with any invasive procedure, complications are an inherent risk of pulmonary artery catheterization. Multiple observational and randomized studies have investigated the incidence and significance of adverse events related to PAC use. Complications have been associated with catheter insertion (pneumothorax, arrhythmia, atrioventricular block) and those associated with the catheter once in place (pulmonary infarction, local thrombosis, pulmonary artery rupture, catheter-related infection).

Arrhythmias and Atrioventricular Block

Though ventricular and atrial ectopy is not uncommon, sustained ventricular arrhythmia is rare. Ventricular tachycardia has been reported in 12% to 68% of patients undergoing PA catheterization.^{25,26} Most episodes resolve with catheter movement and seldom require treatment. PAC-related arrhythmia does not appear to influence patient outcome.

In patients with pre-existing left bundle branch block (LBBB), the insertion of a PA catheter may be associated with the development of concomitant right bundle branch block (RBBB), thereby resulting in complete heart block. However, Sprung and co-workers studied 293 patients undergoing 307 PAC insertions and found a 3% incidence of new RBBB. They found no difference in the incidence of complete heart block in patients with pre-existing LBBB and development of RBBB in those with no underlying conduction disease.²⁷ Though prophylactic pacemaker placement is not indicated, the use of catheters that provide for ventricular pacing is advisable in patients with pre-existing LBBB.

Pulmonary Vascular Damage

Pulmonary artery infarctions appear to range in incidence in earlier studies from 7.2%²⁸ to 1.3% in later studies.^{29,30} These may occur as a result of either damage to the pulmonary endothelium, emboli originating from the catheter shaft, or placement of the catheter in the distal PA. Infarct can be avoided by minimizing the time the catheter is in the distal PA and by preventing migration of the tip into the distal pulmonary vessel.¹ These small, segmental infarcts usually resolve within 48 hours and though undesirable, appear to be of limited clinical significance.

PA rupture, though rare, is the most serious complication associated with PA catheter use. Pulmonary artery rupture has been reported in up to 0.2% of patients undergoing catheter insertion.^{29,31-33} In a retrospective chart review of more than 32,000 patients with PA catheters in a single institution over 17 years, Kearney reported 10 patients with PA rupture (Rate: 0.031%) with 70% mortality. All 10 patients developed hemoptysis and 5 had pulmonary hypertension.³² Risk factors for PA rupture include advanced age, pulmonary hypertension, and cardiopulmonary bypass surgery.^{1,34} Inflation of the balloon in a peripheral diseased pulmonary vessel may produce the force necessary to cause rupture; however, even a deflated catheter tip in the wedge position can cause arterial erosions.¹ The clinician must be careful to limit the length of time the catheter is in a peripheral artery, inflate the balloon only when the catheter

Step 1. Theoretic oxygen-carrying capacity: Hemoglobin (g/dL) × 1.36 (ml of O ₂ /g of Hb) × 10 = _____ ml O ₂ /L blood

Ao, aorta; BA, brachial artery; PA, pulmonary artery. (Adapted from Baim DS [ed]: *Grossman's Cardiac Catheterization, Angiography, and Intervention*, 7th ed. Philadelphia, Lippincott Williams & Wilkins, 2006, p 154.)

position is known, and to confirm a safe “parking spot” of the deflated catheter in the main PA or proximally in the right or left branches.¹ A PA catheter that allows for surveillance of appropriate position by monitoring RV pressure via a middle lumen located 10 cm from the distal tip is available.³⁵ Recording a ventricular pressure tracing from this lumen ensures that the catheter is in the appropriate position.

Infection

Strict sterile technique is paramount with any invasive procedure. The incidence of catheter-related infection ranges from 0.5% to 2%.^{29,36} A recent randomized control study on PAC use in 433 patients found catheter-related infection to be the most common adverse outcome with a incidence of 1.9%.³⁷ Mermel and colleagues prospectively examined 297 PAC cases for infection and found a 22% incidence of local infection of the introducer sheath with only a 0.7% incidence of bacteremia.³⁸ The patient's skin was noted to be the single most important source for infection. Most investigators agree that the risk of catheter-related sepsis increases when a catheter is left in place for greater than 72 hours.^{29,36,38}

Thrombosis

A thin fibrin coating will usually envelope PA catheters within 24 hours of insertion.¹ In an autopsy series of 32 patients with PAC, thrombosis was identified in 53% and intimal fibrin deposition was identified in 66% of patients along the entire length of the PA catheter.³⁹ The incidence of thrombosis was significantly higher in cases where the catheter was left in place for more than 36 hours. A review by Ducatman found no difference in the incidence of pulmonary emboli in those with and without thrombi.⁴⁰ Though these thrombi can possibly embolize or become infected, the incidence and clinical significance appears to be low.

PAC use in the CICU and its complication profile is similar to the procedure performed at other locations; however, there are some important caveats. For instance, the use of anticoagulation such as antiplatelet and antithrombin therapy in the setting of acute coronary syndromes increases the propensity for bleeding and hematoma formation. In addition, the majority of these patients are already at increased risk for morbidity and mortality due to their underlying conditions. The overall morbidity of PAC use should not exceed 2% to 5%. Swan estimated the added mortality risk in the CICU environment to be less than 0.25%.¹

Indications for Pulmonary Artery Catheterization

Hemodynamic data derived from PACs may aid in diagnosis and guide management. The clinical use of invasive hemodynamic monitoring has changed and defined the modern practice of critical cardiac care. Despite the widespread use of PACs the effect on patient outcome remains controversial. The accepted indications for PA catheterization have been based largely on expert opinion.⁴¹ The decision to place a PAC should be based on a clinical question regarding a patient's hemodynamic status that cannot be answered with noninvasive assessment. There needs to be the intent to act on the information gathered by invasive hemodynamic monitoring to justify PAC placement.

In general, patients requiring invasive monitoring include those with homodynamic compromise, including circulatory collapse, cardiogenic shock, and severe heart failure. Right ventricular infarct, ventricular septal rupture, and cardiac tamponade are currently more appropriately diagnosed with echocardiography.

Table 45–4. When Hemodynamic Monitoring May Be Used

In patients with myocardial infarction complicated by:
Severe heart failure
Low output syndrome
Shock
Mechanical lesions
Mitral regurgitation
Ventricular septal rupture
Subacute cardiac rupture with tamponade
Recurrent, severe postinfarction ischemia
In critically ill patients with multiorgan dysfunction such as:
Severe respiratory dysfunction
Severe renal dysfunction
Extensive burns
Extensive trauma
Severe sepsis
Massive pulmonary embolism
Suspected cardiac tamponade
Persistent low cardiac output syndrome
Shock
Cardiogenic or noncardiogenic pulmonary edema
Gastrointestinal hemorrhage
Pancreatitis
Drug overdose
Adult respiratory distress syndrome
In high-risk cardiac patients before, during, and after any surgical procedure
In high-risk obstetric patients who have
Known cardiac disease
Toxemia
Suspected abruptio placenta
In patients with unstable angina, left ventricular dysfunction, or hemodynamic instability if intravenous nitroglycerin or other vasoactive drugs are required
In patients with chronic heart failure to:
Assess ventricular function at rest, during exercise, and in response to therapeutic intervention
Distinguish a specific cause of heart failure, such as constrictive pericarditis
Restrictive cardiomyopathy
Precapillary pulmonary hypertension
A research tool for clinical investigation

Table 45-4 outlines potential indications for invasive hemodynamic monitoring with PA catheterization.

Clinical Applications

Pulmonary Edema

At times, diagnosis of the etiology of pulmonary edema through radiographic and clinical means may be difficult.⁴² Often these patients are critically ill, have severe blood gas abnormalities, and have radiographic evidence of generalized interstitial and alveolar infiltrates. In noncardiogenic pulmonary edema, the PCWP would be normal. This distinction is critical for the appropriate choice of therapy (i.e., diuretics and vasodilators in cardiogenic pulmonary edema versus supportive care in the case of adult respiratory distress syndrome). Often for patients in shock, a therapeutic trial of volume expansion may be indicated. PAC is indicated in these patients when these initial strategies may be contraindicated, have failed, or when there are coexisting features of cardiac and noncardiac etiologies making therapeutic decision making difficult. Following the diagnosis, PA catheterization may be helpful in effectively titrating doses of diuretics, vasodilators, inotropes, and vasopressors.

Pericardial Tamponade

Pericardial tamponade is a clinical diagnosis (distant heart sounds, pulsus paradoxus, and hypotension) best made by echocardiography. When echocardiography is unavailable or technically suboptimal, PAC can provide support for the diagnosis.

The low ventricular volume during systole creates a dominant x descent on the RA tracing. The y descent is attenuated or absent. During inspiration, the mean RA pressure declines allowing one to distinguish tamponade from constriction and right ventricular (RV) infarction where there is equalization of RA and wedge pressure⁴³ (Fig. 45-4). Therapeutic intervention should never be delayed in unstable patients to await a right heart catheterization.

Severe Heart Failure

Invasive hemodynamic measurements may be useful for effectively treating some episodes of severe acute decompensation of chronic heart failure by allowing more precise adjustments of therapy, including diuretics, vasopressors, vasodilators, and inotropes⁴⁴ based upon real time assessment of hemodynamics. Stevenson and colleagues outlined a concept of "tailored therapy" for advanced heart failure in 152 patients awaiting heart transplant that included use of nitroprusside, furosemide, and oral vasodilators with target PAOP and SVR. They demonstrated a correlation between mortality and failure to improve PAOP during therapy.⁴⁵

Acute Myocardial Infarction

The routine use of a PAC in the setting of uncomplicated acute myocardial infarction has never been the practice. A prospective study by Gore observed PAC use in acute MI over the 70s and 80s in hospitals in Worcester, Mass. More than 96% of the instances of PAC use were in the setting of congestive heart

Figure 45-4. Right atrial (RA) and aortic pressure tracings from a patient with pericardial tamponade. Aortic pressure declines by 20 mm Hg during inspiration (pulsus paradoxus). RA pressure declines normally during inspiration. A dominant x descent can be seen. (Adapted from Sharkey SW: *Beyond the wedge: clinical physiology and the Swan-Ganz catheter*. *Am J Med* 1987;83:118.)

failure (CHF), hypotension, and cardiogenic shock.⁴⁶ A retrospective analysis of two large randomized acute coronary syndrome trials looking at PAC use found an overall use of 2.8%. Those undergoing PAC insertion were more likely to have ST elevation MI and advanced Killip classification (III and IV).⁴⁷ As per the current American College of Cardiology/American Heart Association (ACC/AHA) guidelines, indications for PAC are related to specific complications of myocardial infarction including (1) hypotension, low cardiac output, and cardiogenic shock due to LV failure; (2) acute mechanical complications (MR from papillary muscle rupture/ischemia, ventricular septal defect (VSD), or ventricular free wall rupture; (3) complicated right ventricular infarction; and (4) heart failure or pulmonary edema refractory to usual management.⁴¹

Shock/Low Cardiac Output

Diminished cardiac output is typically the result of several mechanisms but most often due to decreased contractility as a result of infarct, ischemia, or arrhythmia. Mechanical causes such as mitral insufficiency and ventricular septal defect, though less frequent, are not uncommon causes of low cardiac output states.¹⁵ PAC is recommended in the setting of shock to confirm hemodynamic criteria and assess filling pressures to distinguish cardiogenic from other causes of shock including hypovolemia. Patients that exhibit progressive hemodynamic deterioration with cardiac indices less than 1.8 L/min/m², elevated PA pressure, and PCWP above 25 mm Hg, may require mechanical ventilation, afterload reduction, heart rate control, and various vasoactive medications and devices. CO measurements can be followed to assess the response to therapy.¹ An analysis of the The SHould we emergently revascularize Occluded Coronaries for cardiogenic shock (SHOCK) registry of patients with acute myocardial infarction complicated by cardiogenic shock found overall use of PA catheters in 66% of patients. However, there

was a significant decrease in use from the early to late 1990s.⁴⁸ Though there is no data that proves a survival benefit in cardiogenic shock patients associated with the use of PAC, most studies have been limited by selection bias that precludes clear conclusions.^{46,49}

Mitral Regurgitation Due to Papillary Muscle Rupture

Though acute mitral regurgitation (MR) can be accurately diagnosed by echocardiography, severe mitral regurgitation associated with papillary muscle rupture is an indication for prompt right and left heart catheterization and Cardiac surgery evaluation for possible valve replacement. The ejection of blood into a normal-sized, noncompliant left atrium causes a giant *v* wave on the wedge pressure tracing. The giant V wave is transmitted to the PA tracing yielding a bifid PA waveform composed of a pulmonary systolic wave and V wave⁴³ (Fig. 45-5). Inflation of the balloon obliterates the systolic wave as the catheter is wedged but the V wave remains. Careful attention needs to be paid to avoid mistaking the wedge and PA tracing in these patients. The systolic wave in the PA tracing occurs earlier in QRS cycle than does the V wave. Prominent V waves are not specific to acute MR but can also be seen with dilated or ischemic heart disease where a noncompliant LA experiences increased blood flow such as in acute ventricular septal rupture. Bedside PAC may help guide vasodilator and inotropic therapy in acute MR.

Ventricular Septal Defect

Echocardiography is highly sensitive and specific for the diagnosis of ventricular septal defect and can provide quantitative measures regarding the magnitude of the shunt, pulmonary artery pressures, and right ventricular function.⁴¹ Though not typically required, PAC can be helpful if echocardiography is unavailable or suboptimal in evaluating the magnitude of the shunt. Clinical differentiation of acute MR and VSD can be difficult. PAC would be

Figure 45-5. Arterial, pulmonary artery (PA), and wedge pressure waveforms in a patient with acute mitral regurgitation. A prominent V wave is present in pulmonary artery and wedge tracings. The bifid PA waveform reflects the systolic (S) and V wave. The double arrow denotes inflation of the balloon and wedging, which obliterates the S wave. (Adapted from Sharkey SW: *Beyond the wedge: clinical physiology and the Swan-Ganz catheter*. *Am J Med* 1987;83:115.)

helpful in distinguishing VSD from acute MR if echocardiography is unavailable. Rupture of the septum causes acute volume overload into the right ventricle with increased pulmonary to systemic blood flow ratio greater than 2:1.⁴³ The diagnosis is confirmed with the presence of a step up in oxygen saturation of greater than 10% between the right atrium and pulmonary artery.⁹

Right Ventricular Infarction

Right ventricular infarction complicates acute inferior wall MI in up to 30% of cases.⁴³ The characteristic hemodynamic profile of acute RV dysfunction includes RA pressure disproportionately increased relative to wedge pressure; a steep y descent and RV pressure tracing that may show a diastolic dip and plateau referred to as the square root sign¹⁸ (Fig. 45-6). Though a prominent x and y descent are typical, the y descent may exceed the x descent because of the presence of a dilated noncompliant RV that is confined by the pericardium.⁴³ During inspiration, the RA pressure may increase response known as Kussmaul's sign.⁴³ Tricuspid insufficiency due to papillary muscle dysfunction and RV dilation may complicate RV infarction.⁴³ These findings may be detected in only about 50% of patients with acute RV dysfunction. Volume loading may be necessary to unmask these hemodynamic abnormalities.¹⁸

Constrictive Pericarditis

As in tamponade, constrictive pericarditis produces diastolic pressure equalization with elevated right- and left-sided filling pressures. However, unlike tamponade, constriction displays an early diastolic dip followed by a pressure plateau in both right and left ventricular pressure tracings.¹⁸ The RA tracing displays the characteristic M or W shape with a preserved x descent and a prominent early y descent (Fig. 45-7).

Restrictive Cardiomyopathy

The hemodynamic profiles of restrictive and constrictive pericarditis do mirror each other. Though both display the characteristic M or W shaped RA pressure tracing and diastolic dip and plateau, a differentiation of these two can be made. The left-sided filling pressure tends to be higher than the right-sided pressures in patients with restriction. Also the diastolic pressure plateau is usually less than one third the RV systolic pressure in restrictive cardiomyopathy.¹⁸

Controversies

The PAC has become a widely used monitoring device in critically ill patients since its introduction in 1971. Its initial use, however, was not supported by clinical trials, but instead benefit was assumed. Retrospective analyses from the 1980s^{46,49} studying PAC use in acute myocardial infarction, found no difference in mortality after adjusting for severity of illness. This prompted more interest in the potential benefit or harm of PAC use. In 1996, a retrospective observational study of more than 5500 cardiac and noncardiac critically ill patients concluded that, after adjustment for treatment selection bias, the PAC was associated with increased mortality and increased length of stay.⁵⁰ An accompanying editorial proposed a moratorium on RHC use.⁵¹ This prompted a response by multiple organizations including the ACC/AHA who issued a consensus statement. The ACC concluded that, despite attempts to account for selection bias by the authors, flaws existed. Patients with lack of response to initial therapy were more likely to undergo PAC placement. In addition patients with PACs in place were more likely to enter the study with multiorgan failure, respiratory failure, and congestive heart failure—all factors associated with higher mortality. These criticisms did not discount the possibility that PAC use may be associated with detrimental outcomes, but instead highlighted the need for further trials, randomized if possible. However, the consensus committee also cautioned that even data from randomized trials may not resolve the issue because of the difficulty in controlling for the effects of therapies administered and to accommodate the large numbers of patients necessary to be enrolled.⁴¹

In 2005, two large multicenter randomized trials were published examining the effectiveness of PAC in management of critically ill patients. The first reported on more than 1000 critically ill patients enrolled between 2001 and 2004. Patients were randomized to PAC insertion or no PAC use. The authors found no statistical difference in hospital mortality between the groups (68% versus 66%, $p = 0.39$, adjusted hazard ratio 1.09 (0.94–1.27)).⁵² It also found that the less than 10% complication rate did not directly lead to any increase in mortality. Later that year, the second trial was published. Patients admitted with severe symptomatic and recurrent heart failure from 2000 to 2003 were randomized to PAC or no PAC insertion. The authors found that therapy in both groups lead to substantial reduction in

Figure 45-6. **A**, Right atrial (RA) pressure waveform in a patient with right ventricular infarction. Note the steep x and y descents. **B**, The inspiratory increase of RA pressure in right ventricular infarction is known as Kussmaul sign. Figure 45-7. **A**, Simultaneous right ventricular (RV) and left ventricular (LV) tracings show equalization of end-diastolic pressures along with the “square root sign” (i.e., early diastolic dip and late diastolic plateau). **B**, Kussmaul sign—the inspiratory increase in right atrial pressure.

symptoms, jugular venous pressure, and edema. The use of PAC did not significantly affect the primary end point of 6-month mortality.³⁷ Therefore basing the decision to administer vasodilator and diuretic therapy on PAC data plus clinical judgment was not superior to decisions based on clinical judgment alone.³⁷ The authors did note there was a trend toward better outcomes using PAC-guided therapy in centers with large numbers of patients. Ultimately the data from both trials found PAC use to be safe and did not substantiate previous retrospective reports of excessive mortality associated with PAC use.

Safe and effective PAC use should be predicated on careful catheter placement, attention to measurement techniques, and thoughtful interpretation of data. Iberti and colleagues published a multicenter evaluation of physician knowledge of PAC use in 1990.⁵³ The authors used a 31-question multiple-choice examination of 496 physicians to assess physician understanding of PAC use. They found a mean test score of 67% correct with a standard deviation 5.4. Mean scores varied independently by training and with the frequency and use of PAC in clinical practice.

Every physician who performs hemodynamic monitoring should understand the indication for the procedure, be technically competent with insertion techniques, and have the ability to interpret data obtained⁵⁴ (see [Table 45-5](#)).

Table 45-5. Technical Skills Needed to Perform Hemodynamic Monitoring*

1. Ability to perform venous access from two (or multiple) sites with the percutaneous technique. Ability to do cutdowns is also desirable.
2. Ability to perform arterial access (primarily radial artery puncture), although the ability to do arterial cutdown is desirable.
3. Ability to operate all instrumentation involved in hemodynamic monitoring, including catheters, introducers, strain gauges and recorders and to perform calibration, balancing, and zeroing techniques
4. Knowledge and ability to correct (“trouble shoot”) common artifacts and technical problems with recording instrumentation and catheter/tubings

Intra-Aortic Balloon Pump Counterpulsation

Nehal D. Patel, Luis Gruberg

CHAPTER 46

Physiologic Principles
Monitoring of IABP Counterpulsation
Contraindications to the Use of IABP Counterpulsation
Insertion, Removal, Maintenance, and Complications

Cardiogenic Shock
High-Risk Percutaneous Coronary Intervention
Cardiac Surgery
Transplantation and Dysrhythmias
Conclusion

INTRA-AORTIC BALLOON PUMP (IABP) counterpulsation has emerged as one of the most effective and most frequently employed methods of mechanical circulatory support. Specifically, it relies on the twin concept of diastolic augmentation and afterload reduction to facilitate the functioning of an ischemic and failing myocardium. This concept was originally proposed by Mouloupoulos and associates in 1962; subsequently, they documented improvement in hemodynamic parameters in experimental animal models.¹ The first clinical report of human use by Adrian Kantrowitz appeared 6 years later.² During the last 4 decades, IABP has experienced a technological evolution. With the advent of a percutaneous approach to insertion, the device has been used in an expanding array of clinical settings: managing cardiogenic shock; treating persistent and intractable angina; during weaning from cardiopulmonary bypass; during thrombolytic therapy in patients at high risk for occlusive rethrombosis; during complex and high-risk coronary angioplasty; and in the setting of severe stenosis of the left main coronary arterial trunk or critical aortic stenosis before surgical intervention.³ Due to its widespread usage, practitioners in the critical care setting need to be familiar with the fundamental principles of IABP counterpulsation therapy to effectively manage cardiac patients. As evidence of its prevalent usage, one report estimates that more than 70,000 IABP devices are annually placed in the United States.⁴

Physiologic Principles

The IABP has two main hemodynamic effects: during the diastolic phase of the cardiac cycle, a volume of blood is displaced to the proximal aorta following inflation; during the systolic phase, a vacuum effect is created in the proximal aorta following rapid deflation, thereby reducing the afterload experienced by the contracting left ventricle. To optimize these two hemodynamic effects, the IABP must inflate and deflate in synchrony to a patient's cardiac cycle. Since 1970, observations have revealed that the single most important determinant of effective balloon-assisted circulation is the balloon pump's timing to the cardiac cycle.⁵ Once proper timing has been established, an IABP will achieve three goals: an improvement in myocardial oxygen delivery via an increase in coronary perfusion pressure;

a reduction in cardiac work by a decrease in systolic blood pressure (afterload); finally, an improvement in forward blood flow in patients with impaired cardiac contractile function.⁶ Following technological advancements during the past three decades, modern intra-aortic balloon pumps now use a closed-loop control system to automatically optimize pump timing.⁷⁻¹¹

The principal objective of balloon counterpulsation is to enhance the balance between myocardial oxygen consumption and supply. Several factors affect the achievement of a favorable balance: the volume of the balloon; its position in the aorta; the underlying heart rate and rhythm; the compliance of the aorta; lastly, the systemic vascular resistance.¹² For instance, an increase in arterial elastance (a property which is affected by compliance) is associated with a greater degree of hemodynamic improvement from an IABP.¹³ Despite the presence of multiple factors that can cause variability in the effects of an IABP, a majority of patients do exhibit a specific hemodynamic profile in the setting of cardiogenic shock (Table 46-1).

Table 46-1. Effect of Intra-aortic Counterpulsation on Hemodynamic Parameters

Hemodynamic Parameter	Effect
Aortic systolic pressure	Decrease
Aortic diastolic pressure	Increase
Mean aortic pressure	Increase
Left ventricular afterload	Decrease
Mean pulmonary capillary wedge pressure	Decrease
Cardiac output	Increase
Left ventricular ejection fraction	Increase
Diastolic pressure-time index (DPTI)	Increase
Tension-time index (TTI)	Decrease
Endocardial viability ratio (DPTI/TTI)	Increase

Data abstracted from Scheidt S, Wilner G, Mueller H, et al: Intraaortic balloon counterpulsation in cardiogenic shock. *N Engl J Med* 1973;288:979.

This profile includes the following parameters: a decrease in systolic pressure by 20%; an increase in diastolic pressure by 30%, which may subsequently enhance coronary blood flow to a territory perfused by an artery with a critical stenosis; a reduction of heart rate by less than 20%; a decrease in the mean pulmonary capillary wedge pressure by 20%; and an elevation in the cardiac output by 20%.¹⁴ The reduction in aortic pressure, which is caused by the rapid deflation of the balloon, effectively decreases left ventricular afterload, and consequently diminishes myocardial workload.⁶ Afterload (pressure work) is significantly more costly in terms of myocardial oxygen consumption than cardiac output (volume work).¹⁵ In fact, many authorities in this field maintain that afterload reduction is the most beneficial aspect of balloon counterpulsation on a failing left ventricle.^{16,17} Two indices that are measured during IABP counterpulsation include the tension-time index (TTI), which is the time integral of left ventricular pressures during systole, and the diastolic pressure-time index (DPTI), which is the time integral of the proximal aortic pressures during diastole. Proper balloon inflation augments diastolic pressure (i.e., increases DPTI) whereas rapid balloon deflation decreases left ventricular afterload (i.e., decreases TTI). A ratio can be constructed from these two indices (DPTI:TTI ratio); this ratio has been termed the endocardial-viability ratio and illustrates the relationship between myocardial oxygen supply and demand. With IABP counterpulsation optimally synchronized to a patient's cardiac cycle, the endocardial-viability ratio will be increased.^{6,18}

Monitoring of IABP Counterpulsation

The appropriate timing of balloon counterpulsation to the mechanical events of the cardiac cycle is crucial to deriving optimal hemodynamic benefits (Fig. 46-1). To maximize diastolic augmentation, the balloon should inflate at end-systole, immediately after closure of the aortic valve. Balloon inflation augments coronary perfusion pressure, thereby providing greater myocardial oxygen delivery. Mean diastolic pressure (MDP) correlates well with coronary perfusion and hence oxygen delivery.⁶ Smith and colleagues confirmed the proposal that maximal coronary perfusion occurs when balloon inflation coincides with end-systole.^{9,19} The timing of balloon deflation, which best decreases left ventricular oxygen consumption, is less well defined. Deflation before the ventricular ejection of blood unequivocally creates a vacuum effect in the proximal aorta, which in turn reduces afterload and peak systolic pressure. The resultant net decrease in oxygen consumption is difficult to quantitate. However, peak systolic pressure is directly related to ventricular wall stress; a decrease in the latter parameter is associated with a reduction in myocardial oxygen consumption.⁶

The triggering of balloon counterpulsation requires the existence of a predictable, reproducible, and reliable event. The trigger marks a time point in which balloon inflation and deflation are planned. In most cases, the R wave of the surface ECG serves as the triggering event. The more sophisticated IABP systems do offer other triggering capabilities, such as arterial pressure waveforms, and ventricular or atrioventricular pacer spikes. The IABP can also function in an asynchronous pumping mode with a trigger rate set by the operator. Such a mode can be employed during cardiopulmonary resuscitation.⁶

Loss of optimal hemodynamic effect occurs when balloon counterpulsation is not appropriately timed to the mechanical

events of a patient's cardiac cycle. Mahaffey and colleagues have provided lucid descriptions of four different scenarios involving faulty coupling of balloon counterpulsation with the cardiac cycle.²⁰

During late inflation, the dirotic notch on the aortic pressure waveform is clearly visualized. The balloon inflates well beyond closure of the aortic valve. In this scenario, diastolic augmentation of central aortic pressure is decreased, whereas ventricular afterload is minimally affected. The classic morphologic finding on the central aortic pressure tracing is the presence of a distinct dirotic notch with the augmented diastolic pressure wave occurring well afterward. To correct late inflation of the intra-aortic balloon pump, the timing interval should be gradually decreased until the onset of inflation coincides with the dirotic notch on the arterial pressure waveform.

During early inflation, the balloon inflates before closure of the aortic valve. Pressure augmentation is thus superimposed upon the systolic aortic pressure tracing thereby leading to the following hemodynamic effects: a decrease in left ventricular emptying (a decrease in stroke volume); a decrease in cardiac output; an increase in left ventricular afterload; an overall increase in myocardial oxygen consumption. In this scenario, there is loss of the distinct systolic peak of the central aortic pressure waveform and loss of the dicrotic notch. To correct early inflation, the timing interval should be slowly increased until the onset of inflation occurs at the dicrotic notch.

The two previously described scenarios dealt with inappropriate timing of balloon inflation. However, the following two scenarios involve faulty timing of balloon deflation.²⁰

During late deflation, the balloon is deflated after the onset of systole and the opening of the aortic valve. The resultant hemodynamic profile is similar to the one observed with early inflation: afterload is increased, thereby leading to increased left ventricular work and myocardial oxygen consumption along

Figure 46-1. Optimal timing of an intra-aortic balloon pump. Arterial pressure tracing from a patient with an intra-aortic balloon pump. The balloon was set at 2:1 to evaluate timing. Inflation (INF) was timed to the dicrotic notch to follow aortic valve closure. There is augmentation of diastolic pressure (ADP) and reduction of the end-diastolic pressure with augmented beats (AEDP) compared with the unaugmented end-diastolic pressure (UEDP). The augmented systolic pressure (ASP) is often lower than the unaugmented systolic pressure (USP) as well. (*Adapted from Holleney S, Saltzberg M, Soble J, Parrillo J. Heart Failure and Cardiomyopathy. In Crawford MH, Dimarco JP, Paulus WJ (eds): Cardiology. London, Mosby, 2001.*)

with reduced stroke volume and cardiac output. Analysis of the arterial pressure tracing usually reveals the loss of a distinct valley representing the end-diastolic pressure before the central aortic systolic wave. To correct late deflation, the timing interval should be decreased gradually until the balloon deflates before the onset of cardiac systole.

During early deflation, the balloon deflates prematurely and consequently the benefits of diastolic augmentation disappear. Analysis of the arterial pressure tracing reveals the presence of a peaked diastolic augmentation wave along with a broad U-shaped wave preceding the onset of cardiac systole. Early deflation is not as detrimental as the other counterpulsation timing abnormalities. However, the potential benefits of diastolic augmentation are not optimized in this scenario. To correct early deflation, the timing interval should be increased until the augmented diastolic wave becomes appropriate.

Contraindications to the Use of IABP Counterpulsation

When intra-aortic counterpulsation therapy is being considered, the risks and benefits of this modality must be individually assessed for each patient (Table 46-2).

Absolute Contraindications. These include the following situations: distal aortic occlusion or severe stenosis, suspected aortic dissection, documented abdominal or thoracic aortic aneurysm, and severe aortic regurgitation.²¹

Relative Contraindications. They are more frequent and must be taken into account when deciding to use intra-aortic counterpulsation therapy. These include the following scenarios: severe peripheral vascular disease (PVD), aortic or iliofemoral arterial grafts, a contraindication to the usage of heparin or other parenteral anticoagulation, moderate aortic regurgitation, and uncontrolled sustained tachyarrhythmias (heart rate exceeding 160 beats/min).²¹ Patients with vascular abnormalities such as distal aortic stenosis, aortic dissection, or aortic aneurysm have a significantly increased risk of catastrophic vascular complications. The presence of PVD or iliofemoral grafts

increases the risk of complications associated with balloon insertion and removal. Aortic regurgitation can potentially lead to further cardiac decompensation. During balloon inflation, an increased regurgitant volume may be generated across the incompetent aortic valve, thereby resulting in increased left ventricular volumes. Data from animal studies have demonstrated increased regurgitant flow but also enhanced left ventricular stroke volumes, despite the increased diastolic volumes.²² Therefore, although patients with severe aortic valvular insufficiency should be excluded from IABP counterpulsation therapy, patients with lesser degrees of aortic regurgitation should be considered but with close monitoring during the initial phase of the therapy. Sustained tachyarrhythmias with heart rates exceeding 160 beats/min hamper the ability of the balloon drive system to accurately track the mechanical events of the cardiac cycle and provide hemodynamic support. A cardiac electrophysiologic evaluation can be considered before implementation of intra-aortic counterpulsation therapy in such patients.²⁰

Insertion, Removal, Maintenance, and Complications

Placement of the IABP Is the First Step for Counterpulsation Therapy

The percutaneous route via cannulation of the femoral artery is most often employed. Once it is concluded that the patient no longer requires circulatory support, the removal of the IABP is also a straightforward process. Mahaffey and colleagues have devised a simple stepwise approach to device insertion and removal (see Appendix A).²⁰

A thorough vascular physical examination should precede the insertion of the IABP. This examination should include palpation of all lower extremity pulses along with auscultation of the lower half of the abdomen and of the femoral arteries. The femoral artery with the best palpable pulsation should be selected to minimize any vascular complications.³ Early single-lumen balloons were inserted via a femoral artery cutdown or a large (11F) sheath. Newly available balloons (7.5F) are inserted percutaneously over a guidewire using a smaller sheath (8F to 9F) or sheathless. The downsizing of IABP catheters and sheathless insertion has significantly reduced the incidence of ischemic peripheral vascular complications, especially in patients with small or atherosclerotic arteries. In patients with severe peripheral atherosclerosis or distal abdominal aortic aneurysms, the IABP can be inserted through the axillary or the brachial arteries.

Following insertion of the device, fluoroscopy can be used to ensure that the device has been placed in the descending thoracic aorta distal to the origin of the left subclavian artery. Intra-aortic counterpulsation can begin thereafter with augmentation in one inflation for each cardiac cycle (1:1 ratio) being ideal for optimal hemodynamic support. However, adjusting counterpulsation timing is best done with the console set at 1:2 pumping so that the pressure tracings with and without counterpulsation can be compared. Daily chest films and continuous monitoring of hemodynamic parameters ensures good placement and appropriate timing of the device.

No conclusive data support the need for intravenous anticoagulation in the setting of IABP use. A trial involving 153 patients found no difference in vascular complications or laboratory end points in patients undergoing intra-aortic counterpulsation

Table 46-2. Contraindications to Intra-aortic Balloon Pump Counterpulsation Therapy

Absolute Contraindications	Relative Contraindications
Occlusion or severe stenosis of distal aorta	Severe peripheral vascular disease
Aortic aneurysm	Aortic or iliofemoral bypass grafts
Aortic dissection	Contraindication to intravenous anticoagulation
Severe aortic regurgitation	Moderate aortic regurgitation Sustained tachyarrhythmias (with ventricular rate >160 beats/min)

Data from Mahaffey KW, Kruse KR, Ohman EM: Perspective on the use of intra-aortic balloon counterpulsation in the 1990s. In Topol EJ (ed): Textbook of Interventional Cardiology, Update Series, No. 21. Philadelphia, WB Saunders, 1996, pp 303-320.

therapy, with and without continuous heparin anticoagulation.²³ Industry guidelines do not require continuous anticoagulation therapy, especially when the device is set in a 1:1 assist ratio. Currently, it is reasonable to use intravenous heparin with the goal of maintaining an aPTT of 60 to 75 seconds in a patient without contraindications to anticoagulation and when IABP counterpulsation therapy is planned for greater than 24 hours or at lesser assist ratios.³

Although no conclusive data exist in the literature, some authorities recommend gradual weaning of the balloon pump before it is finally removed. Typically, a gradual reduction in the assist ratio from 1:1 to 1:2 and then to 1:3 over several hours is done. If hemodynamic stability is demonstrated at lesser assist ratios, the device can be safely removed. Another weaning protocol involves the gradual reduction of the balloon volume over the course of an hour. This latter method may provide a more gradual resumption of the demands of intrinsic hemodynamic support on the heart.²⁰

Complications. Complications arising from IABP counterpulsation therapy can be categorized into vascular and non-vascular events. In the Benchmark Registry, which included almost 17,000 patients who had an IABP inserted between 1996 and 2000, major complications (defined as major limb ischemia, severe bleeding, balloon leak, and death related directly to device insertion or to device failure) occurred in 2.6% of the patients.²⁴ In this registry, the overall in-hospital mortality rate was 21%, one half of which occurred while the IABP was in place. However, mortality directly stemming from usage of the IABP was only 0.5%.²⁵

The true incidence of complications associated with placement of an IABP is difficult to determine because of differing definitions. However, the frequency of complications is most likely decreasing as techniques, equipment, and experience with the device improve.³ Studies citing complication rates are diverse in terms of the indications for intra-aortic counterpulsation therapy, the insertion technique (surgical or percutaneous), the duration of use, and the specific definitions of a complication.^{24,26-30} The most common reported complications are bleeding and arterial trauma.³

Vascular complications occur in 6% to 25% of cases. The most common types of vascular complications include limb ischemia; vascular laceration necessitating surgical repair; and major hemorrhage.^{25,31-33} Arterial obstruction and limb ischemia can occur when the IABP is inadvertently placed into either the superficial or profunda femoral artery, instead of the common femoral artery. The superficial and the profunda femoral arteries are usually too small to accommodate the IABP without compromising blood flow to the limb. In this scenario, prompt removal of the device and contralateral insertion (with avoidance of an excessively low needle puncture) is the best solution. Arterial dissection can occur with improper advancement of a guidewire with subsequent insertion of the IABP into a false lumen. Vascular complications of lesser frequency include spinal cord ischemia along with visceral organ ischemia. Less frequent but nevertheless feared complications of IABP counterpulsation include cholesterol embolization, stroke, sepsis, and balloon rupture.²⁵ Balloon rupture is uncommon, but because helium is insoluble in blood, helium embolization can cause prolonged ischemia or stroke. These patients can be treated with hyperbaric oxygen to maintain tissue viability. Various multivariate regression analyses have been performed in an effort to identify clinical variables

Table 46–3. ACC/AHA Practice Guidelines: Indications for IABP Counterpulsation Therapy

Clinical Scenario	ACC/AHA Recommendation	Level of Evidence
Severe or refractory unstable angina	Class IIa	C
Refractory decompensated heart failure	Class IIb	C
Cardiogenic shock	Class I	B
Refractory polymorphic ventricular tachycardia	Class IIa	B

Data from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. *J Am Coll Cardiol* 2004;44:671-719.

that predispose to a higher rate of complications. The presence of peripheral arterial disease (including a history of limb claudication, femoral arterial bruit, or absent pulsations) has been the most consistent and reproducible clinical predictor of subsequent complications.^{3,24,34-36}

Clinical Efficacy and Indications

Counterpulsation therapy with IABP improves the hemodynamic and metabolic derangements that are associated with circulatory collapse.²¹ Historically, this modality has been mainly used in the setting of acute ischemic syndromes associated with hemodynamic decompensation. In the decades since its introduction, more data have accumulated supporting the use of intra-aortic counterpulsation therapy in a variety of clinical scenarios (Table 46-3).²⁴ Santa-Cruz and colleagues have recently performed a comprehensive survey of the literature and have formulated an outline of the current evidence-based indications for IABP counterpulsation therapy.³

Unstable Angina. Data are sparse regarding the use of IABP counterpulsation in patients having unstable angina. These data are mostly confined to small observational retrospective studies. Gold and colleagues studied 11 patients experiencing persistent angina despite aggressive medical therapy after an acute myocardial infarction (AMI); 9 of these patients exhibited symptomatic improvement following placement of an IABP.³⁷ Fuchs and colleagues examined 7 patients who had proximal LAD arterial stenoses exceeding 90% along with unstable angina.³⁸ The use of intra-aortic counterpulsation before intervention improved symptoms and enhanced coronary arterial blood flow (as assessed with a Doppler flow wire).³⁸ Despite the small sample sizes, these trials support the use of the IABP in patients with refractory angina until definitive therapy can be instituted. The ACC/AHA practice guidelines give a Class IIa indication for intra-aortic counterpulsation therapy in unstable angina patients, before or after cardiac catheterization, whose ischemic symptoms are not alleviated by aggressive medical therapy.³

Acute Myocardial Infarction. The use of IABP counterpulsation as an adjunct therapy and support device has been tested in the setting of thrombolytic therapy, primary percutaneous coronary intervention (PCI), and rescue PCI in patients having acute myocardial infarction (AMI). The benefits of the IABP in these settings are postulated to result from a multitude of factors: increased recovery of ischemic myocardium; decreased arterial

Figure 46-2. Clinical outcomes of patients with acute myocardial infarction randomly assigned to intra-aortic balloon pump (IABP) after percutaneous revascularization. (Data from Ohman EM, George BS, White CJ, et al; Randomized IABP Study Group: Use of aortic counterpulsation to improve sustained coronary artery patency during acute myocardial infarction: results of a randomized trial. *Circulation* 1994;90:792-799.)

reocclusion; enhanced lysis of thrombus within the coronary arterial lumen; and higher flow within the coronary arterial vasculature.^{39,40,41}

Two randomized trials have studied the clinical and hemodynamic effects stemming from intra-aortic counterpulsation therapy in the setting of AMI and PCI. Van't Hof and colleagues enrolled 284 high-risk AMI patients following the completion of primary PCI to either intra-aortic counterpulsation or to standard medical therapy. No difference was detected between the two treatment groups with respect to the primary end point of death, nonfatal MI, stroke, and LVEF. However, a weakness of this trial was the occurrence of a significant treatment arm crossover (25%).⁴² Ohman and colleagues conducted another randomized controlled trial in which 182 patients with AMI and subsequent emergent PCI (<24 hours) were divided into two treatment arms: prophylactic intra-aortic counterpulsation therapy for 48 hours versus standard medical therapy. Patients randomized to the counterpulsation therapy arm experienced less recurrent ischemia, fewer repeat emergency PCI procedures, and a significantly lesser rate of reocclusion of the infarct-related artery (8% versus 21%, $P < 0.03$) at median follow-up angiography 5 days afterward (Fig. 46-2). The composite end point of death, stroke, reinfarction, need for emergent revascularization, or recurrent ischemia was significantly lower in patients randomized to IABP (24% versus 13%, $P < 0.04$). Although there was a trend toward increased hemorrhagic complications, the overall bleeding complication rate in the intra-aortic counterpulsation therapy arm was still low (2%).⁴³

The TAMI trials prospectively evaluated a variety of therapeutic strategies following fibrinolytic therapy for AMI.³⁹ Multivariate analysis revealed that the primary predictors of infarct artery reocclusion were Thrombolysis In Myocardial Infarction (TIMI) flow grade, treatment with tPA, heart rate, and the anatomic location of the infarct.⁴⁴ The addition of IABP counterpulsation therapy to the multivariate logistic regression model indicated that this therapeutic strategy was associated with a significant decrement in arterial reocclusion ($P < 0.0003$).⁴⁵ However, use of the IABP was associated with significantly higher rates of bleeding and vascular complications.

The PAMI-2 trial data extend the benefit and safety of intra-aortic counterpulsation therapy to patients with AMI who underwent PCI.^{46,47} In this trial, 904 patients who were going to undergo PCI were classified into high- and low-risk cohorts.

This risk-stratification scheme was constructed using clinical and angiographic features. The high-risk cohort included patients with the following characteristics: age older than 70 years; LVEF less than 45%; presence of three-vessel coronary artery disease; suboptimal PCI result; vein graft occlusion; and occurrence of dysrhythmia. Patients in this high-risk cohort were then randomized to PCI with either IABP therapy or to standard medical therapy. The use of IABP was associated with fewer ischemic events, repeat interventions, reinfarctions, and a lesser number of episodes of decompensated heart failure. The vascular complication rates between the intra-aortic counterpulsation and standard medical therapy groups were 2.2% and 4.7%, respectively. The use of intra-aortic counterpulsation did not confer any observable benefit in the patients from the low-risk AMI cohort who received PCI.

A registry of 1490 patients with AMI who were then treated by primary PCI was analyzed by Brodie and colleagues.⁴⁸ In this observational study, a total of 105 patients had an IABP placed before PCI, whereas 108 patients had an IABP inserted following the completion of PCI. Although the former cohort of patients exhibited a higher prevalence of cardiogenic shock and multivessel CAD, they still had substantially higher procedural success and less adverse events (e.g., dysrhythmias and shock) during the PCI. In this observational study, the initiation of IABP counterpulsation therapy before PCI was an independent predictor of lower periprocedural complications.

The Benchmark Registry was the first large database to be formulated on patients receiving intra-aortic counterpulsation.³⁰ Of the 22,663 patients who were registered into this computerized database, 5495 (24%) had a diagnosis of AMI. An IABP was placed for the following indications: cardiogenic shock (27%), support of high-risk PCI (27%), preoperative support for high-risk cardiac surgery (11%), and refractory post-MI unstable angina (11%). Intra-aortic counterpulsation was associated with an average increase in mean arterial pressure postinsertion (87 mm Hg versus 82 mm Hg, $P < 0.001$), whereas no significant difference was observed with the heart rate (90 beats/min versus 89 beats/min, $P = 0.59$). Patients treated with an IABP in this registry constituted a high-risk population. The overall in-hospital mortality rate was 20%. However, the complication rate directly stemming from IABP placement was low; specifically, only three patients (0.05%) died from complications of device placement. Other complications cited in the Benchmark Registry included severe bleeding at the vascular access site (1.4%), major limb ischemia (0.5%), and limb amputation (0.1%).

Another analysis of the Benchmark Registry performed by Urban and colleagues revealed that patients who received IABP counterpulsation therapy in conjunction with surgical (19.2%) or percutaneous (18.8%) revascularization had a lower in-hospital mortality rate when compared with patients treated medically (32.5%).²⁶ Obviously, it is difficult to precisely quantitate how much of the mortality benefit in this analysis stemmed exclusively from intra-aortic counterpulsation therapy and not from the revascularization strategy. The primary reason for IABP insertion in these patients was cardiogenic shock. Moreover, the highest mortality was clustered in the first 3 days of hospitalization. Urban and colleagues recommend rapid risk-stratification and early use of IABP counterpulsation therapy in such patients.

Although only a few randomized trials exist; review of the previously cited studies consistently indicates that intra-aortic counterpulsation in the setting of AMI as an adjunctive measure

to percutaneous revascularization is associated with a decreased incidence of ischemic events along with vascular and hemorrhagic complications. The current ACC/AHA guidelines state a Class I indication for IABP counterpulsation therapy in the setting of AMI associated with the following sequelae: recurrent postinfarction angina, reinfarction, and the mechanical complications of AMI (specifically, interventricular septal rupture and acute mitral valvular insufficiency due to papillary muscle dysfunction or rupture).

Cardiogenic Shock

Cardiogenic shock occurs in 5% to 10% of patients who have AMI and is still associated with high mortality rates despite the availability of more aggressive interventional strategies.^{49,50} The 30-day mortality rate for the 0.8% of GUSTO I trial patients with cardiogenic shock treated with thrombolytic therapy was 58%.⁵¹ In the interventional era, the mortality rate of cardiogenic shock still remains substantially high with estimates ranging from 50% to 80%.^{52,53} Before the advent of the thrombolytic era, two small randomized trials of intra-aortic counterpulsation showed no benefit in the setting of cardiogenic shock.^{54,55} Since the advent of thrombolytic therapy, several observational series have supported the potential benefits of IABP counterpulsation therapy in the setting of AMI complicated by cardiogenic shock.⁵⁶⁻⁵⁸

In the Duke Cardiovascular Databank, 200 patients who had AMI complicated by cardiogenic shock were managed by an early aggressive strategy.⁵⁰ The in-hospital mortality of this cohort was 53%. Infarct-related artery patency, cardiac index, and peak creatine kinase enzyme levels were the most important variables in predicting in-hospital mortality. An IABP was placed in 99 patients within this cohort. The patients receiving intra-aortic counterpulsation had an in-hospital mortality rate of 48% whereas the patients not receiving an IABP had a mortality rate of 57% ($P = 0.23$). Based on subgroup analysis, a decrement in mortality rate was conferred when IABP counterpulsation therapy was used in conjunction with PCI compared with when intra-aortic counterpulsation was used alone (38% versus 63%, $P = 0.01$).

In the SHOCK trial, 302 patients having cardiogenic shock were randomized to receive initial emergent revascularization versus medical management. An IABP was placed in 86% of these patients. At a 6-month interval, the patients who had been randomized to the early intervention treatment arm exhibited a lower mortality rate when compared with those patients who were managed medically (50.3% versus 63.1%, $P = 0.027$). When compared to data from historical controls, both treatment arms in the SHOCK trial still exhibited lower overall mortality rates. This discrepancy may have arisen from intensive medical management and the increased usage of IABP counterpulsation therapy.⁵⁹ A retrospective analysis of the SHOCK trial revealed a trend toward a decreased mortality rate in the medical stabilization arm when patients were treated with fibrinolytic therapy and intra-aortic counterpulsation (41% versus 64%, $P = 0.07$).⁶⁰ Although intra-aortic counterpulsation does not substantially enhance blood flow distal to a critical coronary arterial stenosis, it does increase total blood flow to coronary vascular beds that are maximally dilated by ischemia; as a result, there is increased delivery of the fibrinolytic agent to the region of occlusive thrombus, thereby enhancing the overall thrombolytic effect.^{14,61-64}

In the GUSTO I trial, 7% of the patients ($n = 2972$) developed cardiogenic shock in the setting of ST segment elevation myocardial infarction. Intra-aortic counterpulsation was used in 734 of these patients and eventually showed a trend toward decreased mortality at a 30-day interval when the IABP was placed before or at the time of PCI versus when the device was placed late or not at all (47% versus 60%, $P = 0.06$).⁵¹

The International Shock Registry, the SHOCK Trial Registry, and the National Registry of Myocardial Infarction-2 (NRM-2) provide the largest and most contemporary clinical experience with patients in cardiogenic shock.³ In the International Shock Registry, 251 patients having cardiogenic shock were enrolled. The unadjusted mortality was lower in the 173 patients who received an IABP compared with those without this device (57% versus 72%, $P = 0.039$).⁵² In NRM-2, the largest registry to enroll patients with AMI ($n = 23,180$), 31% of the patients in cardiogenic shock received an IABP. When IABP usage was combined with a reperfusion strategy, especially thrombolytic therapy, a substantial mortality benefit was observed (49% versus 67%). However, when primary PCI was the sole reperfusion strategy, the overall mortality rate was lower and was not influenced by the use of intra-aortic counterpulsation (45% versus 47%). During a subgroup analysis of 12,730 patients from the NRM-2 registry, hospitals with a higher frequency of IABP usage showed a lower cardiogenic shock mortality rate when compared with hospitals with a lower frequency of device usage (50.6% versus 65.4%, $P < 0.001$). This finding was independent of other factors such as baseline patient characteristics, treatment strategy, and procedures performed (including PCI).⁶⁵ The hospitals with a higher volume of IABP usage may have had more expertise with the device, which eventually translated into better outcomes among the patients having cardiogenic shock.³

High-Risk Percutaneous Coronary Intervention

Patients with significant comorbidities and higher cardiac risk (poor LVEF, multivessel coronary artery disease, left main stenosis, hemodynamic instability) are also treated with percutaneous interventions in the current era as a result of refinements in catheterization technology and techniques.⁶⁶⁻⁶⁸ In this subset of patients, placement of an IABP before the intervention may be beneficial because of enhancement of coronary perfusion pressure and stabilization of hemodynamic parameters.

Small retrospective studies have reported the use of elective IABP counterpulsation support before high-risk PCI and have found good results with no major adverse events transpiring within 72 hours of the intervention.^{61,70,71} Briguori and colleagues reported on 133 consecutive patients who were undergoing high-risk PCI. The patients were divided between two groups: those with an elective preprocedural placement of an IABP and those with provisional (i.e., standby) usage of an IABP. Among patients with a low LVEF, the rate of major adverse cardiac events (acute myocardial infarction, shock, stroke, emergent CABG, or death) was 17% in the standby IABP group versus 0% in the group that received an elective preprocedural IABP ($P = 0.001$).⁷²

There is also evidence that supports the use of intra-aortic counterpulsation therapy before emergent CABG after coronary angiography. In these patients, the IABP improves

hemodynamic parameters and also contributes to resolution of ECG changes.^{73,74} One small study examined 32 patients who required emergent CABG following a failed PCI attempt. Preoperative ST segment elevation was observed in 21 patients; 15 of these patients were managed with intra-aortic counterpulsation. Although a statistically significant difference was not seen, a lower rate of postoperative myocardial infarction was observed in those managed with an IABP before CABG (20% versus 33%). Because of the absence of solid, incontrovertible evidence, the decision to use intra-aortic counterpulsation therapy preceding high-risk PCI should be based on a case by case evaluation by the clinician.^{3,37}

Cardiac Surgery

Intra-aortic counterpulsation therapy is recommended in the setting of left main disease detected after coronary angiography. However, the indication for its usage is less clear in patients with significant left main disease but with minimal or no symptomatology.⁷⁵ Increasing evidence corroborates the placement of a prophylactic IABP before CABG in patients possessing certain high-risk features: critical coronary arterial anatomy (including presence of left main disease), severe left ventricular dysfunction, or unstable angina.⁷⁶⁻⁷⁸

In a small prospective study, Christenson and colleagues randomized 60 consecutive high-risk patients who were going to receive CABG to either conservative management or to preoperative intra-aortic counterpulsation commencing 2, 12, or 24 hours before surgery. Most of these patients had left ventricular dysfunction, unstable angina, and/or left main stenosis. Although no mortality benefit was ultimately observed, patients who were randomized to preoperative intra-aortic counterpulsation of any duration did have significantly higher cardiac output levels, shorter intervals on mechanical ventilation, and shorter lengths of hospitalization.⁷⁷

Off-pump coronary arterial bypass grafting is another setting where IABP counterpulsation may be a valuable modality.^{3,79} In a retrospective study, Suzuki and colleagues examined 32 high-risk patients with preoperative intra-aortic counterpulsation compared with 101 moderate- to low-risk patients without intra-aortic counterpulsation scheduled for off-pump bypass surgery. Although patients treated with preoperative intra-aortic counterpulsation had substantially higher frequencies of left main trunk disease and emergent surgeries, outcomes were similar in both groups. The authors surmised that the insertion of the IABP had improved the intraoperative hemodynamic state of the patients, thereby stabilizing their postoperative course. In the end, the high-risk patients experienced a similar mortality rate when compared with the low- to moderate-risk cohort.⁸⁰

Transplantation and Dysrhythmias

In patients with severe end-stage cardiomyopathy who are being prepared for cardiac allograft transplantation, intra-aortic counterpulsation can be used as a bridging modality. Some case series have reported successful bridging via intra-aortic counterpulsation in both the critical care and the ambulatory settings.⁸¹ However, some of the pretransplant patients are now more successfully bridged via left ventricular assist devices. Hemodynamic support following transplant rejection could be accomplished via intra-aortic counterpulsation therapy.

Arafa and colleagues reviewed a series of patients experiencing postcardiac transplant allograft rejection requiring mechanical circulatory support. An IABP was inserted in five patients who exhibited predominantly right ventricular failure. After 12 hours, significant improvements in pulmonary vascular resistance (4.6 wood units versus 1.8 Wood units, $P < 0.05$), mean arterial pressure (53 mm Hg versus 74 mm Hg, $P < 0.05$), and a trend toward enhanced cardiac output were demonstrated. The use of intra-aortic counterpulsation to unload the left ventricle and to increase perfusion of the right ventricle could possibly improve outcomes in such patients.^{3,82}

Severe malignant ventricular tachyarrhythmias can be associated with an uncorrected ischemic substrate. In the literature, several anecdotal reports have described cessation of ventricular tachycardia and fibrillation following the initiation of intra-aortic counterpulsation therapy.²¹ The current ACC/AHA guidelines have given a Class IIa recommendation to the use of IABP counterpulsation therapy for treating malignant dysrhythmias that are perpetuated by underlying myocardial ischemia and are refractory to medical therapy.

Conclusion

IABP has emerged as an effective and widely used mechanical circulatory assist device. Based on the dual physiologic concept of diastolic augmentation and systolic afterload reduction, intra-aortic counterpulsation has become an important strategy to salvage the function of an ischemic and failing left ventricle. The development of a percutaneous approach to insertion has enhanced the speed and the ease with which this device can be placed in patients experiencing hemodynamic decompensation from an acute cardiovascular event. Moreover, refinements in device technology have decreased the complications associated with the IABP. As a result of this improved risk-benefit profile, the IABP has become a prevalent modality in the current cardiac intensive care setting.

APPENDIX A

Insertion and Removal of the Intra-Aortic Balloon Pump

The following steps are involved during insertion of an IABP:

1. An initial physical examination focusing on peripheral vasculature should be conducted including palpation and demarcation of the femoral, popliteal, dorsalis pedis, and posterior tibial pulses and auscultation for femoral and abdominal bruits.
2. The side with the better arterial pulsations should be selected for insertion.
3. The inguinal region should be inspected for landmarks and the femoral artery should be identified.
4. The inguinal region should be prepared and draped in a sterile fashion.
5. Following administration of a local anesthetic agent, a skin incision is made 2 to 3 cm below the inguinal ligament.
6. Using a modified Seldinger technique, the femoral artery is cannulated with a needle and a J-tipped guidewire is then advanced through the needle after brisk flow of arterial blood is confirmed.
7. The guidewire should be advanced to the level of the descending aorta under fluoroscopic guidance.
8. A dilator is inserted and removed until an arterial sheath can be safely placed.
9. The intra-aortic balloon is passed over the guidewire to a position just distal to the origin of the left subclavian artery.
10. The guidewire is subsequently removed and the catheter lumen is aspirated to remove any residual air or thrombus.
11. The intra-aortic balloon is connected to the drive system console and counterpulsation can subsequently begin.
12. The hemodynamic tracing should be inspected for proper timing.
13. A chest radiograph should be obtained to document correct positioning.
14. The intra-aortic balloon catheter and femoral sheath should be secured with sutures.

Removal of an IABP:

1. Anticoagulation should be stopped; confirm that the activated clotting time (ACT) is less than 180 seconds or the activated partial thromboplastin time (aPTT) is less than 40 seconds.
2. Conscious patients should receive a low dose narcotic and/or analgesic agent.
3. The securing sutures are cut.
4. The drive system console is turned off.
5. The intra-aortic balloon is completely deflated by aspiration with a 20-mL syringe attached to the balloon inflation port.
6. The sheath and intra-aortic balloon catheter are pulled as one unit.
7. Blood is allowed to flow from the arterial access site for a few seconds to remove any thrombi.
8. Manual pressure is applied above the puncture site for 30 minutes or longer if hemostasis is not obtained; a mechanical compression device can also be used to help apply pressure to promote hemostasis.
9. Distal arterial pulsations are palpated.
10. The patient should remain recumbent for a minimum of 6 hours to prevent any subsequent hemorrhage or vascular complications at the arterial access site.

Ventricular Assist Device Therapy in Advanced Heart Failure—State of the Art

CHAPTER 47

Background
LVAD as Bridge to Transplantation
LVADs as Destination Therapy
Axial Flow Pumps

Future Directions
Bridge to Recovery
Conclusion

THE BURDEN of congestive heart failure (CHF) continues to grow, with more than 500,000 new cases annually. Fortunately, increased understanding of the disease process, and advances in pharmacologic and pacemaker-based therapies have led to significant improvements in survival for patients with CHF over the past 2 decades.¹ For example, 1-year mortality in subjects with NYHA class IV CHF participating in clinical trials investigating ACE-inhibitors, β -blockers and aldosterone antagonists has decreased from approximately 50% in 1986 to less than 15% in 2002.²⁻⁴ However, many patients with advanced CHF continue to have significant symptoms despite these interventions. For these patients, prognosis remains very poor with 1-year mortality rates approaching 75%.⁵

When CHF is refractory to medical therapy, and in appropriate candidates, cardiac transplantation is the most effective treatment modality. Refinement in techniques and immunosuppressive regimens has produced 1-year survival rates of approximately 90%.^{6,7} However, the number of transplants performed annually in the United States has plateaued at 2200 because of a limited number of donor organs (Fig. 47-1), and many patients die while waiting for a transplant.⁸

In the last 15 years, left ventricular assist devices (LVADs) have emerged as a method to prolong the survival of these patients as they wait for a suitable donor heart. By mechanically unloading the failing heart and improving systemic end-organ perfusion, LVADs can reverse the systemic abnormalities seen in advanced CHF, improving survival and quality of life. Advances in design and clinical experience have significantly reduced the morbidity and mortality associated with LVADs, and have led to the continual spread of this technology.⁹ Further advances are currently under evaluation and promise to make LVADs available to a greater number of patients. Importantly, use of LVADs is no longer limited to subjects waiting for heart transplants, but is now approved to treat end-stage heart failure refractory to medical therapy in patients not suitable for transplantation because of age and/or comorbidities. This review discusses the evolution of LVAD devices, the current uses of this therapy, and its potential future applications.

Background

Mechanical circulatory support devices were initially developed in the 1960s as a means to assist patients who could not be weaned from cardiopulmonary bypass following cardiac

surgery. Dr. Michael E. DeBakey implanted the first device in 1963 to treat cardiogenic shock following aortic valve surgery. Although the patient did not survive to hospital discharge, this operation proved the feasibility of mechanical circulatory assistance.¹⁰ Through the 1960s and 1970s, researchers developed several devices for investigational use. These “early” LVADs caused significant hemolysis and had high rates of bleeding and infection because of their size and extracorporeal location. Furthermore, patients with otherwise good clinical recovery remained significantly limited in their mobility because of the large power consoles (Fig. 47-2).

Limitations of the early devices, however, provided the impetus for development of an intracorporeal LVAD powered from an external source through a percutaneous driveline. Situating the pump inside the body provided patients with greater independence, allowed discharge from the hospital, and substantially improved quality of life. In addition, outpatient LVAD management led to significant cost savings over prolonged inpatient stays.¹¹ Consequently, the Heartmate 1000 IP (Thoratec Corp., Pleasanton, Calif.) received FDA approval as a bridge-to-transplantation device in 1994. The power console of this pneumatic LVAD was smaller than that of earlier pumps, but its size remained a significant limitation. Further research produced an electric power source connected to a wearable battery pack. An LVAD using this technology, the Heartmate Vented Electric (VE) (Thoratec Corp.), was approved by the FDA in 1998 (Fig. 47-3).

Figure 47-1. Number of heart transplants performed annually in the United States, 1970-2005.

LVAD as Bridge to Transplantation

Currently, there are two LVADs approved for bridge to transplantation: the Heartmate I and the Novacor (World Heart Corp., Ottawa, Ontario, Canada). Both are surgically implanted in a pocket in the abdominal wall (see Fig. 47-3). An inflow conduit is attached to the left ventricular apex and an outflow conduit is anastomosed to the ascending aorta. Bioprosthetic valves ensure unidirectional blood flow. The blood is expelled by electromagnetically powered pusher plates that contract a polyurethane diaphragm and provide pulsatile flow to the aorta. The devices can pump blood at rates up to 10 L/min. Each device is connected to a wearable battery pack through a percutaneous line that also houses the venting system.

In patients refractory to medical therapy, LVAD support leads to improved renal function, right heart function, and overall physical conditioning.^{11,12} Multiple studies have shown that LVADs can be successfully used as a bridge to transplantation,¹³⁻¹⁶ with one prospective series showing an increase in survival to transplant from 33% to 71% with use of the Heartmate LVAD (when compared with historical controls managed

with medical therapy alone).¹⁵ By implanting an LVAD in these patients, surgeons reduce their subsequent operative risk for transplantation, making them better transplant candidates and improving their posttransplant outcomes.^{15,16}

Although most commonly implanted into patients with symptoms of Class IV CHF that are refractory to medical therapy, intracorporeal LVADs have also been used for the treatment of post-cardiotomy shock, myocardial infarction complicated by cardiogenic shock, myocarditis, and primary graft failure following cardiac transplantation.¹⁷⁻²⁰ The following criteria should generally be met before consideration of LVAD implant: clinical evidence of impaired end-organ perfusion with cardiac index less than 2 L/min/m², pulmonary capillary wedge pressure greater than 20 mm Hg, and systolic blood pressure less than 80 mm Hg despite maximal medical support including inotropes and an intra-aortic balloon pump if indicated.²¹ Although it is important to meet these criteria, LVAD implantation needs to be performed before extensive end-organ damage for maximal chance of success.

Adverse Events

Table 47-1 shows the most commonly encountered adverse events in patients who receive LVADs as a bridge to transplant. Different complications are seen in the early period following LVAD implantation and the later period following prolonged use.

The two major *perioperative* complications are bleeding and right ventricular (RV) failure. Bleeding causes significant morbidity and mortality, and often requires exploration of the surgical site. The degree of RV failure is difficult to predict before LVAD implantation, although the presence of elevated central venous pressure (CVP), high pulmonary vascular resistance, and significant RV dilation raise concern that additional RV support may be required postoperatively. The importance of the RV in the management of LVAD patients cannot be underestimated. With a functioning LVAD in place, cardiac output is dependent on the ability of the RV to provide sufficient preload to the left side of the heart. Postsurgical RV dysfunction can compound underlying contractile weakness and cause right heart failure, which is correlated with worse outcomes.²² Treatment consists

Figure 47-2. ABIOMED BVS 5000 extracorporeal ventricular assist device.

Table 47–1. Adverse Events in Patients with the Heartmate VE When Used as a Bridge-to-Transplantation

Event	Frequency
Bleeding	48%
Infection	48%-55%
Neurologic event	10%-27%
RV failure	7%-11%
Thromboembolism	12%
Device failure	12.8%

Adapted from references 6, 15, and 25.

of pharmacologic augmentation of RV contractility and reduction of pulmonary vascular resistance (see “Management of Acute Complications” later). Occasionally, refractory RV failure dictates placement of a right ventricular assist device (RVAD).

With *intermediate and long-term use*, the most common complication is infection, occurring in up to 55% of patients.²³⁻²⁵ The relative immunosuppression of critical illness and the presence of large amounts of foreign material leaves LVAD patients particularly susceptible to infectious complications. Infections can occur in the device pocket or surrounding surgical area, along the percutaneous drive lines and inside the device itself. Prevention efforts, including enhanced prophylactic antibiotic regimens, new surgical techniques, improved drive line design, and attention to drive line management are critical in reducing the overall infection rate.²⁶

With prolonged use, device failure can occur. Most commonly, this is due to deterioration of the device inflow valves and resultant regurgitation. Bearings attached to the motor are also subject to decay because of the repetitive wearing motion of the pump. Additionally, the electrical system can malfunction, causing abrupt cessation of LVAD function. These complications are medical emergencies, and often necessitate explantation or replacement of the device.

The risk of thromboembolism and neurologic events has been significantly reduced through the introduction of the Heartmate LVAD. The Heartmate I has a unique, textured design that promotes the formation of an endothelial layer on its blood-contacting surfaces. This “natural” surface has low thrombogenicity, and the Heartmate therefore does not require systemic anticoagulation.²⁷ With other devices, thrombotic complications remain prevalent and necessitate anticoagulation.

LVADs as Destination Therapy

As patients with LVADs survived for longer periods of time before transplantation, the concept of using LVADs as “destination therapy” arose. In the late 1990s, researchers conducted the REMATCH study, a randomized, controlled, clinical trial of LVADs compared with optimal medical management.⁵ One hundred and twenty-nine subjects with NYHA Class IV CHF who were not candidates for transplantation were followed for 2 years. The results showed a 48% reduction in the risk of all-cause mortality at 2 years with LVAD therapy. In the LVAD group, the primary causes of mortality were sepsis and device failure, whereas in the medical management cohort, almost all patients died from progressive heart failure. REMATCH must

No. at risk

be considered a seminal study because it conclusively demonstrated that subjects in the most advanced stages of CHF (nearly all of them inotrope-dependent) can survive a major cardiac operation and that the small increase in short-term mortality because of perioperative deaths is significantly outweighed by the long-term benefits of device therapy. Indeed, patients in this cohort who were on inotropic therapy at randomization derived the largest benefit.²⁸ In addition to reduced mortality, patients with LVADs spent fewer days in the hospital and had a higher quality of life. Following the publication of REMATCH, the Heartmate LVAD received FDA approval for use as destination therapy in 2002. As with bridge to transplantation, employment of destination therapy early in the clinical course is recommended as high-risk patients have significantly worse survival than low-risk patients.²⁹

Despite the superiority of LVADs to medical therapy for this group of patients (Fig. 47-4), the absolute mortality rate for LVAD patients in REMATCH was still 48% at 1 year and 75% at 2 years. These statistics indicate the severity of illness in the REMATCH cohort and emphasize the need for further improvements in pump design and management. Since REMATCH, further clinical experience with destination therapy has produced lower complication rates and 2-year mortality in REMATCH type patients has been reduced to 60% at experienced centers.²⁶

Axial Flow Pumps

The LVADs currently in use have several significant drawbacks. Their size is a source of patient discomfort, and implantation requires a large operation, increasing the risk of both bleeding and infection. The pump is noisy and subject to failure because of the presence of wearing mechanical parts. Valves inside the pump decay over time. The percutaneous drive lines remain major sources of infection. Each of these problems has spurred the development of new devices designed to overcome the limitations of the first-generation LVADs. An ideal device would be small, quiet, totally implantable, and durable.

With respect to pump design, it is important to recognize that as blood moves through the systemic circulation, the initial pulsatile flow in the aorta is progressively dampened,

transforming into continuous flow at the level of the capillary (Fig. 47-5). Thus, pulsatile flow may not be necessary for humans. An understanding of this particular aspect of circulatory physiology fueled the development of axial flow pumps.³⁰ These LVADs propel blood forward in a continuous fashion with a rotary impeller (Fig. 47-6). With this design, the device has only one moving part and does not require valves, reducing the long-term risk of mechanical failure. Axial flow pumps are also smaller and lighter than the first-generation LVADs, and they function in virtual silence. Early concerns about the adverse effects of continuous flow on end-organs have been alleviated with successful long-term use of these devices.³¹

Three axial-flow devices are in advanced stages of clinical testing (Fig. 47-7): the Thoratec Heartmate II (Thoratec Corp.), the MicroMed-DeBakey VAD (MicroMed Cardiovascular, Inc., Houston) and the Jarvik 2000 (Jarvik Heart, Inc., New York). Early clinical data suggest that the axial flow devices have comparable success in bridge to transplantation as pulsatile flow devices.³²⁻³⁴ Because of their small size, the axial flow devices have fewer perioperative complications, with less bleeding and a shorter duration of intensive care.^{34,35} By nature of their small size, these devices eliminate the infections associated with a large abdominal pocket and also reduce the incidence of drive line infections.^{35,36} Mechanical failure is less frequent as well.³⁷ On the other hand, thromboembolism has been a significant issue and all axial flow pumps require systemic anticoagulation.^{37,38} An ongoing clinical trial will provide the first head-to-head comparison of pulsatile (Heartmate I) and axial flow (Heartmate II) pumps as destination therapy (see Figs. 47-3 and 47-7).

Future Directions

With the advent of the continuous flow pumps and improved operative experience, the risk associated with LVAD implantation has decreased substantially. The Jarvik 2000 allows placement through a lateral thoracotomy rather than the traditional median sternotomy, allowing the surgery to be performed without cardiopulmonary bypass and substantially reducing recovery time. As more advances such as this are incorporated into the design of subsequent devices, we believe that LVAD implantation will increasingly be used earlier in the clinical course, in the same way that valve surgery is most therapeutic when performed at the beginning, not end, of a downward spiral. Further refinements may ultimately allow these devices to be used to improve the quality of life for patients with earlier stages of heart failure.

The two primary obstacles left to conquer are drive line infections and the risk of thromboembolism with the continuous flow pumps. A transcutaneous energy transfer system that would replace the percutaneous drive line is in the early stages of clinical testing. Increasing clinical experience with the anticoagulation regimens needed in continuous flow pump recipients should prove successful at reducing the thromboembolic complications. Finally, third-generation devices are entering the clinical trial phase of development. These pumps feature electromagnetically levitated motors that would eliminate the need for bearings, and thus reduce the risk of device failure.

Figure 47-8. Cardiac pathophysiology after left ventricular assist device (LVAD) implantation. Red lettering and lines indicate causes of poor cardiac output and systemic hypoperfusion. LV, left ventricle; PVR, pulmonary vascular resistance; RV, right ventricle.

Management of Acute Complications

Figure 47-8 shows cardiac physiology following LVAD implantation, and identifies causes of decreased cardiac output, which can be divided into three general categories:

1. Decreased pump preload
2. Increased pump afterload
3. Intrinsic pump malfunction

Decreased Preload: Reduced filling of the LVAD chamber can be device-related (inflow cannula obstruction, usually in the early postoperative period and secondary to malpositioning against the ventricular septum) or patient-related. RV failure will be the most common cause of low pump flows. Hypovolemia from any cause also has decreased preload and can worsen underlying RV dysfunction.

Increased Afterload: An inability to fully empty the LVAD chamber can occur with obstruction of the outflow cannula by mechanical kinks and infections. Injection of radio-paque dye may be used to identify the source of the problem, and LVAD replacement is the primary solution to outflow cannula obstruction. Systemic hypertension can also prevent complete emptying of the LVAD chamber and afterload reduction is crucial to maintaining adequate LVAD blood flow.

Pump Malfunction: Disruption of the LVAD's motor or electrical system is usually evident to both the patient and physician. Pulsatile-flow LVADs can be attached to a pneumatic hand pump and manually operated until the source of the problem can be found. This option is not available for axial flow pumps. Replacement of the battery pack is often sufficient to repair electrical failures. Worn bearings or a malfunctioning motor require replacement of the entire LVAD.

Right heart catheterization can differentiate causes of low pump output (Table 47-2). Low central venous pressure (CVP) and low pulmonary capillary wedge pressure (PCWP) indicate hypovolemia. A finding of elevated CVP with a low PCWP is most likely because of RV dysfunction. Elevated CVP and PCWP are seen with inflow cannula obstruction, pump malfunction, and outflow cannula obstruction. Echocardiography can pinpoint the source of the problem.

Hypotension or poor systemic perfusion can also be seen in the setting of normal or elevated pump flows. Vasodilation due to sepsis is the most likely cause in these situations and

Table 47-2. Differentiation of the Etiology of Hypotension in the LVAD Patient Using Intracardiac Pressure Measurements

	CVP	PCWP	LVAD Output	Cardiac Output
Hypovolemia	↓	↓	↓	↓
Sepsis	↓	↓	↑	↑
RV failure	↑	↓	↓	↓
Pump failure or cannula obstruction	↑	↑	↓	↓
Valvular regurgitation	↑	↑	↑	↓

Abbreviations: (CVP), Central venous pressure; (PCWP), pulmonary capillary wedge pressure; (LVAD), Left ventricular assist device; (SG), Swan-Ganz catheter; (RV), Right ventricular.

an infectious source should be sought aggressively. Infections within the pump itself often necessitate explantation of the device. In the absence of infection, the patient with hypoperfusion and preserved device flow should be evaluated for valvular incompetence. If the cardiac output obtained from the Swan-Ganz catheter is low and the cardiac output reported by the pump is high, the most likely cause is regurgitation through either the native aortic valve or one of the valves within the LVAD. Echocardiography can localize the culprit valve.

Bridge to Recovery

The ability of LVADs to support an acutely failing heart while it recovers function is well documented.^{17,18} However, observations have also noted the potential for myocardial recovery in patients with chronic heart failure. In many patients with LVAD support, the size of the left ventricle (LV) decreases,³⁹ the myocardial pressure-volume relationship normalizes,⁴⁰ and the LV function improves.⁴¹ The exercise capacity of patients with LVADs improves dramatically.⁴² At the cellular level, there is a regression of myocyte hypertrophy,⁴³ a downregulation of

Figure 47-9. Long-term freedom from recurrent heart failure after treatment with the Harefield protocol and left ventricular assist device explantation.

cytokines that are elevated in CHF,⁴⁴ and an upregulation of β -adrenergic receptors.⁴⁵

These findings encouraged the explantation of LVADs in select patients who had demonstrated sufficient recovery of myocardial function. Recovery is less likely in patients with ischemic cardiomyopathy, and most data have shown that few patients achieve enough recovery of function to allow explantation.^{46,47} Recurrence of heart failure is common following removal of the LVAD.⁴⁸ Recently, physicians in Harefield, England have reported provocative findings using high-dose neurohormonal blockade and clenbuterol, a β_2 -adrenergic receptor agonist, to promote myocardial recovery in LVAD patients. With this protocol, 73% of patients were explanted, and 73% of these patients demonstrated sustained recovery over 4 years (Fig. 47-9).⁴⁹ A multicenter trial is ongoing in the United States to confirm these results.

Conclusion

Ventricular assist device therapy has made tremendous progress since the first devices were tested in the 1960s. The success of the LVAD as a bridge to transplantation and as destination therapy provides cardiologists and cardiothoracic surgeons with a new tool for the management of advanced heart failure. The current devices offer significant benefits to patients' quality and quantity of life. With continued device improvement and clinical experience, LVADs may not only become a viable alternative to transplantation, but may be used to improve the quality of life of patients in earlier stages of advanced CHF. The application of the LVAD as a bridge to recovery is an exciting development with significant potential to alter physicians' approach to the management of congestive heart failure.

CHAPTER 48

Stage D Identification and Candidate Selection Criteria Pretransplant Patient Management

Posttransplantation Management in the Critical Care Setting Future Directions

DESPITE NUMEROUS advances, heart failure remains a leading cause of morbidity and mortality in the United States. Roughly 5 million Americans are presently afflicted with heart failure, and each year approximately 550,000 new cases are identified.¹ Considerable effort, expense, and resources continue to be dedicated to improvements in heart failure prevention and treatment.

Cardiac transplantation remains the most effective treatment for selected patients with end-stage heart failure. Once transplanted, survival is routine, as shown in Figure 48-1.² Most infections and rejection episodes are either preventable or treatable. Furthermore, advances in mechanical circulatory support have expanded the candidate pool, enabling additional critically ill heart failure patients to undergo successful heart transplantation.

In recent years, however, the number of cardiac transplants performed has declined to approximately 2000 per year in the United States and 3000 per year worldwide. Transplant candidates now generally wait longer before transplantation than in earlier eras, in many cases waiting a year or longer. The increased waiting times have precipitated a rise in the number of patients who deteriorate and therefore require hospitalization or mechanical circulatory support before transplantation.² Because heart transplantation depends on a limited supply of donor hearts, individuals listed as candidates for transplantation should be those who are most likely to benefit.

Those involved in cardiac intensive care need a sound understanding of issues surrounding cardiac transplantation. In addition to being expert at managing acute decompensated heart failure, cardiac intensivists must be able to: (1) determine which patients have stage D heart failure; (2) determine which stage D heart failure patients are potentially suitable heart transplant candidates; (3) manage critically ill transplant candidates, escalating therapies from intravenous diuretics, to intravenous inotropes and vasodilators, and finally to mechanical circulatory support, as required; (4) manage or assist in managing recipients immediately following heart transplantation; and (5) evaluate and manage longer-term posttransplant complications that necessitate cardiac intensive care. Moreover, a strong collaborative approach with a transplant cardiologist is vital for overall patient care. Specifically, pretransplant evaluation and care, early identification of patients having posttransplant comorbidities, including hemodynamically compromising cardiac allograft

rejection, atypical infections, immunosuppressive therapy and its potential adverse effects, among others, must be seamlessly coordinated.³

Stage D Identification and Candidate Selection Criteria

Stage D heart failure patients have end-stage disease and a short life expectancy, typically only 50% at 1 to 2 years. Medications that previously were beneficial are no longer well tolerated and hospitalizations are frequent. As shown in Figure 48-2, therapeutic options are limited to end-of-life strategies, transplantation, or support with a left ventricular assist device intended as permanent or “destination” therapy.^{3,4}

Once a stage D heart failure patient is identified, transplant candidacy should be determined. Careful candidate selection

Figure 48-1. Kaplan-Meier survival for adult heart transplants performed between January 1982–June 2005. Recipient survival improves with each successive 5- to 10-year era; however, the major gains in survival are limited to the first 6 to 12 months, with the long-term attrition rate being unchanged. (Adapted from Taylor DO, Edwards LB, Boucek MM, et al: Registry of the International Society for Heart and Lung Transplantation: Twenty-fourth Official Adult Heart Transplant Report—2007. *J Heart Lung Transplant* 2007;26:773.)

Figure 48-2. Pathophysiologic mechanisms in heart failure and treatment options for end-stage disease. An insult such as a myocardial infarction or a viral infection initiates the decline toward symptomatic heart failure, stage C (current or past symptoms associated with structural heart disease) and stage D (refractory, end-stage disease). Repetitive and iterative pathophysiologic derangements occur, as depicted schematically here. The sequence of events is myocardial insult → myocardial dysfunction → neurohormonal activation → altered gene expression and apoptosis → adverse remodeling → further myocardial dysfunction. Many stage D patients become poorly tolerant of previously beneficial drugs. End-of-life strategies, permanent or destination left ventricular assist device (LVAD) support, or heart transplantation is required.

rations the limited supply of donor hearts to patients most likely to benefit from transplantation. The question, “Is this patient a suitable heart transplant candidate?” must therefore be asked and answered. The evaluation is comprehensive, including the elements outlined in Table 48-1. However, a thorough evaluation is either unnecessary or could be delayed, if indications are not met (Table 48-2) or if risks are inordinately high (Table 48-3). A history of severe heart failure or suboptimally treated heart failure is, per se, an insufficient indication for heart transplantation. These patients may actually still have stage C heart failure.³

Specific selection criteria vary among transplant centers, but several general patient characteristics and factors are common among the majority of programs. Table 48-2 lists the indications generally used when a patient is considered for cardiac transplantation. Left ventricular function parallels the prognosis in severe cardiac failure. Survival dwindles as objective measures of left ventricular function decline. However, a low left ventricular ejection fraction alone is an inadequate indication for heart transplantation. Additional objective evidence of severe cardiac impairment is needed. For example, objective determinations of exercise capacity and oxygen consumption have proven useful in determining the degree of cardiac dysfunction and

prognosis.^{5,6} A peak oxygen consumption ($\dot{V}O_2$) of ≤ 14 mL/min/kg or ≤ 12 mL/min/kg in patients on β -adrenergic receptor antagonists⁷ indicates a degree of cardiac dysfunction sufficient to warrant consideration for transplantation. Alternatively, a peak $\dot{V}O_2$ of less than 50% of predicted for age and gender can prompt consideration for cardiac transplantation evaluation.⁶ Serial measurements provide a way to gauge the effectiveness of current therapies and the progression of disease during the waiting period. It is recommended that peak $\dot{V}O_2$ values be adjusted for patient age, gender, and weight.

Subjective measures also influence the decision to proceed with cardiac transplantation as part of the management of chronic heart failure. An unsatisfactory quality of life and intolerable symptoms of cardiac disease despite maximal medical therapy are key factors to consider. Although refractory heart failure is the principal reason by far for considering cardiac transplantation, numerous other cardiac disease entities also have been proposed as bases for transplantation, as shown in Table 48-2. Whatever the cause underlying the cardiac impairment, a predicted survival of 50% at 1 to 2 years without cardiac transplantation warrants proceeding with transplant evaluation and placement on the waiting list while conventional therapies are continued.

Table 48–1. Evaluation of Potential Cardiac Transplant Candidates

Detailed medical history and thorough physical examination
Laboratory evaluation:
CBC
Renal function tests (BUN/creatinine, creatinine clearance, GFR)
Liver function tests (alkaline phosphatase, bilirubin, albumin, transaminases)
Coagulation (prothrombin time, partial thromboplastin time)
Urinalysis
ABO blood type and antibody screen
Serologies for hepatitis A, B, C; HIV; cytomegalovirus; Epstein-Barr virus; herpes simplex virus I, II; <i>Toxoplasma gondii</i> ; syphilis; skin test for tuberculosis with controls
Right heart catheterization
Left heart catheterization/coronary angiography (if indicated)
Echocardiogram (or other form of ventriculography, if indicated)
ECG and/chest x-ray
Carotid ultrasound (if indicated)
Pulmonary function tests
Exercise testing with measured oxygen consumption $\dot{V}O_2$
Histocompatibility leukocyte antigen (HLA) typing/panel reactive antibody (PRA)
Psychosocial/financial consultation

CBC, complete blood count; BUN, blood urea nitrogen; GFR, glomerular filtration rate; HIV, Human immunodeficiency virus; ECG, electrocardiogram.

Table 48–2. Indications for Heart Transplantation

Heart failure requiring respirator, intra-aortic balloon pump, or ventricular assist device
Heart failure requiring continuous inotropic support
Refractory NYHA Class III or IV symptoms despite maximal medical and surgical therapy
Estimated 1-year survival without transplantation $\leq 50\%$
Peak oxygen consumption $\dot{V}O_2 \leq 12$ -14 mL/kg/min or marked serial decline over time
Hypertrophic or restrictive cardiomyopathy with NYHA Class IIIb-IV symptoms
Refractory angina pectoris despite optimal medical, surgical, and/or interventional therapy
Recurrent life-threatening ventricular arrhythmias despite optimal medical, electrophysiologic, device, and surgical therapy
Cardiac tumors with low likelihood of metastasis
Medically refractory NYHA Class III-IV heart failure due to surgically untreatable complex congenital heart disease
Hypoplastic left heart syndrome

NYHA, New York Heart Association.

Table 48–3. Risk Factors

Age ≥ 65 years
Diabetes mellitus if:
End-organ dysfunction (retinopathy, nephropathy, neuropathy)
Poor glycemic control despite aggressive medical and dietary therapy
Intractable pulmonary hypertension despite maximal vasodilators/inotropes
Transpulmonary gradient ≥ 15 to 20 mm Hg
PVR ≥ 4 -6 Wood units
Extensive peripheral vascular disease
Significant cerebrovascular disease
Marked renal impairment
Serum creatinine >2.5 mg/dL
Creatinine clearance <50 mL/min
Marked hepatic impairment
Serum bilirubin >2.0 mg/dL
Serum transaminases $>$ twice upper limits of normal
Elevated prothrombin time without anticoagulation
Significant pulmonary dysfunction
Active infection
Malignancy/history of malignancy without evidence of cure
Obesity: BMI >40 kg/m ²
Active psychiatric disorders
Inadequate financial resources/social support

PVR, pulmonary vascular resistance; BMI, body mass index.

Once the degree of cardiac impairment meets one of the preceding indications, a comprehensive evaluation is performed to detect conditions that decrease the likelihood of a favorable posttransplant outcome. Table 48-3 delineates many of the risk factors that help determine the safety and appropriateness of transplantation for stage D heart failure. Most of these are no longer viewed as contraindications to cardiac transplantation, but risk factors only. In fact, while not routinely advisable, most have been successfully overcome in carefully selected individual patients.

Age

Most centers set a specific age limit beyond which patients are not considered as potential candidates.^{8,9} Although survival in older patients has modestly improved in recent years, the registry of the International Society for Heart and Lung Transplantation (ISHLT) indicates that older age remains a continuous predictor of 1-year and 5-year mortality following transplantation.² Enthusiasm for transplanting patients older than 65 to 70 years of age is further tempered by the scarcity of donor hearts and the higher prevalence of coexistent medical illnesses in the older patient population. Although not a universally accepted practice, alternate waiting lists have been used for candidates over the age of 70 years. Transplantation then proceeds using donor hearts that otherwise would not have been used.

Diabetes Mellitus

Some patients with diabetes mellitus and no, or minimal end-organ damage have been transplanted with excellent short and intermediate outcomes. Yet diabetes still poses additional challenges posttransplant. Patients with less than optimal glycemic control often worsen considerably with the use of corticosteroids following transplantation. Insulin may be required for a time postoperatively even in those patients previously well controlled with dietary measures or oral hypoglycemic agents. Evidence of end-organ damage before transplantation may identify patients with more advanced diabetes and define a subset of diabetics likely to suffer considerable deterioration of diabetes following the procedure. In general, those patients with manifestations of proliferative retinopathy, nephropathy, neuropathy, or peripheral vascular complications secondary to their diabetes are considered higher-risk candidates for cardiac transplantation. The most recent ISHLT registry indicates a significant 1-year mortality risk in insulin-dependent diabetic recipients.²

Pulmonary Hypertension

Elevated pulmonary arterial pressures and pulmonary vascular resistance are common in patients with the degree of cardiac failure that compels consideration of cardiac transplantation. However, excessive elevations of pulmonary vascular resistance identify patients at high risk following the transplant procedure. Several studies have shown that marked pulmonary hypertension is associated with increased early mortality secondary to right ventricular failure during the perioperative period.^{10,11,12} During the initial evaluation of a patient under consideration, right heart catheterization and direct measurement of the hemodynamic parameters is performed. A pulmonary artery systolic pressure of 50 mm Hg, a transpulmonary gradient of 15 mm Hg, or a pulmonary vascular resistance of 3 Wood units should prompt a challenge with a vasodilator and/or an inotropic agent. If these parameters can be corrected during initial hemodynamic measurement (e.g., with the administration of intravenous nitroprusside or inotropic agent), then it can safely be assumed that these abnormalities are secondary to the marked degree of cardiac dysfunction. Alternatively, patients whose initial hemodynamic status precludes consideration may be re-evaluated after a period of augmented medical therapy, particularly if earlier therapies had not yet been maximized. Patients with persistent pulmonary arterial hypertension despite a trial of different medical therapies may be considered for mechanical circulatory support to decrease left ventricular filling pressures over a period of months and assessing whether pulmonary pressures have become acceptable for heart transplantation. Serial measurements of hemodynamic status are routinely performed during the waiting period, not only to monitor the effectiveness of current medical therapies, but also to allow intervention if worsening pulmonary hypertension and elevated pulmonary vascular resistance are detected. On occasion, it is necessary to hospitalize patients and administer continuous intravenous vasodilators or inotropes to avoid the development of irreversible pulmonary hypertension, which would prohibit cardiac transplantation. In some instances, using a larger donor heart than would normally be required based upon the recipient body surface area may offer increased right ventricular work capacity to overcome the elevated pulmonary vascular resistance. Otherwise, only a combined heart-lung transplantation or heterotopic heart transplantation to surmount excessive pulmonary

hypertension would be feasible.¹³ In this age of increased use and better timing of mechanical circulatory support, these latter options are seldom used.

Peripheral Vascular Disease and Cerebrovascular Disease

Symptomatic peripheral vascular disease and significant cerebrovascular disease pose additional hazards following transplantation. Severe peripheral vascular obstruction can occasionally preclude the use of an intra-aortic balloon pump and may impede the functional capacity of the transplant recipient in the long run. The risk of stroke and lower extremity ischemia following transplantation should be assessed. As part of the routine pretransplant evaluation, carotid Doppler ultrasound should be performed in patients with coronary artery disease or in patients older than 40 to 50 years of age. If significant carotid occlusive disease is identified, surgical correction should be strongly considered before transplantation.¹⁴

Renal and Hepatic Impairment

Abnormal renal and hepatic function are common consequences of poor cardiac performance. Restoration of adequate perfusion following heart transplantation resolves the dysfunction. In cases of irreversible dysfunction of liver or kidneys not due to poor pretransplant perfusion, however, the dysfunction may worsen after transplantation due to the well-described hepatic and renal toxicities of the immunosuppressive agents used to prevent rejection.

Pulmonary Function

Severe chronic lung disease not only carries an increased risk of complications during the perioperative period, but also independently lessens the patient's functional capacity and survival following transplantation. An increased incidence of pulmonary infection has been noted in patient's with pulmonary dysfunction who receive immunosuppressive therapy. As a general rule, a forced expiratory volume in 1 second (FEV₁), a forced vital capacity (FVC), or an FEV₁/FVC ratio of $\leq 60\%$ of predicted despite maximal therapy identifies a serious impediment to a successful transplantation.

Infection

Active infection greatly increases the risk of transplantation as the infection will worsen after immunosuppression is begun. Hospitalized patients awaiting transplantation are at particular risk for exposure to various nosocomial infections. Diligent evaluation of any clinical or laboratory abnormality that suggests the possibility of infection should be undertaken. Any febrile syndrome or leukocytosis must be thoroughly investigated to avert potential disaster once immunocompetence is diminished. Candidacy is deferred until adequate treatment of active infection is assured.

However, a patient who tests positive for cytomegalovirus, *Toxoplasma gondii*, Epstein-Barr virus, or who has a positive tuberculin skin test is not excluded from consideration; rather the patient requires additional care and treatment after immunosuppression is begun. A thorough dental examination, with appropriate treatment, and screening for hepatitis B and C and human immunodeficiency virus (HIV), are warranted. Positive testing for hepatitis B or C does not necessarily preclude transplant consideration but requires additional evaluation.

Furthermore, even a patient who is HIV positive without a history of an AIDS-defining illness may not be excluded from transplant evaluation. These patients should be evaluated on an individual basis.¹⁵

Malignancy

Transplantation of a patient with a malignancy without evidence of cure is extraordinarily risky. Despite some reports indicating moderate short-term success in patients with malignancies undergoing successful transplantation,¹⁶ consideration should be given only to those patients who have a suitable response to medical or surgical therapy, have a low malignancy recurrence rate, and have been disease-free for a sufficient period of time following the initial diagnosis.

Obesity

At most transplant centers, class III or morbid obesity (body mass index [BMI] ≥ 40 kg/m²) has been considered a relative contraindication. This degree of obesity may predispose to poor wound healing, higher infection risk, and worse functional recovery after transplantation. Obesity has also been associated with increased cardiac allograft vasculopathy and worse survival after transplant.^{17,18} In addition, difficulty is encountered identifying a suitable donor heart, which can accommodate the size match required for a morbidly obese transplant candidate.

Psychosocial Issues

Psychiatric illness can impede a patient's ability to understand, consent to, and comply with a complex medical regimen. Simple reactive depression associated with severe cardiac impairment is not unexpected and likely does not preclude cardiac transplantation. A careful and thorough evaluation by qualified professionals, though, is essential for a comprehensive pretransplant examination. In addition to active psychiatric illness, certain behaviors can reduce a patient's suitability for transplant. Active substance abuse, or prior substance abuse without clearly documented abstinence, may profoundly increase the risk of both posttransplant medical noncompliance and substance abuse recidivism. Tobacco use and alcohol abuse should be categorized with illicit drugs in estimating the scope of active or previous substance abuse. Psychosocial concerns must be resolved so that participation in the intricate and continual process of care after transplantation can be assured.

Finances

Most insurers and third-party carriers will cover the expenses incurred in the transplant procedure itself. Some even have allowances for medications and long-term care. However, the costs of future care and the need for psychosocial support must be evaluated and addressed. Undergoing a heart transplant is challenging and when onerous financial issues are added to the complexity, noncompliance, and suboptimal outcomes may result.

Pretransplant Patient Management

To care for a patient with end-stage heart failure awaiting heart transplantation, the physician must determine whether ongoing therapy, be it outpatient, inpatient, or intensive care unit-based, is sufficient. If the care is insufficient, metabolic, cellular, and nutritional health is compromised. Transplantation at a

time when end-organ function is marginal, increases posttransplant morbidity and mortality. Many patients may have a very low functional threshold beyond which additional demands upon their cardiac performance lead to decompensation and end-organ compromise. Frequent and diligent examination of candidates awaiting cardiac transplantation is needed to ensure continued suitability for transplantation. The common symptoms, physical signs, and objective measures of cardiopulmonary status that are regularly assessed are listed in Table 48-4. Evidence of deterioration is often heralded by an increase in the

Table 48-4. Evidence of Instability in Heart Failure

Indications of Intolerance of Current Medical Management

Worsening Cardiovascular Symptoms

- Easy fatigability
- Increasing frequency and severity of angina
- Exertional dyspnea/shortness of breath at rest
- Orthopnea/paroxysmal nocturnal dyspnea
- Dysrhythmia (tachycardia, palpitations)

Worsening Cardiovascular Physical Signs

- Hypotension/low pulse pressure
- Resting tachycardia/frequent ventricular ectopy/atrial fibrillation
- Elevated jugular venous pressure
- Prominent S₃/S₄
- Loud murmur of mitral/tricuspid regurgitation
- Hepatomegaly/ascites/hepatojugular reflux
- Edema/anasarca
- Diminished peripheral perfusion (cyanosis/delayed capillary refill)

Worsening Objective Measures of Cardiac Performance

- Diminished renal perfusion (prerenal azotemia/rising serum creatinine)
- Hepatic congestion (elevated liver function tests)
- Decreased end-organ perfusion (metabolic acidosis/elevated serum lactate)
- Deteriorating left ventricular function by echocardiogram
- Decreased left ventricular ejection fraction by radionuclide ventriculography
- Worsened cardiomegaly/pulmonary edema on chest x-ray
- Diminished maximal oxygen consumption $\dot{V}O_2$ on exercise testing
- Abnormal parameters on right heart catheterization
- Elevated central venous pressure
- Worsening pulmonary arterial hypertension/pulmonary vascular resistance
- Declining cardiac output/cardiac index
- Increasing arteriovenous oxygen difference (A- $\dot{V}O_2$)

frequency and severity of these parameters. Continued decline despite appropriate adjustments to the patient's medical regimen signals a severity of illness beyond the capacity of ongoing therapy and should prompt an escalation in the therapeutic intensity.

Invasive hemodynamic monitoring plays an integral role in the management of any patient awaiting cardiac transplantation. As discussed earlier, it is essential to accurately determine the reversibility of the elevated pulmonary arterial pressures and pulmonary vascular resistance to ensure the highest likelihood of a favorable outcome following transplantation. Furthermore, the determination of cardiac filling pressures is a valuable aid in predicting prognosis during the waiting period. As an adjunct to a detailed history and physical examination, and the laboratory and other studies previously described, periodic hemodynamic evaluation is essential to successful pretransplant patient management.

Medical Therapy in Advanced Cardiac Failure

Effective management of the patient awaiting cardiac transplantation requires an intricate strategy, and no single approach will be equally effective in all patients with severe cardiac dysfunction. Numerous general guidelines do exist. The medical evidence behind current heart failure treatment algorithms is found elsewhere in this textbook. Broadly speaking, there should be a low threshold for hospitalization and more intensive heart failure care for hemodynamic deterioration. Therapy should be escalated as needed from intravenous diuretics to intravenous inotropic agents and from intravenous inotropic agents to intra-aortic balloon pump or mechanical circulatory support. Further, drugs that earlier in the course of heart failure were beneficial and well-tolerated frequently are no longer tolerated at prior doses, if at all. The following list briefly addresses situations encountered in candidates awaiting heart transplantation.¹⁹

Relief of congestion. Effective diuresis can generally be achieved using loop diuretics in high doses or in continuous infusions, in combination with metolazone or intravenous thiazides, or at times with support from inotropic infusions or the administration of nesiritide. Ultrafiltration or even dialysis may occasionally be necessary.^{20,21} Thoracentesis for significant pleural effusions and paracentesis for ascites not resolving with diuresis is occasionally used.

Restoration of normal fluid status markedly enhances the response to vasodilators. Previously ineffective doses now lead to effective or even excessive vasodilation. Careful assessment generally distinguishes between excessive vasodilation and excessive diuresis. Diuretics should not needlessly be withheld.

Many patients effectively treated will have some increase in creatinine and blood urea nitrogen, often by as much as 50%. Slowing the rate of diuresis and avoiding excessive vasodilation will often allow renal function to stabilize.

Intravenous inotropic and vasodilator therapy. All inotropic agents should be used in as low a dose as possible and initially only to achieve a short-term goal, such as promoting effective diuresis or treating hypoperfusion with end-organ dysfunction. Although dobutamine, milrinone, and occasionally dopamine are the agents of choice, epinephrine and rarely isoproterenol can also be considered for very short-term support. Combining phosphodiesterase inhibitors with β -agonists may provide sufficient inotropic response with less than usual quantities of either agent, potentially averting the adverse effects of each when used

at higher doses. Dependence upon continuous intravenous inotropic support is a significant indicator of illness severity in patients awaiting cardiac transplantation. Those who require this mode of therapy to maintain hemodynamic stability are afforded a higher priority on the transplant waiting list.

Although intravenous inotropic agents are effective in improving cardiac hemodynamics acutely, they are unsafe for intermediate or chronic use. Administration should be limited to severely decompensated heart failure patients or patients who repeatedly demonstrate an inability to be weaned. Attempts to discontinue intravenous inotropes should be made. This requires careful titration of vasodilators and volume status. Some patients will have symptomatic hypotension on a dose of an angiotensin-converting enzyme (ACE) inhibitor that was tolerated during the inotrope infusion. Lower ACE inhibitor doses or other vasodilators should be attempted. One of the most common reasons patients do not tolerate the addition of ACE inhibitors during the weaning and discontinuation of intravenous inotropes is over-vasodilation and intravascular volume depletion. This is often indicated by a low systemic vascular resistance (SVR), which can be derived from Swan-Ganz catheter measurements. Furthermore, a rise in serum creatinine may also be observed given the concomitant renal vascular vasodilation. Modest adjustments in oral vasodilators to maintain appropriate SVR and cardiac output are essential before discontinuation of inotropic therapy. If repeated weaning attempts are unsuccessful, chronic inotropic therapy may be necessitated. If used in outpatients awaiting a suitable cardiac donor, an implantable cardioverter-defibrillator is warranted (ICD).

In some patients with marked systemic vasoconstriction, nitroprusside or nitroglycerin may provide similar acute hemodynamic benefits as inotropic therapy and allow more direct transition to oral regimens. Nitroprusside may be particularly beneficial when mitral regurgitation is severe. Nitroglycerin is also a very effective arteriolar vasodilator in the setting of severe vasoconstriction, but may be particularly helpful for initial symptom relief in patients with high pulmonary artery pressures and severe right heart failure in whom diuresis is not proceeding as rapidly as desired.

Oral vasodilator regimens: ACE inhibitors are the vasodilators of choice in stage D heart failure patients awaiting transplantation.³ It is generally not helpful to introduce or increase ACE inhibitors when patients remain unstable despite moderate inotropic support (e.g., dobutamine $\geq 5 \mu\text{g/kg/min}$).

Unfortunately, patients with resting systolic blood pressures of less than 85 mm Hg without vasodilators often do not tolerate ACE inhibitors. Patients with serum sodium less than 132 mM/L are at increased risk for symptomatic hypotension with ACE inhibitors but derive the greatest benefit. An elevated creatinine is not a reason, per se, to withhold ACE inhibitors. However, when effective diuresis is limited by deteriorating renal function, ACE inhibitors are generally withdrawn. Shock and hyperkalemia are contraindications to ACE inhibitor use. ACE inhibitor-induced symptomatic hypotension or significant renal dysfunction could prompt a trial of hydralazine and oral nitrates.²²

Angiotensin receptor blockers (ARBs) can be used as an alternative in ACE inhibitor-intolerant patients or as an addition in tolerant patients already on ACE inhibitors and β -adrenergic receptor antagonists.²³

Precipitating factors. Patients should be closely monitored for conditions that aggravate heart failure. Arrhythmias, anemia, infection, thyroid dysfunction, and medications with adverse hemodynamic effects on cardiac output or fluid retention are frequent culprits. These conditions should be treated as indicated.

Antiarrhythmic and cardiac resynchronization therapy. The technical sophistication, safety, and reliability of electrophysiologic devices have improved in recent years. The majority of heart transplant candidates will have undergone ICD implantation and cardiac resynchronization therapy, if also indicated.²⁴ Generally, these strategies will have been used earlier in the course of disease. The use of cardiac resynchronization therapy in stage D heart failure is rarely, if ever, even palliative.⁴

Patients with frequent or incessant arrhythmias or in whom the arrhythmias appear to be contributing to poor hemodynamics should undergo further therapy, which may include combination drug therapy and in some cases attempts at ablation of arrhythmic foci. Vigorous efforts should be made to establish and maintain sinus rhythm. Amiodarone is frequently the antiarrhythmic drug of choice.

Other medications. Patients taking β -blockers who develop decompensated heart failure should be maintained on β -blockers, if possible. The doses may need to be decreased to achieve hemodynamic goals. As heart failure progresses, β -blockers may not be tolerated at any dose, but, given that β -blockers have been studied in more than 20,000 patients with heart failure and the collective evidence from more than 20 placebo-controlled clinical trials is overwhelmingly positive, β -blockers should be reinstituted if at all possible.²⁵⁻²⁷ They will generally not be tolerated in patients with recurrent fluid retention or other signs of clinical instability. Typically, the combination of β -agonists and β -blockers administered simultaneously makes little sense.

When using aldosterone antagonists, close monitoring of serum electrolytes and renal function is a must, especially when used with ACE inhibitors or ARBs. Renal dysfunction (serum creatinine >2.5 mg/dL in men, >2.0 mg/dL in women), or a serum potassium level greater than 5.0 mmol/L usually prompts discontinuation, especially in older patients.^{28,29}

Digoxin remains an important adjunct. Low-dose digoxin, targeting serum levels between 0.5 and 0.8 ng/mL, may be used.³⁰ Vigilant observation is critical especially when fluctuating renal function is present. Calcium-channel blockers are not encouraged; however, amlodipine can be given for angina pectoris. Current heart failure guidelines do not recommend routine anticoagulation solely on the basis of a low left ventricular function in patients in sinus rhythm. On the other hand, the presence of atrial fibrillation, a previous thromboembolic event, or a left ventricular mural thrombus should prompt anticoagulation. Patients less than 3 months after a myocardial infarction or who have a patent foramen ovale with right ventricular failure are at increased thromboembolic risk, and anticoagulation could be considered.

Nutritional support. Nutritional support should be instituted if oral intake is inadequate. Early intervention with enteral (preferred) or parenteral supplementation is essential. Malnutrition impairs wound healing and increases the risk of perioperative infection.

Physical therapy. The prospect of potentially shorter recovery times, less perioperative functional impairment, and improved quality of life during the waiting period warrant consideration of rehabilitation therapy. Patients unable to participate in active

therapy should at least receive passive exercise. Subsequent rehabilitation should include bedside exercise and supervised walking as soon as possible.

Emotional support. The emotional and psychiatric aspects of chronic illness and uncertainty greatly influence a patient's sense of well-being and perceived benefits of therapy. Regular counseling sessions should be initiated and continue throughout the waiting period. Patients and their families must be informed about all aspects of heart transplantation.

Mechanical Circulatory Support

Mechanical circulatory support, discussed more fully elsewhere in this text, includes percutaneously and surgically implanted mechanical modalities intended to augment univentricular or biventricular function. Temporary devices may also incorporate membrane oxygenators to support gas exchange. Mechanical circulatory support allows patients to be "bridged" to transplantation and improve their chances of posttransplant survival.^{31,32}

The medical management of the mechanical circulatory support patient is challenging. It requires knowledge of individual device characteristics and expertise managing the critical illness related to surgical implant and physiologic changes associated with loading or unloading of native ventricles. Factors in the immediate postoperative period requiring acute intervention involve right ventricular optimization (including management of inotropes, intravascular volume, pulmonary vascular resistance, arrhythmias, tricuspid regurgitation, and interventricular septal shifts), systemic vasodilation, hemorrhage and coagulopathy, mechanical ventilation, and glycemic control.

In recent years, the percentage of patients supported on ventricular assist devices to cardiac transplant has doubled (from 11% to 22%, comparing periods 1999-2001 to 2002-2004).² Out-patient management of left ventricular assist devices in transplant candidates has likewise contributed to the large decline (45% from 72%) in patients requiring hospitalization while they await transplantation.

Surveillance anti-HLA Antibodies

The danger of acute, antibody-mediated rejection markedly increases when high titers of preformed anti-human leukocyte antigen (HLA) antibodies are present in the recipients serum. HLA antibody formation may occur with blood transfusion (e.g., at the time of coronary artery bypass grafting or following a left ventricular assist device implantation). Past pregnancies and infections with HLA cross-reacting bacterial or viral antigens may potentially prompt HLA antibody formation. Therefore, antigen exposure must be minimized. Any required transfusions should be leukocyte depleted. Serial measurement of reactive antibody titers referred to as panel reactive antibodies (PRA) are performed. If the PRA is significantly elevated, prospective cross-matching with a specific donor is performed before transplantation. Different inconclusive immunomodulation interventions have been attempted to lower pretransplant PRA. This process, however, imposes additional limitations on securing a suitable donor heart and increases the pretransplant risk and likely the posttransplant risk.

Immediate Pretransplant Considerations

Donor hearts are allocated based on degree of illness in the recipient, blood type compatibility, size disparity, and how long the candidate has been actively waiting for transplantation.³³

There are three gradations in severity of illness. Status 1A patients receive first priority. These include severely ill candidates who require invasive monitoring and multiple inotropic agents or a high-dose single inotropic agent, or recipients of mechanical circulatory support devices within the first month of implant or with a significant device malfunction. Status 1B includes candidates requiring intravenous inotropes, whereas Status 2 is assigned to any other actively listed candidate.

A blood type O donor can be used for a recipient of any blood type, a blood type A donor for either a blood type A or AB recipient, a blood type B donor for either a blood type B or AB recipient, and a blood type AB donor only for a blood type AB recipient. In general, the donor is usually no less than 80% of the recipients weight, but height disparity and recipient pulmonary hypertension are also considered.

Taking into account blood type and size, allocation is first to Status 1A, then to Status 1B, and finally to Status 2 patients. Within each group, those who have actively waited the longest are given preference on an individual donor.

Once a donor heart becomes available for a specific candidate, the patient is evaluated and prepared for surgery. The evaluation assesses whether any new medical information is manifest that would preclude a successful transplant (e.g., the presence of a new, active infection). Past medical history is reviewed to ensure that postoperatively no issues are forgotten (e.g., the treatment of chronic hypothyroidism). Anticoagulation, if present, is reversed with vitamin K and fresh frozen plasma. Prophylactic antibiotics are prescribed, typically a cephalosporin. Pretransplant immunosuppression is administered and the ICD, if present, is turned off.

Posttransplantation Management in the Critical Care Setting

Immediate Posttransplant Care

The management of a newly transplanted patient is both complex and challenging. The delivery of prompt and attentive care in the immediate postsurgical phase is crucial to future success. Following surgery, recipients return to the intensive care unit immediately, as would any patient undergoing a median sternotomy. Newly transplanted patients are hemodynamically monitored in the intensive care unit for a few days. A unique consideration in these patients is the totally denervated and somewhat dysfunctional heart due to the ischemic insult that occurred at the time of donor heart procurement and recipient implantation. Attempts are made to coordinate the donor heart procurement and subsequent transplant to minimize the ischemic time—time from cross-clamp application in the donor to its release in the recipient—to less than 4 hours.

The transplanted heart usually requires inotropic support and a higher preload (right atrial pressure of 8 to 15 mm Hg and pulmonary capillary wedge or left atrial pressure of 15 to 20 mm Hg) to achieve hemodynamic stability. Isoproterenol in doses of 0.25 to 5.00 $\mu\text{g}/\text{min}$ is an excellent choice because of its chronotropic and inotropic properties. Its lusitropic effect is also an added bonus in enhancing diastolic relaxation of the stiff heart with diminished diastolic compliance. Due to the limited stroke volume early on, heart rates of 110 to 120 beats/min are targeted to maintain adequate cardiac output. When further inotropic

support is needed, dobutamine (5 to 20 $\mu\text{g}/\text{kg}/\text{min}$), milrinone (0.2 to 0.75 $\mu\text{g}/\text{kg}/\text{min}$), and/or epinephrine (1.0 to 5.0 $\mu\text{g}/\text{min}$) may be used. The β -adrenergic receptors of the denervated heart are especially responsive to the full β -adrenergic agonist epinephrine because of the lack of neuronal uptake. On a rare occasion, pure α -adrenergic agonists such as phenylephrine may be used when faced with excessive vasodilation. The duration of inotropic support may be related to the effectiveness of the cardioplegia, donor age, and ischemic time, but typically lasts 2 to 5 days.³⁴

The sinus node is especially susceptible to cold ischemia because of its closeness to the cardiac epicardium. As a consequence, transient sinus bradycardia is not uncommon, especially in recipients previously treated with amiodarone. Cardiac pacing through surgically placed epicardial leads is effective on a temporary basis. Alternatively, theophylline may also be used with moderate success. Fewer than 5% of patients will require permanent pacing due to persistent bradycardia.

Perhaps the most important physiologic alteration of the denervated heart to be aware of is its propensity to respond differently to drugs, both commonly or uncommonly used. For example, cardiac allografts are exquisitely sensitive to adenosine and possibly epinephrine. Adenosine may induce prolonged asystole and, if used, should be initiated at half the usual recommended dose. On the other hand, the inotropic or chronotropic effects of drugs such as dopamine and ephedrine may be diminished. Finally, atrioventricular nodal blockers, such as digoxin, atropine, or quinidine, will have negligible or absent effects due to the lack of vagal innervation.³⁵

Posttransplant Immunosuppression

In the absence of immunosuppression, the patient's immune system will begin a cascade of events that eventually leads to cardiac allograft destruction. As shown in [Figure 48-3](#), this cascade involves antigen recognition, the process whereby the foreign tissue is recognized as non-self; T cell-centered events, which include the generation of growth factors; and cell proliferation and differentiation.³⁶

Multiple drugs are used, sequentially and in combination, to decrease the overall toxicities. Early rejection prophylaxis refers to agents used early after transplantation. Maintenance immunosuppression refers to drugs used early after transplantation but continued chronically. Many of the drugs used in early rejection prophylaxis can also be used to treat established rejection episodes. The commonly used drugs are listed in [Table 48-5](#).^{36,37}

Typically, recipients are treated with a three-drug combination, so called “triple drug therapy,” a calcineurin inhibitor (cyclosporine or tacrolimus), an antiproliferative (mycophenolate mofetil, mycophenolic acid, or azathioprine) or a proliferation signal inhibitor (an inhibitor of the molecular target of rapamycin [mTOR], e.g., sirolimus), and a corticosteroid. In early rejection prophylaxis, an interleukin-2 receptor blocker (basiliximab or daclizumab), a polyclonal antibody (thymoglobulin or antithymocyte globulin), or the murine monoclonal anti-CD3 antibody, may be used resulting in so called “quadruple therapy,” especially to delay the use of nephrotoxic calcineurin inhibitors.

Over time during maintenance immunosuppression, attempts to minimize the doses of all immunosuppressive drugs should be made, especially decreasing the target ranges of the calcineurin inhibitors and minimizing or eliminating corticosteroids.

Figure 48-3. Cascade of events leading to cardiac allograft rejection and destruction. Antigen processing leads to the presentation of a donor peptide (depicted as a red diamond) on an antigen presenting cell. Antigen recognition occurs as the T-cell receptor (TCR) is engaged by the donor peptide when coupled with a secondary signal. Calcium-dependent activation of calcineurin occurs, which enables the dephosphorylation of nuclear factor of activated T cells (NFAT). NFAT is able to cross into the nucleus and with other transcription factors synthesize various immune components, including interleukin-2 (IL-2). IL-2 and other growth factors activate the molecular target of rapamycin (mTOR), which activates cyclin-dependent kinases (CDK). CDK initiate the cell cycle, which, with the incorporation of purines and pyrimidines, leads to the synthesis of nucleic acids and cell division. Under the influence of various growth factors, proliferation and differentiation occur resulting eventually in cell-mediated and antibody-mediated immunity.

Posttransplant Complications that may Necessitate Intensive Care

In addition to immediate, postoperative management, transplant recipients may on occasion require evaluation, management, and treatment in cardiac intensive care.³⁸ Typically this will occur for cardiovascular, infectious, or other reasons. The causes of death following transplantation, as shown in Figure 48-4, indicate some of the challenges an intensivist may face.² Early on, cardiac and infectious causes predominate. Later, although cardiac causes diminish, they remain prominent, shifting from acute rejection to cardiac allograft vasculopathy as a cause of death. Also, while deaths due to infections diminish, death due to malignancy and renal failure increase.

The cardiovascular reasons for cardiac intensive care include ventricular dysfunction, arrhythmias, and cardiac allograft rejection, which usually have typical heart failure symptoms, hypotension, palpitations, or simply malaise and fatigue. The infectious causes typically present with fever, hypoxia, or simply malaise and fatigue. Other reasons prompting patients to come to the attention of critical care specialists are other critical care issues (e.g., gastrointestinal hemorrhage or those due to immunosuppressive drug toxicities).

Appropriate intensive care for the heart transplant recipient depends on both the ability to render excellent intensive care as one normally would and the recognition of the unique challenges of the transplant recipient. Care for a transplant recipient with a severe gastrointestinal hemorrhage has more to do with the gastrointestinal hemorrhage than with the transplant status, although the transplant status cannot be ignored.

Ventricular dysfunction. The transplanted heart has normal left and right ventricular function. Thus, any degree of dysfunction is abnormal, potentially life threatening, and requires explanation. The differential diagnosis includes cardiac allograft rejection and cardiac allograft vasculopathy. Once ventricular dysfunction is diagnosed, usually by echocardiography, an endomyocardial biopsy is emergently performed. The false negative rate is low so the absence of histological evidence of rejection prompts urgent coronary angiography.

Treatment of rejection depends on the type of rejection, cell-mediated or antibody mediated, histologic grade, degree of ventricular dysfunction, time after transplantation, past rejection history, and the current doses of immunosuppressive agents prescribed. Table 48-6 provides the grading scheme used and treatments generally prescribed.^{39,40} In situations where there is scant evidence of cellular rejection coupled with significant antibody-mediated rejection, plasmapheresis is recommended.

Treatment of cardiac allograft vasculopathy depends on the location of the disease, proximal or distal, the extent of the disease (focal or diffuse), the degree of disease in distal vessels, and the viability of the myocardium. The cardiac allograft vasculopathy that develops early after transplantation portends a poor prognosis. It is often extensive and diffuse with little, if any, hope of meaningful intervention. Later on, the disease tends to be more proximal and focal. In these situations, percutaneous intervention and even coronary artery bypass surgery may be appropriate. The proliferation signal inhibitors, mTOR inhibitors (e.g., sirolimus), decrease the incidence of cardiac allograft vasculopathy when used early after transplantation and appear to decrease progression of disease once cardiac allograft

Table 48–5. Immunosuppressive Agents in Heart Transplantation

Agent	Type	Use	Side Effects	Considerations
Cyclosporine	Calcineurin inhibitor	M	Nephrotoxicity, HTN, hirsutism, GH, neuro-toxicity, hypatotoxicity, hyperglycemia	Increased levels with ketoconazole, diltiazem, verapamil, erythromycin; decreased levels with phenytoin, phenobarbital, isoniazid, rifampin, carbamazepine
Tacrolimus	Calcineurin inhibitor	M	Nephrotoxicity, HTN neurotoxicity, hepato-toxicity, hyperglycemia	Increased levels with ketoconazole, diltiazem, verapamil, erythromycin; decreased levels with phenytoin, phenobarbital, isoniazid, rifampin, carbamazepine
Mycophenolate mofetil	Antiproliferative	M	Leukopenia, anemia, GI distress	
Mycophenolic acid	Antiproliferative	M	Leukopenia, anemia, GI distress	
Azathioprine	Antiproliferative	M	Leukopenia, anemia, pancreatitis	Increased levels with allopurinol
Sirolimus	Proliferation signal inhibitor	M	Hyperlipidemia, anemia, leukopenia, GI distress, dermatologic	Increased levels with ketoconazole, diltiazem, verapamil, erythromycin; decreased levels with phenytoin, phenobarbital, isoniazid, rifampin, carbamazepine
Prednisone, methylprednisolone, others	Corticosteroids	E M R	Pituitary-adrenal suppression, cushingoid habitus, glucose intolerance, hyperlipidemia, HTN, posterior subcapsular cataracts, myopathy, osteoporosis, skin fragility, peptic ulcer disease	
Basiliximab	Interleukin receptor blocker	E	GI distress	
Daclizumab	Interleukin receptor blocker	E	GI distress	
OKT3	Murine monoclonal anti-CD3 antibody	E R	Fever, chills, GI distress, pulmonary edema, HAMA antibody formation	First-dose reactions with profound vasodilation can occur
Thymoglobulin	Rabbit polyclonal lymphocyte immune globulin	E R	Leukopenia, thrombocytopenia, fevers, chills, arthralgias, serum sickness	
ATGAM	Equine polyclonal lymphocyte immune globulin	E R	Leukopenia, thrombocytopenia, fevers, arthralgias, serum sickness	

E, early rejection prophylaxis; M, maintenance immunosuppression; R, treatment of established rejection; HTN, hypertension; GH, gingival hyperplasia; GI, gastrointestinal; HAMA, human antimouse antibody.

vasculopathy is established.^{41,42} The physician should consider either adding an mTOR inhibitor or substituting one for another antiproliferative.⁴² In some cases, retransplantation is the only viable option, and it is only a viable option if the patient is a suitable transplant candidate. Survival after retransplantation is worse than after primary transplant, especially if the time between transplant and retransplant is short.²

Arrhythmias. Atrial arrhythmias occasionally occur and ventricular arrhythmias uncommonly occur after transplantation. Rhythm disturbances should be approached as in any other patient with the following caveats. In general, cardiac allograft rejection should be excluded as a cause, or treated if diagnosed, regardless of time posttransplant. Digoxin is not likely to be

beneficial in slowing the rate of atrial fibrillation, especially early after transplantation, since its mechanism of action depends primarily on cardiac innervation. Early after transplantation, especially in the postoperative period, β -blockers and the calcium channel blockers verapamil and diltiazem may not be well tolerated as the cardiac allograft is still recovering from an ischemic insult. Additionally, caution should be exercised when using verapamil and diltiazem because they will increase the levels of calcineurin inhibitors and mTOR inhibitors (see Table 48-5).³⁶ With ventricular arrhythmias, not only should cardiac allograft rejection be excluded as a cause and treated if diagnosed, but cardiac allograft vasculopathy should be considered in the differential diagnosis.

Infections. When infections occur, the etiologic agent is usually dependent on the time following transplantation.⁴³ Early after transplantation, usually up to 1 month, most infections are nosocomial and bacterial. Wound and line infections predominate but pneumonias also occur. Often, these infections are predisposed in patients who are poorly nourished and debilitated before transplantation or who have long postoperative intensive care unit stays. Later on, in the 2 to 4 month range, opportunistic infections appear. Cytomegalovirus and *Pneumocystis carinii* occur during this time frame as a result of the high dose immunosuppression used early on. Fortunately, prophylaxis is available and effective, valganciclovir or intravenous immunoglobulin for the former and trimethoprim sulfamethoxazole for the latter. Prophylaxis is used for other

Figure 48-4. Causes of death after transplantation. The cause of death after transplantation is influenced by time after transplantation. Light blue bars indicate recipients dying in the first 3 post-transplant years, and dark blue bars indicate recipients dying after the first 3 years. Although cardiac and infectious causes of death diminish after the first 3 years, deaths resulting from malignancy and renal failure increase. (Adapted from Taylor DO, Edwards LB, Boucek MM, et al: Registry of the International Society for Heart and Lung Transplantation: Twenty-fourth Official Adult Heart Transplant Report—2007. *J Heart Lung Transplant* 2007;26:773.)

common entities (e.g., acyclovir for *Herpes simplex* [if not on valganciclovir] and nystatin for oral candidiasis [when the patient is on high dose corticosteroids], and pyrimethamine for toxoplasmosis [during the first 6 weeks posttransplant if a toxoplasmosis positive donor was used]). Fungal infections peak in the first 1 to 2 months posttransplant and usually occur in patients who also have a bacterial infection treated with broad-spectrum antibiotics at the time they are also heavily immunosuppressed.

Once a transplant recipient is beyond the first 6 to 12 months posttransplant, most infections are typically those found in the general community. In general, this means that a patient having pneumonia at 12 months posttransplant is likely to have a community-acquired pneumonia and the usual approaches and treatments are appropriate. This contrasts sharply with a patient presenting at 3 months posttransplant with hypoxia and interstitial infiltrates. This latter patient should undergo urgent bronchoscopy to search for opportunistic agents.

If a heart transplant recipient presents to the cardiac intensive care unit with virtually any presentation, it is wise to assess the status of the cardiac allograft with an electrocardiogram and an echocardiogram. If ventricular function is not normal, one should proceed as outlined above.

Other. Unfortunately, while the immunosuppressive drugs decrease the risk of rejection and treat established rejection, they, as a group, have multiple side effects. The deleterious effects of the immune suppression are suggested by the increase in the malignancy as a cause of death after the first 3 years following transplant.

Future Directions

The future of cardiac transplantation will continue to be both intriguing and enigmatic. The continued trend of recipient demand exceeding donor heart supply compels continued exploration of alternative therapies for advanced cardiac failure. Further refinement of mechanical alternatives, immune or genetic modulation, and investigational agents are required to meet this challenge. Improved candidate selection and meticulous pretransplant management must suffice until these aspirations are realized.⁴⁴

Table 48-6. Cardiac Allograft Rejection: Grading* and Treatment

Qualitative Grade	Cellular Grade	Antibody-Mediated	Treatment†
None	0	Negative	None
Mild	1R	Positive	No treatment (followed by rebiopsy at shorter time interval), change calcineurin inhibitor, change antiproliferative, add an antiproliferative, or oral corticosteroid augmentation
Moderate	2R	Positive	Oral or intravenous corticosteroids or, if persistent on subsequent biopsy, antilymphocyte antibody + intravenous corticosteroids
Severe	3R	Positive	Antilymphocyte antibody + intravenous corticosteroids

*Based on the International Society for Heart and Lung Transplantation (ISHLT) Grading Scheme.

†In all situations, the dose of calcineurin inhibitor and antiproliferative agent(s) is(are) optimized; R, refers to the revised grading scheme; Oral corticosteroid augmentation, approximately 1 mg/kg/day for 5-10 days followed by tapering to prerejection doses; Intravenous corticosteroid, approximately methylprednisolone 500-1000 mg/day for 3 days followed by a rapid taper to prerejection doses.

Emergency Airway Management

Anushirvan Minokadeh, William C. Wilson

CHAPTER 49

Requirements for Safe Airway Management
Techniques of Emergency Airway Management
The Difficult Airway
Emergency Airway Management Complications

Anesthesia Induction Drugs for Rapid-Sequence Intubation
Clinical Scenarios
Conclusion

MAINTENANCE of adequate gas exchange is the fundamental responsibility of the physician managing the airway in emergency (i.e., “code blue”) situations. Failure to maintain a patent airway for more than a few minutes can lead to brain injury or death.¹ This chapter reviews the principles of emergency airway management, placing special emphasis on the critically ill or cardiac intensive care unit (CICU) patient.

This chapter is illustrated with numerous figures and tables demonstrating how to perform various airway management techniques. Emphasis is on illustrating the “when and why” of employing various airway management modalities, rather than merely providing a technical guide.

Regardless of the airway management situation, there are several essential requirements for safe airway management (including evaluation of the patient and the airway), discussed in the second section of this chapter. The third section reviews the various techniques and apparatus used in emergency airway management. The fourth section places the airway techniques in context by reviewing the essential airway complications that must be avoided. Essential components of this “disaster avoidance” discourse include management of the “difficult airway” and avoidance of esophageal intubation, aspiration, and hemodynamic compromise. Following the introduction of these fundamental principles of emergency airway management, several commonly encountered clinical scenarios are reviewed, with focus on their emergency airway management ramifications.

Requirements for Safe Airway Management

Regardless of the emergent nature of the “code blue,” some key drugs and several pieces of emergency airway equipment should be available before manipulation of the airway (Table 49-1).

Oxygen (O₂)

Oxygen should always be applied during assessment of the patient and before implementing airway management techniques. The application of supplemental oxygen can be lifesaving because oxygen deficiency is commonly encountered in

critically ill patients suffering from respiratory failure. Furthermore, the concept of *preoxygenation* (increasing the alveolar oxygen concentration before tracheal intubation) is a critical tenet of emergency airway management.

Supplemental Oxygen

The primary reason for oxygen administration is the prevention or treatment of hypoxemia. Numerous causes of hypoxemia exist and all are improved with the administration of 100% O₂ (Table 49-2).

Hypoxia is defined as oxygen deficiency at the tissue level. Anything that decreases oxygen delivery ($\dot{D}O_2$) may lead to hypoxia. Oxygen delivery depends upon cardiac output ($\dot{Q}$), hemoglobin concentration (Hgb), and arterial oxyhemoglobin saturation (SaO₂), as follows:

$$\dot{D}O_2 \text{ (mL O}_2\text{/min)} = \dot{Q} \text{ (mL/min)} \times \text{Hgb (gm/dL)} \times \text{SaO}_2 \times 1.34 \text{ (mL O}_2\text{/gm Hgb)}$$

Hypoxia occurs when $\dot{D}O_2$ decreases below adequate levels because of impaired myocardial function, anemia, or hypoxemia (due to decreased fraction of inspired O₂ [FiO₂] or increased shunt). Hypoxia can also occur secondary to increased metabolic rate or decreased utilization at the tissue level (e.g., cyanide poisoning). By administering oxygen to critically ill patients in respiratory failure, one can increase SaO₂, thereby improving $\dot{D}O_2$ until anemia, myocardial dysfunction, or right-to-left transpulmonary shunting abates.

Preoxygenation (Before Induction and Intubation)

Preoxygenation of the lungs is an essential component of any intubation technique that might involve a period of apnea. Preoxygenation is especially important for a rapid-sequence intubation because it allows for a reserve of oxygen in the lungs during apnea. For a patient who has been rendered apneic there is a finite period before arterial oxyhemoglobin desaturation. This period is related to the reservoir of oxygen in the lungs, or functional residual capacity (FRC), and is inversely related to the oxygen consumption (Fig. 49-1). Preoxygenation with 100% O₂ allows for up to 10 minutes of oxygen reserve following apnea (in a patient with healthy lungs); however, the patient

Table 49–1. Essential Preparatory Requirements for Safe Airway Management “Code Box”

Requirement	Equipment
Oxygen	BVM with oxygen inflow tubing
Ventilation	Soft nasal airway Rigid oral airway Emergency cricothyroidotomy device, or transtracheal jet ventilation (TTJV) equipment, LMA, ETC
Intubation	Laryngoscope with new tested batteries No. 3 and No. 4 Macintosh blades with functioning light bulbs No. 2 and No. 3 Miller blades with functioning light bulbs Endotracheal tubes - various sizes styletted with balloon pretested Laryngeal mask airway Esophageal-tracheal Combitube Tracheal tube guides (semirigid stylets, ventilating tube changer, light wand) Flexible fiberoptic intubation equipment Retrograde intubation equipment Adhesive tape or umbilical tape for securing ETT
Suction	Yankauer, endotracheal suction
Monitor	PETCO ₂ monitor, esophageal detector device
Drugs	IV induction and paralytic medication Topicalization drugs DeVilbiss sprayer for application of topical drugs Resuscitation drugs (epinephrine, atropine, etc.)
Miscellaneous	Various syringes, needles, stopcocks, IV connector tubes

Abbreviations: BVM, bag-valve mask; EDD, esophageal detector device; ETC, esophageal tracheal Combitube; ETTs, endotracheal tubes; IV, intravenous; LMA, laryngeal mask airway; PETCO₂, end tidal CO₂; TTJV, transtracheal jet ventilation.

who is preoxygenated with only room air (21% O₂) would have only about one fifth the time (or 2 minutes) before desaturation. Patients in respiratory failure frequently desaturate sooner owing to higher O₂ consumption, reduced FRC, and possibly lung disease with increased right-to-left transpulmonary shunting (Fig. 49-2).

Mask Ventilation Capability

It is critical to ensure the ability to apply oxygen in the CICU using positive pressure via a bag-valve-mask (BVM) device, along with oral and nasal airway adjuncts. BVM ventilation devices, such as an AMBU bag, deliver a significantly higher FIO₂ than either nasal cannulae or a mask alone (Table 49-3). Additionally, a BVM device enables one to ventilate a patient who is apneic or to assist ventilation in the patient with respiratory failure. The keys to using BVM devices are to provide adequate flow (10 to 15 L/min) and to ensure a tight seal between the mask and the patient's face so as not to entrain any room air during ventilation.

Intubation Equipment Check

Typically, the anesthesiologist, or other airway expert, brings the essential emergency intubation equipment to the resuscitation site in a “code box” (see Table 49-1). The user must inspect the “code box” each time he or she comes on call to make sure that the items listed in Table 49-1 are present and in working order before he or she is summoned to respond to a “code blue” situation and use the equipment.

All code box items need to be verified as present and in good working condition. The BVM device, styletted endotracheal tubes (ETT), and the laryngoscope, however, require some special notes about preparation and checkout.

The BVM device should be tested for integrity of the system and ability to generate positive pressure without leaks at connections. This can be done by using one's thumb to occlude the 15-mm exit flow orifice of the elbow connector (where it connects to a mask) while flowing O₂ through the O₂ connection tubing. The bag should inflate at a rate proportionate to the O₂ gas flow until one's occluding thumb is removed from the elbow connector exit flow orifice. If a self-inflating (AMBU) type of bag-mask device is used, pressure testing can be accomplished as already described, except that the bag will already be filled when the pressure test is begun.

The various sized styletted ETTs (balloon pretested) should be prepared as follows: An adult-sized ETT (size 7.0 or 8.0) should have a malleable stylet passed through its interior to a position just short of the tip (by approximately 5 to 10 mm). The malleable stylet allows the distal end of the ETT to be molded into a configuration that will most easily pass through the patient's vocal cords. Additionally, a styletted 6.0 ETT (or 5.0 ETT) should be prepared as a backup for patients who have small glottic openings or a difficult airway. The smaller ETTs commonly pass through a swollen or small glottic opening and into the trachea when a larger tube will not.

The rigid direct laryngoscope (RDL) with several blades is another critical piece of equipment. First, one must make sure the laryngoscope handle is clean and that the electrical connections are free of any corrosion or debris. Next, one should check that the batteries are fresh and generating a bright beam of light when the laryngoscope blades are attached. There must be at least two sizes of Miller and Macintosh blades (No.3 and No.4) so that various types of airway problems can be solved.

All of the items listed in Table 49-1 are essential and constitute the minimum airway equipment that the anesthesiologist or other airway expert should bring to the “code blue” situation.

Suction

Patients in respiratory failure may have thick secretions and/or may have vomited. To protect against aspiration and to better visualize the laryngeal anatomy, suctioning of the airway is frequently required during a “code blue.” The suction apparatus should be continuous (not intermittent) and of sufficient force to allow rapid clearance of thick oropharyngeal secretions or vomitus. During initial airway management, a Yankauer suction tip should be used to suction debris out of the oropharynx. After tracheal intubation, however, endotracheal suction catheters may be useful to clear secretions and aspirated material out of the airways.

Table 49–2. Causes of Hypoxemia in Critical Illness Requiring Emergency Airway Management

Causes	Example	P(A-a)O ₂	Response to 100% O ₂ *	Paco ₂	Therapy
Environmental causes (low P _{IO₂})	Low P _B (altitude)	Normal	↑ P _a O ₂	Normal	Give O ₂
	Low F _{IO₂} (e.g., excess N ₂ O)	Normal	↑↑ P _a O ₂	Normal	Give O ₂
Hypoventilation	- Respiratory depressant - Heroin OD - SCI	Normal	↑ P _a O ₂	↑↑	Give O ₂ then ↑ V _A
$\dot{V}_A/\dot{Q}_t$ mismatch	- Hypovolemia - Excessive V_T - Excessive PEEP	↑↑	↑↑ P _a O ₂	Normal	Give O ₂ then ↑ intravascular volume and adjust ventilation
Shunt($\dot{Q}_s/\dot{Q}_t$ R→L trans-pulmonary shunt)	- Lung collapse (HTX, PTX, atelectasis) - Pneumonia (aspiration) - Pulmonary contusion - Fat embolus - TRALI - ARDS (Sepsis/SIRS)	↑↑	No improvement in Q _s /Q _t units, but never all 2° to shunt	Normal	Give O ₂ then add PEEP, ↑ I:E ratio as tolerated
Diffusion	- Massive fluid resuscitation (interstitial edema) - ARDS	↑↑	↑ P _a O ₂	Normal	Give O ₂ then ↑ PEEP, diurese when clinically applicable
Anemia	Hemorrhage	↑	↑ P _a O ₂ (↑O ₂ content)	Normal	Give O ₂ , then transfuse PRBCs
↓ $\dot{Q}$	- Hypovolemia - Myocardial ischemia - Cardiac tamponade - PTX/HTX	↑↑	↑ P _a O ₂ (↑O ₂ content)	May ↓ in response to metabolic acidosis	Give O ₂ , then treat 1° cause
Histocytic hypoxic conditions	- CN toxicity - CO toxicity	↑↑	↑ P _a O ₂	May ↓ initially then ↑ as respiratory failure occurs	Give O ₂ , then add HBO for CO poisoning and d/c SNP for CN ⁻ toxicity

*Compared to F_{IO₂} = 0.21

↑, increased; ↓, decreased; P_{IO₂} (partial pressure of inspired O₂), F_{IO₂} × P_B; P_B, barometric pressure; F_{IO₂}, fraction of inspired oxygen; N₂O, nitrous oxide; P(A-a)O₂, partial pressure difference in O₂ between the alveolus (A) and arterial blood (a); P_aCO₂, partial pressure of CO₂ in arterial blood; O.D., overdose; SCI, Spinal cord injury; V_A, alveolar ventilation; $\dot{V}_A/\dot{Q}_t$ mismatch, alveolar ventilation/perfusion mismatch; V_T, tidal volume; PEEP, Positive end-expiratory pressure; PTX, pneumothorax; HTX, hemothorax; Asp, aspiration; TRALI, Transfusion related acute lung injury; ARDS, Acute respiratory distress syndrome; PRBCs, Packed red blood cells; $\dot{Q}$, Cardiac output; CN⁻, Cyanide; CO, Carbon monoxide; HBO, Hyperbaric oxygen.

Functioning Intravenous Catheter

A functioning intravenous catheter (IV) is mandatory when airway control is urgent but not emergent. The ability to administer fluids and cardiovascular support drugs is essential. Thus, after application of O₂ by mask, assessment of the airway, and establishment of ventilation, an IV line should be established before any attempts at airway manipulation. In a patient in full arrest, the trachea must be intubated first, and IV access may be secured secondarily. All advanced cardiac life support (ACLS) protocol drugs can be administered via the ETT except for ionic compounds (calcium, bicarbonate, and magnesium).

Monitoring (Pulse Oximetry, Blood Pressure, Electrocardiogram)

The airway expert must ensure that the patient is monitored with pulse oximetry, blood pressure cuff, and electrocardiogram (ECG) before attempting to intubate the trachea (whenever time allows). Vital sign stability and adequate arterial oxyhemoglobin

saturation are the goals of supportive measures before airway instrumentation and during and after intubation of the trachea.

Vasopressors and Inotropic Drugs

Vasopressors and inotropic drugs must be available for immediate use because hypotension is a common side effect of tracheal intubation. Hypotension can occur from the administration of anesthetic drugs, the use of positive pressure ventilation (PPV), or from relief of endogenous catecholamines elevated during respiratory failure and normalized following tracheal intubation. Furthermore, premorbid conditions in previously ill or elderly patients will further increase the likelihood of hypotension following intubation.

Airway Evaluation

Before attempting endotracheal intubation, the clinician should obtain historical and physical examination information to assess the patient's airway for technical ease of ventilation/intubation. If evaluation reveals that the patient's airway will be difficult to

Figure 49-1. FRC and relationship of oxygen reserve. This figure illustrates the factors that determine the time from apnea until desaturation, including the functional residual capacity (FRC), the concentration of oxygen in this reservoir (F_{IO_2}), and the oxygen consumption ($\dot{V}O_2$) of the patient. The spirometric trace on the left side of the figure depicts the relative volumes of the FRC, tidal volume (V_T), residual volume (RV), and vital capacity (VC). The reservoir of oxygen in the lungs at end exhalation (FRC) in a normal 70 kg patient is approximately 2.5 L, and the resting $\dot{V}O_2$ is approximately 250 mL/min. If the patient is breathing 100% oxygen, then there is theoretically 10 minutes before desaturation. Whereas, if the patient is breathing room air (21% oxygen), there is only 2 minutes before desaturation. Furthermore, ICU patients are typically sicker with lower FRCs, increased $\dot{V}O_2$, and increased shunting, all of which can cause more rapid desaturation following apnea. (From Wilson WC: *Emergency airway management of the ward*. In Hannowell LA, Waldron RJ (eds): *Airway Management*. Philadelphia, Lippincott-Raven Publishers, 1996, pp 443-451; with permission.)

intubate, the patient should be intubated while awake. Several outstanding reviews on evaluation of the difficult airway exist.^{2,4} In this section, a definition of the difficult airway is provided, and historical and physical examination keys for predicting airway difficulty are described.

Definition of Difficult Airway

Airway difficulty can occur during mask ventilation or during endotracheal intubation. The two are not synonymous, and indeed, some patients who are difficult to ventilate with a mask (edentulous, large-jawed) may be quite easy to intubate. The difficulty of maintaining gas exchange with mask ventilation can range from zero to infinite (Fig. 49-3, top).

Difficulty of intubation using direct laryngoscopy proceeds along a similar continuum from easy to nearly impossible (Fig. 49-3, bottom). *Difficult intubation* has been defined as requiring multiple attempts with multiple maneuvers, including external laryngeal pressure, multiple blades, and/or multiple endoscopists.

Probably the best definition of difficult intubation for documentation (from one anesthesiologist to another) or for research purposes involves the grading of laryngoscopic views (Fig. 49-4): Grade I is visualization of the entire laryngeal aperture; grade IV is visualization of the soft palate only; grades II and III are intermediate views.³ Grade III or IV laryngoscopic views correlate well with difficult intubations in the vast majority of patients.^{3,5} There are, however, some clinically relevant situations that provide exceptions to this rule. First, the skill of the endoscopist in manipulating the endotracheal tube and laryngoscope may have a significant effect on the grade of laryngoscopic view. Second, a grade III laryngoscopic view has been described differently by different investigators.^{3,6} Third, the blade used for laryngoscopy affects the grade applied to the situation. A long floppy epiglottis

Figure 49-2. SaO_2 versus time of apnea (in minutes) for various types of patients. Time to hemoglobin desaturation with initial F_{IO_2} is 0.87. The physiologic characteristics of these patients can be obtained from the author upon request. The SaO_2 versus time curves were produced by the computer apnea model. The mean times to recovery from 1 mg/kg intravenous succinylcholine are shown in the lower right hand corner. (From Benumof JL: *Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg IV succinylcholine*. *Anesthesiology*, 1997;87:979-982, with permission.)

may yield a high grade view (III or IV) with a MacIntosh blade and a relatively low grade (I or II) with a straight blade. Finally, traumatic conditions such as cervical spine injury (inability to move the neck into “sniffing” position), laryngeal fractures, or expanding hematomas may disassociate the laryngoscopic view from the difficulty of tracheal intubation.

Historical Indicators of Airway Difficulty

Any patient who is awake and capable of coherent conversation should be queried about prior intubation and ventilation successes or failures. Commonly, patients in the intensive care

unit (ICU) or CICU requiring emergent airway management are disoriented and unable to contribute historical data. Regardless of the patient's mental state, if time permits, the physician must review the patient's chart for details of previous intubations (easy or difficult) and other concurrent problems that may complicate the intubation plan. A good place to look is the anesthetic record for patients who have had prior surgery. If an obese patient relates that he or she requires nasal continuous positive airway pressure (CPAP) at night to sleep, mask ventilation or intubation may be more difficult than in a thin patient without such a history. Once the patient is recognized to have a difficult airway, the clinician should plan to secure the airway with the patient awake.

Table 49-3. Actual Fio_2 Achievable with Commonly Used Oxygen Administration Devices in Patients with Normal Ventilatory Breathing Patterns

Device	Flow Rate (L/min)	Achievable Fio_2
Nasal prongs	2	0.28
	6	0.44
Simple face mask	5-6	0.44
	7-8	0.6
Bag-mask device	6	0.6
	10	0.8+
	15	0.9+

Fio_2 , fraction of inspired O_2 .

Pathologic and Anatomic Predictors of Airway Difficulty

The patient who presents with stridor and cyanosis (from infectious, malignant, or traumatic causes) is easily recognized as having a potentially difficult airway. More subtle anatomic or pathologic causes of airway difficulty can go unrecognized in the ICU or CICU patient, however, owing to a hasty preintubation evaluation or to preoccupation with other aspects of the patient's care (e.g., acute myocardial ischemia or congestive heart failure [CHF]).

Pathologic Causes of Airway Difficulty

Several pathologic causes of airway difficulty are known to cause difficulty with mask ventilation (bull neck, thick beard, massive jaw, edentulousness, large tongue, mandibular fractures). Only some of these (bull neck and large tongue), however, are associated with difficulty of intubation. Indeed, edentulousness

Figure 49-3. Degree of airway difficulty continuum for mask ventilation and direct vision laryngoscopy at intubation. This illustration serves to provide a conceptual frame work for the definition of airway difficulty with mask ventilation (*top*) and direct vision laryngoscopy (*bottom*). The degree of difficulty ranges from zero degrees of difficulty to the impossible or infinitely difficult airway. The amount of difficulty can vary in the same patient with different anesthesiologists using various techniques. The grade of laryngoscopic view refers to grades defined by Cormack and Lehane (see Fig. 49-4). (From Benumof JL: *Management of the difficult airway. Anesthesiology* 1991;75:1087, with permission.)

Figure 49-4. Four grades of laryngoscopic view. The grading of laryngoscopic view is based upon the anatomic features that are visualized during the performance of direct laryngoscopy. (From Cormack RS, Lehane J: *Difficult tracheal intubation in obstetrics. Anesthesia* 1984;39: 1105, with permission.)

and mandibular fractures can actually make intubation of the trachea easier.

Pathologic factors associated with difficult intubation include congenital facial and upper airway deformities, cervical trauma, rheumatoid arthritis (because of decreased neck movement), intraoral tumor or abscess, and maxillary or facial airway trauma (in which edema, blood, and pus may obscure the view).

Anatomic Characteristics That Impair Laryngoscopy

Anatomic characteristics that are known to impair direct laryngoscopy are listed in Table 49-3. Of the seven predictors shown in Table 49-3, none is by itself predictive of airway difficulty. However, when taken in combination, airway difficulty can be predicted. Receding mandible or anterior larynx is evaluated in the fully extended adult neck. When the distance between the mandible and the upper border of thyroid cartilage is less than 6 cm, visualization of the vocal cords is predictably difficult.⁶

Airway Examination Principles

The 11-Step Airway Exam of Benumof

Although emergency conditions do not always allow for enough time, a physical examination of the airway should be conducted before the initiation of airway management of all patients. The intent of the airway examination is to detect anatomic and pathologic physical characteristics that may indicate that airway management will be difficult.

Currently, the American Society of Anesthesiologists Difficult Airway (ASA DA) guidelines have endorsed an easily performed 11 step airway physical examination, as originally proposed by Benumof (Table 49-4).⁷ The decision to examine all or some of the components listed in Table 49-4 depends upon the clinical context and judgment of the practitioner. The order of presentation in the table follows the “line of sight” that occurs during conventional oral laryngoscopy and intubation. Of note, several of the examination components listed in Table 49-4 require an awake, cooperative patient. Even in the noncooperative, semi-urgent situation, the airway expert can check the length of the upper incisors, the mandibular space compliance, thyromental distance, and neck length and neck thickness to assess the relative difficulty of intubation, as the aforementioned components do not require patient cooperation. Because certain elements of this 11-step examination cannot be practically evaluated in the all critically ill patients, an abbreviated airway examination is recommended.

Table 49-4. Anatomic/Pathologic Predictors of Difficult Intubation/Ventilation

Anatomy	Difficult Ventilation	Difficult Intubation
Neck	Bull neck Obesity	Bull neck Obesity Decreased head extension or neck flexion
Tongue	Large tongue	Large tongue
Mandible	Thick beard	Receding mandible Decreased jaw movement

Three Easy Airway Evaluation Tests

Missed signs of a difficult airway can be minimized if one looks carefully for both pathologic and anatomic abnormalities. Investigators have sought to determine anatomic characteristics that correlate with intubation difficulty. Three airway evaluation tests that are easy to perform have emerged as highly predictive indicators of intubation difficulty: Mallampati class, thyromental distance, and atlanto-occipital (AO) extension. When these three tests are used in the same patient, their combined predictive power becomes quite substantial.

Relative Tongue/Pharyngeal Size (Mallampati Class)

Mallampati and associates⁸ in 1985 proposed the size of the tongue in relation to the size of the oral cavity as a clinical sign of the difficulty of tracheal intubation (Fig. 49-5). Lewis and colleagues⁹ have demonstrated that the Mallampati classification is best obtained with the patient in the sitting position, with the head in full extension, with tongue out, and with phonation, because the test is more predictive and easier to perform under these conditions.

Thyromental Distance or Mandibular Space

Space anterior to the larynx—thyromental distance—greater than 6 cm suggests that direct laryngoscopy will be relatively easy.¹⁰ Because the tongue must be moved anteriorly and caudad

(in a supine patient) by the laryngoscope, the mandibular space must be large enough to accommodate the tongue and allow exposure of the glottis.

Atlanto-Occipital Joint Extension

Normally, 35 degrees of atlanto-occipital (AO) extension are possible at the AO joint. Bellhouse and Dore¹¹ have demonstrated that AO joint extension can be easily measured clinically, and that the measurement is highly predictive of the ease of intubation.

Evaluating the Airway of the Trauma Patient

In trauma patients (with suspected cervical spine injury), the neck must not be moved until radiographically and clinically confirmed as uninjured. Thus, such patients are analogous to those with little or no AO extension. Fortunately, the combined power of a favorable thyromental distance (>6 cm) and low Mallampati classification (I or II) provides quite strong predictors of an easy intubation.^{12,13}

Patient Preparation and Positioning

Regardless of whether an awake, topicalized technique or a rapid-sequence technique is chosen, proper patient positioning and preparation are important.

Preparation for Awake Technique

If a blind nasal or fiberoptic intubation is planned, the head of the patient's bed should be elevated at least 45 degrees to facilitate intubation. The patient should be psychologically prepared, and the airway expert must be thorough in ensuring that the nasopharynx, oropharynx, and larynx are properly anesthetized with topically applied local anesthesia before beginning intubation.

"Sniffing" Position (Preparation for Rapid-Sequence Technique)

The "sniffing" position is the optimum position for direct laryngoscopy and endotracheal intubation using a rapid-sequence technique. One of the most common reasons for difficulty with laryngoscopy and intubation is failure to place the patient in an adequate sniffing position. The sniffing position involves forward flexion of the neck on the chest and atlanto-occipital extension of the head at the neck. This maneuver aligns the oropharyngeal, laryngeal, and tracheal axes (Fig. 49-6). The easiest way to accomplish this is to place at least two folded towels under the head of the supine patient. The first attempt at laryngoscopy should be a well-prepared one. Once the patient is placed in an adequate sniffing position, a helper should apply cricoid pressure to protect against regurgitation of gastric contents.

Alternative Plan and Extra Help

After assessing the airway and evaluating the patient's underlying pathologic condition, one must devise a plan for intubation. If there is any concern that the patient's airway will be difficult to intubate, an awake technique with spontaneous ventilation should be chosen. Regardless of the primary plan, there must always be a "plan B."

Whenever securing the airway, one must make sure to have extra help available. The expert should communicate with the patient and the assistants to ascertain that everyone understands the plan.

Figure 49-5. Mallampati classification. Classification of the upper airway relating to the size of the tongue to the pharyngeal space based upon the anatomic features seen with the mouth open and the tongue extended. (Modified from Mallampati, SR et al. *A clinical sign to predict difficult tracheal intubation: a prospective study.* *Can J Anaesth* 1985;32:429, with permission.)

Techniques of Emergency Airway Management

Mask Ventilation

Types of Masks Used for Ventilation

Face masks come in a variety of shapes, but most airway experts prefer anatomically shaped masks because they fit the patient's face and the clinician's hand best. Adult masks come in small, medium, and large (sizes 3, 4, and 5). Most adults can be ventilated with a size 3 or 4 mask, but occasionally, a patient with a large jaw requires a size 5 mask.

Mask Ventilation Technique

The face mask must be applied firmly to the patient's face to ensure an adequate seal, although care must be taken not to injure the bridge of the nose with excessive pressure. A single-hand technique is acceptable if the airway is easy to ventilate (Fig. 49-7). If, however, ventilation is not easy, two hands should be used to hold the mask in place while another person depresses the bag in an attempt to ventilate the patient (Fig. 49-8). Frequently, the application of jaw thrust (backward and upward pull of the jaw in a supine patient) opens an airway and allows ventilation.

Oropharyngeal and Nasopharyngeal Airways

When the tongue and other soft tissues are maintained in the normal forward position, the posterior pharyngeal wall remains nonobstructed, and the airway is generally open (Fig. 49-9, A).

The most common cause of airway obstruction is falling back of the tongue and epiglottis in supine, unconscious patients (Fig. 49-9, B). This can be alleviated by the jaw thrust maneuver. Regardless of whether jaw thrust is successful, an oral or nasal airway as an adjunct to bag-mask ventilation can open up a closed airway.

Both oral (Fig. 49-9, C) and nasal (Fig. 49-9, D) airways restore airway patency by separating the tongue from the posterior pharyngeal wall. A rigid oral airway may elicit a gag response from an awake patient, which may be followed by emesis. Soft nasal airways provoke less gag response than rigid oral airways. Soft nasal airways are commonly inserted in patients suffering from ventilatory failure, who are more awake and prone to gagging on the rigid oral airway. Coagulopathies and nasal or basilar skull fractures are relative contraindications to nasal airways.

Figure 49-6. Head position and the axis of the upper airway. This diagram demonstrates the various head and neck positions in the supine patient and the corresponding oral axis (OA), pharyngeal axis (PA), and laryngeal axis (LA) in four different head positions. Each head position is accompanied by an inset that magnifies the upper airway and superimposes the continuity of these three axes within the upper airway. The upper left panel (A) shows the head in the neutral position with marked nonalignment of the various axes. In the upper right panel (B), the head is resting on a pillow, which causes forward flexion of the neck on the chest and serves to align the pharyngeal axis and the laryngeal axis. However, the oral axis remains nonaligned. The lower right panel (D) shows extension of the head on the neck without concomitant elevation of the head on the pad resulting in nonalignment of the oral pharyngeal with the laryngeal and pharyngeal axes. The lower left panel (C) shows the head resting on a pad that flexes the neck forward on the chest along with extension of the head on the neck, which brings all three axes into alignment (sniff position). This position allows for a direct view from the oral pharynx to the larynx providing the tongue and soft tissues are elevated out of the way with a rigid direct laryngoscope. (From Benumof JL: *Conventional (laryngoscopic) orotracheal and nasotracheal intubation (single lumen type)*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 123, with permission.)

Laryngeal Mask Airway (LMA)

Ventilatory obstruction above the level of the cords (supraglottic) can be alleviated by the LMA because of its supraglottic placement (Fig. 49-10). However, the LMA is not an effective ventilatory device in cases of periglottic or subglottic pathology (e.g., laryngospasm, subglottic obstruction).¹⁴

The LMA is inserted blindly into the oropharynx forming a low pressure seal around the laryngeal inlet, thereby permitting gentle positive pressure ventilation with a leak pressure in the range of 15 to 20 cm H₂O. Therefore, LMA is relatively contraindicated in the presence of a known supraglottic hematoma or other expanding lesion (e.g., abscess) that might rupture. However, it can be very useful in other supraglottic obstructive conditions such as those due to swelling, edema, or redundant tissues. Placement of an LMA requires a completely anesthetized airway or an anesthetized patient.¹⁵ The LMA has been shown to rapidly restore efficient ventilation in numerous cannot intubate-cannot ventilate situations.¹⁵⁻¹⁷

Rigid Direct Laryngoscopy

Before performing laryngoscopy, the airway expert should test the laryngoscope blade and handle to ensure proper functioning. The laryngoscope is held in the left hand, so that the right hand is free to place the styletted endotracheal tube through the

cords and into the trachea. The patient's mouth is opened by simultaneously extending the head on the neck with the right hand, and using the small finger of the left hand (while holding the laryngoscope) to push the anterior part of the mandible in a caudal direction and opening the mouth (Fig. 49-11).

As the blade enters the oral cavity, gentle pressure is applied on the tongue, sweeping it leftward and anteriorly (Fig. 49-12) so as to expose the glottic aperture. Two basic types of blades are in common use: a curved (MacIntosh) blade and a straight (Miller and Wisconsin) blade. The curved MacIntosh blade (Fig. 49-13) tip is placed in the vallecula after the tongue is slid leftward and anteriorly and while the laryngoscope handle is lifted in a forward and upward direction (stretching the hyoepiglottic ligament). This causes the epiglottis to move upward, exposing the arytenoid cartilages and eventually the vocal cords. The straight Miller blade (Fig. 49-14) is inserted until the epiglottis is visualized, and then the epiglottis is elevated to expose the glottic aperture.

Six common errors can occur during RDL use. First, the blade can be inserted too far into the pharynx, elevating the entire larynx which exposes the esophagus instead of the glottis. Second, for optimal laryngoscopy, the tongue must be completely swept to the left side of the mouth with the flange on the RDL blade. This is slightly more difficult to accomplish with the Miller blade

Figure 49-7. Mask ventilation one-hand technique. This figure shows the one-handed technique in holding a mask properly on a patient's face. The top figure (A) demonstrates the standard one-handed grip of the mask on the face. The thumb encircles the upper part of the patient's mask while the second and third finger are applied to the lower portion of the mask with the fourth and fifth fingers pulling the soft tissue under the mandible up toward the mask. The lower panel (B) demonstrates the one-handed mask grip while maintaining jaw thrust. The hand positions are altered such that only the thumb and the second finger encircle the mask while the third, fourth, and fifth fingers maintain upward and backward pull of the mandible "jaw thrust." Typically an oral airway would have been placed in the patient's oropharynx before manipulating the mandible with the "jaw thrust" maneuver. (Modified from McGee JP, Vender JS: *Nonintubation management of the airway*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 107, with permission.)

Figure 49-8. Two-hand mask ventilation technique. With the two-handed technique, the thumbs are hooked over the collar of the mask while the lower fingers maintain jaw thrust and the upper fingers are pulling the mandible into the mask while extending the head (arrows indicate direction of force). (Modified from McGee JP, Vender JS: *Nonintubation management of the airway*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 109, with permission.)

Figure 49-9. Normal airway, soft tissue obstruction, and use of laryngeal and nasopharyngeal airways. This series of four panels describes in sequence the normal (unobstructed) airway (A), the obstructed airway (B), and use of the oral (C) and nasal (D) airways. The normal airway (A) maintains the tongue and other soft tissues in the forward position, allowing unobstructed passage of air. The next panel (B) demonstrates the typical obstructed airway of an unconscious supine patient. The tongue and epiglottis fall back to the posterior pharyngeal wall and occlude the airway. In panel C, the use of oral pharyngeal airway is demonstrated. The oral pharyngeal airway follows the curvature of the tongue and pulls it and the epiglottis away from the posterior pharyngeal wall providing a channel for air passage. In the last panel (D), the use of the nasal pharyngeal airway is demonstrated. This airway passes through the nose and ends at a point just above the epiglottis clearing the air passage. (Modified from Stone DJ, Gal TJ: *Airway management*. In Miller RD (ed): *Anesthesia*, 4th ed. New York, Churchill Livingstone 1994; 1403–1436, with permission.)

because the flange is less prominent. Third, novice laryngoscopists frequently rock the RDL in the patient's mouth using the upper incisor as a fulcrum in a self-defeating attempt to visualize the glottis. This can chip the patient's upper incisors and moves the glottic aperture further anterior out of view. The correct approach is to lift the handle anterior and forward at an approximately 45° angle (see Fig. 49-14). Fourth, proper sniffing position is not always achieved or indicated. Fifth, in obese barrel-chested patients and large breasted women, it can be difficult to insert the blade in the mouth. Use of a short handled RDL or removal of the blade from the scope handle and reattaching once the blade is positioned in the mouth helps with this predicament. Finally, improper blade selection may hinder laryngoscopy and intubation. If the patient has a long floppy epiglottis, a Miller blade may be best; a large wide tongue may be best managed using a Macintosh blade.

Numerous developments have been made in the last decade combining fiberoptic technology with various configurations of

Figure 49-10. LMA. The normal anatomic position of the laryngeal mask airway. The proximal portion of the laryngeal mask rests upon the epiglottis, whereas the distal end extends into the pharynx at the upper end of the esophagus. The opening on the laryngeal mask overlies the laryngeal inlet. This figure demonstrates a prototypical LMA and is not meant to represent any particular commercially available device. (Modified from Brain AJJ: *The laryngeal mask: a new concept in airway management*. *Br J Anaesth* 1983;55:801, with permission.)

the laryngoscope, with the goal of improving intubation success, and decreasing the need to move the neck when manipulating the airway. Such laryngoscopic devices as the Bullard Laryngoscope (Circon, ACMI, Stamford, Conn.) and the WuScope (Achi Corp., Dublin, Calif.) are representative of this approach and have been in use for more than a decade. More recent innovations include the GlideScope (Verathon, Inc., Bothell, Wash.) (Fig. 49-15, 49-16). In recent studies of simulating easy and difficult airways with novice GlideScope users, the laryngoscopic view was either the same or superior in the difficult intubation scenario.¹⁸

Rapid Sequence Intubation

Patients who require emergency intubation are at increased risk of regurgitation and aspiration, partly because they have not fasted before induction. To minimize the likelihood of regurgitation and aspiration, RSI techniques were developed. Classically, RSI includes preoxygenation with 100% O₂ for 5 minutes (as discussed above), followed by the application of cricoid pressure, and in rapid sequence order an induction drug and a rapid acting neuromuscular blockade (NMB) drug (e.g., succinylcholine 1 to 2 mg/kg or Rocuronium, 1.2 mg/kg) are administered without testing ventilation beforehand. As soon as airway reflexes are lost, the RDL is used to visualize the glottis and facilitate placement of a styletated ETT. Cricoid pressure is maintained until P_{ET}-CO₂ is detected from the putative ETT, equal bilateral breath sounds are auscultated and the intubating anesthesiologist declares that it may be released.

Cricoid pressure (Sellick maneuver) denotes downward (posterior) pressure on the neck overlying the cricoid cartilage. This

Figure 49-11. Opening the mouth for laryngoscopy: use of the little finger. The mouth can be opened wide by concomitantly extending the head on the neck with the right hand while the small finger and the medial border of the left hand pushes the anterior aspect of the mandible in a caudad direction. The laryngoscope is held in the left hand while opening the mouth with this technique. As the blade approaches the mouth, it should be directed to the right side of the tongue. Gloves should be worn during laryngoscopy and the hands should be kept out of the oral cavity to limit contact with the patient's secretions. (From Benumof JL: *Conventional (laryngoscopic) orotracheal and nasotracheal intubation (single lumen type)*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 124, with permission.)

cricoid pressure compresses the esophagus and is intended to decrease the likelihood of gastric contents leaking into the pharynx. Occasionally, cricoid pressure can impair the laryngoscopic view. “Laryngeal manipulation” is not analogous to cricoid pressure; it is the movement of the thyroid cartilage posterior to bring the laryngeal aperture into view. Use of a rigid stylet also increases the likelihood of intubation success in difficult-to-intubate patients.^{19,20} During intubation attempts, the patient should be carefully monitored by pulse-oximetry, heart rate (HR), blood pressure (BP), and ECG. Intubation attempts should be interrupted by reoxygenation using BVM ventilation if the

procedure takes more than 30 seconds or when desaturation ($\text{SpO}_2 < 90\%$) occurs. If intubation attempts fail and adequate oxygenation cannot be achieved with BVM ventilation, a laryngeal mask airway (LMA) should be considered as per the ASA DA algorithm.¹⁴

Modified RSI Techniques

The RSI technique can be modified in at least two major ways: (1) institution of BVM ventilation before placement of the ETT and (2) allowing spontaneous ventilation (SV) to be maintained during placement of the ETT (Table 49-5).

Figure 49-12. Inserting the laryngoscope blade into the right side of the mouth. This figure demonstrates the proper head and neck positioning for insertion of a curved (Macintosh) laryngoscope blade. The inset shows the blade entering the right side of the oral cavity so that the tongue will be moved toward the left side of the mouth with the large flange on the Macintosh blade thereby creating a view of the larynx. (From Benumof JL: *Conventional (laryngoscopic) orotracheal and nasotracheal intubation (single lumen type)*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 125, with permission.)

Figure 49-13. Correct position of the Macintosh laryngoscope blade in the vallecula. This figure demonstrates the correct position of the curved (Macintosh) laryngoscope blade in the vallecula and the angle of pressure that should be applied (45 degrees from the patient's axial line). The inset demonstrates the laryngeal view obtained when the Macintosh blade is used. 1 = epiglottis, 2 = vocal cords, 3 = cuneiform part of arytenoid cartilage, and 4 = corniculate part of arytenoid cartilage. (From Benumof JL: *Conventional (laryngoscopic) orotracheal and nasotracheal intubation (single lumen type)*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 127, with permission.)

Figure 49-14. Laryngoscopic technique with a straight (Miller) blade. A straight (Miller) laryngoscope blade should pass underneath the laryngeal surface of the epiglottis; then the handle of the laryngoscope blade should be elevated at a 45-degree angle similar to that used with a Macintosh blade. By lifting up the epiglottis, the laryngeal aperture should come clearly into view. (From Benumof JL: *Conventional (laryngoscopic) orotracheal and nasotracheal intubation (single lumen type)*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 128, with permission.)

Figure 49-15. GlideScope video laryngoscope Cobalt. Single-use, sterile Cobalt GVL Stat with reusable Video Baton. (Images courtesy of Verathon, Inc.)

The application of BVM ventilation during RSI is indicated in instances where apnea is likely to result in rapid desaturation despite properly performed preoxygenation. Trauma and critically ill patients often suffer from conditions causing increased right-to-left transpulmonary shunting (e.g., pulmonary contusion, pneumonia) and thus require additional O_2 and ventilation after induction and before full effect of NMB drugs. This modification to the RSI technique involves gentle BVM ventilation with 100% O_2 while maintaining cricoid pressure (to prevent gastric insufflation and decrease the risk of regurgitation and/or aspiration).

The RSI technique can also be modified by maintaining SV. This modification is employed in situations where apnea may lead to the inability to ventilate (e.g., patients with partial airway obstruction manifested by audible stridor) and when positive pressure ventilation might extend a partial airway disruption into a complete separation (e.g., tracheal or main stem bronchus

Figure 49-16. GlideScope video laryngoscope. Actual airway view achieved by the GlideScope video laryngoscope. (Images courtesy of Verathon, Inc.)

tears). The maintenance of SV is also indicated in a patient who cannot tolerate the hemodynamic consequence of positive pressure ventilation (e.g., severe cardiac tamponade). An uncooperative patient with an obvious DA represents another patient condition where the maintenance of SV may be indicated. In this setting, a small dose of sedation should be administered to gain control of the situation and SV is preserved while employing cricoid pressure.

In situations where SV is maintained and the patient is sedated as needed, the trachea is often intubated using a fiberoptic bronchoscope (FOB) through an intubating mask (described in detail

Table 49–5. Rapid Sequence Intubation Principles: Classic Versus Modified Techniques

Elements	PRE-O ₂	Cricoid Pressure	Induction Drug Followed by NMBD	BVM Ventilation Deferred until ETT Confirmed	Confirm ETT with Paco ₂
Classical	+	+	+	+	+
Modified: by allowing BVM ventilation (with cricoid pressure) before ETT	+	+	+	(–) Can BVM vent as needed to avoid hypoxemia	+
Modified: By maintaining spontaneous ventilation until ETT placement confirmed*	+	+	(–) Small amounts of sedative or induction drug used, but SV maintained. No NMB given until ETT position confirmed.	(–) Can assist ventilation some, but goal is to maintain SV until ETT placed.	+

*No NMB drugs given until ETT in place or laryngoscopist convinced ETT placement will be easy.

Abbreviations: +, element is used during the technique of classical or modified Rapid Sequence Technique; (–) = not utilized; BVM, bag-valve-mask; ETT, endotracheal tube; NMBD, neuromuscular blockade drug; SV, spontaneous ventilation.

later).²¹ The proper amount of drug required to sedate the patient enough to manipulate the airway, but not so much as to result in apnea, varies based upon the size of the patient, the amount of blood loss, and the levels of other drugs already administered.

The Difficult Airway

The ASA Difficult Airway (DA) Algorithm

Practice guidelines for management of the DA were originally published in 1993²² and were updated recently in a report published by the ASA Task Force on Management of the DA.⁷

The original practice guidelines (1993) were developed by a taskforce of ASA members who expounded upon the original ideas put forth in a medical intelligence article written by Dr. Jonathan L. Benumof in 1991, entitled “Management of the DA.”⁴

In 1996, Dr. Benumof wrote another landmark article discussing the development and use of the LMA and its implications on the ASA DA algorithm.¹⁴ This article contributed to the ASA's decision to revise the 1993 algorithm. The current version has emerged after the ASA Task Force reviewed the literature published over the last 60 years and obtained expert opinions from other ASA members to build a consensus.

There are several critical decision tree elements present in the ASA DA algorithm. These include recognition of the difficult airway, awake intubation techniques, and anesthetized intubation techniques (whether recognized or not) (Fig. 49-17).

Recognition of the Difficult Airway

The ASA DA algorithm begins with recognition of airway difficulty. The patient who sustained penetrating trauma to the neck with stridor and cyanosis is easily recognized as a potentially difficult airway. However, there may be more subtle anatomic or pathologic causes of airway difficulty that can go unrecognized in the traumatized patient due to hasty preoperative evaluation or preoccupation with other aspects of the patient's care. Missed signs of a difficult airway can be minimized if one looks carefully for both pathologic and anatomic abnormalities as previously described. Whenever the patient is recognized to have a difficult airway, the clinician should consider securing the airway using an awake technique, as long as the patient is cooperative, hemodynamically stable, and spontaneously ventilating.

Awake Limb of the ASA Difficult Airway Algorithm

An “awake” intubation technique is recommended for patients with known or anticipated difficult airways provided they are cooperative, stable, and spontaneously ventilating. To optimize the conditions for successful intubation, cooperation is enhanced with proper mental and physical preparation. Although the ASA DA guidelines⁷ do not endorse any particular awake intubation tool or methodology, an awake FOB-guided technique is generally the safest and most appropriate for stable scenarios (discussed later in detail). It does emphasize, however, that the patient must be properly prepared (both mentally and physically) for an awake technique, the physician must ensure that spontaneous ventilation continues and O₂ saturation is maintained throughout the procedure. Even when a tracheostomy is planned, performing an awake FOB assisted intubation under direct vision is recommended whenever able to achieve airway protection before performing the formal tracheostomy.

The basic ASA DA algorithm recommends considering abandoning the airway attempt while maintaining spontaneous ventilation, and allowing the patient to recover from topicalization or sedative medications and resume management later with a better plan (other equipment/personnel). However, stopping is rarely an option in emergency airway management situations (i.e., the patient with cardiorespiratory failure). If at any time during the awake intubation manipulation, the patient is unable to ventilate by mask and intubation is not successful, then consideration should be given to use of emergency airway adjunct devices such as the LMA, esophageal tracheal Combitube (ETC), transtracheal jet ventilation (TTJV), or a surgical airway.

Unstable, Uncooperative, or Apneic Patients with Difficult Airways

There are three scenarios in which the need arises to intubate the trachea of an unstable, uncooperative, or apneic patient with pre-existing difficult airways. These situations include: (1) when the airway is not recognized to be difficult, (2) the DA patient is already unconscious before presentation to the “code blue” scenario, and (3) the DA patient is hemodynamically unstable or unable to cooperate with an awake technique. In all of these conditions, the generally anesthetized limb of the ASA DA algorithm is followed. In the uncooperative patient,

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:
 - A. Difficult Ventilation
 - B. Difficult Intubation
 - C. Difficult with Patient Cooperation or Consent
 - D. Difficult Tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:
 - A. Awake Intubation vs. Intubation Attempts After Induction of General Anesthesia
 - B. Non-invasive Technique for Initial Approach to Intubation vs. Invasive Technique for Initial Approach to Intubation
 - C. Preservation of Spontaneous Ventilation vs. Ablation of Spontaneous Ventilation

4. Develop primary and alternative strategies:

Figure 49-17. ASA difficult airway algorithm. (Modified from ASA Task Force: Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists' task force on management of the difficult airway. *Anesthesiology* 2003;98(5):1269-1277, with permission.)

Figure 49-18. Frontal view of the esophageal-tracheal Combitube. This figure demonstrates the two longitudinally fused tubes comprising the Combitube; both cuffs are inflated with their corresponding syringes. Lumen No.1 is the longer tube located on the left and lumen No.2 is on the right. (Modified from Wissler RN: *The esophageal-tracheal Combitube*. *Anesthesiol Rev* 1993;20:147-151, with permission.)

preinduction assessment should have identified factors that might make intubation of the trachea difficult and the airway expert should consider using a technique that maintains spontaneous ventilation despite the need for anesthesia. If intubation cannot be achieved, BVM ventilation should be attempted with enriched O₂ while applying cricoid pressure. In the cannot intubate-cannot ventilate (CNI-CNV) patient, the emergency limb of the ASA DA algorithm (Fig. 49-17) is followed. Various intubation modalities can be employed to maintain oxygenation before definitive ETT placement, the LMA being first. If ventilation is not successful with the LMA, other secondary emergency airway tools are tried including the ETC, TTJV, and the rigid ventilating bronchoscope. Various surgical airway techniques (cricothyroidotomy, tracheostomy) can also be considered.

Esophageal-Tracheal Combitube

The esophageal-tracheal Combitube (Sheridan Catheter Corporation, Argyle, N.Y.) was developed specifically for emergency airway management.²³ The Combitube consists of longitudinally fused tubes made of polyvinylchloride (PVC) with a standard 15-mm airway connector on the proximal end of each tube. There are two inflatable balloons on the Combitube: a proximal 100-mL latex pharyngeal balloon, and a 15-mL PVC balloon near the distal tip (Fig. 49-18). The Combitube has a distal curve to match the adult human hypopharynx. More than 96% of the times that a Combitube is inserted blindly into the oropharynx, esophageal placement results.²⁴

Figure 49-19. Esophageal trachea Combitube in the usual (esophageal) position. This figure demonstrates the ventilatory pattern usually encountered when the Combitube is blindly placed in the esophagus. (Modified from Wissler RN: *The esophageal-tracheal Combitube*. *Anesthesiol Rev* 1993;20:147-151, with permission.)

The Combitube is inserted until the two proximal black rings lie between the patient's upper incisors. At this time, the proximal balloon is inflated with 100 mL of air via the blue pilot tube. Next, the distal balloon is inflated with 15 mL of air via the white pilot tube. Ventilation is then initiated via the No. 1 tube, and CO₂ should be detected. Detection of CO₂ indicates that the Combitube was placed esophageally, so the air enters tube No. 1 and then enters the laryngeal aperture (Fig. 49-19). In the rare cases (less than 3%) in which the Combitube enters the trachea, ventilating with tube No.1 will not move the lungs, and CO₂ will not be detected from the exhalate of tube No.1.²³ At this point, tube No.2 should be ventilated and assessed for CO₂ (Fig. 49-20). The ETC is a commonly employed rescue method for gaining emergency airway access, especially in the "cannot intubate-cannot ventilate" patient.²¹

Laryngeal Mask Airway

The LMA is not only an emergency aid used to establish ventilation in the CNI-CNV situation; it can also serve as a conduit for intubation once ventilation has been established. The ASA DA Algorithm and guidelines do not endorse a particular brand or subtype of LMA (Classic, Fastrach, ILA). However, whenever gastric volumes are expected to be large (e.g., following large meal, known bowel obstruction), the ProSeal may be superior. Whenever the LMA will likely be used as a conduit for FOB-assisted intubation, the Cookgas ILA (Fig. 49-21) may be better because the ventilation tubing is wider and shorter than the other conventional LMAs, and does not have the epiglottis elevating bar that is present with the Fastrach.

Only in situations where there is absolutely no concern of airway swelling (i.e., partial airway obstruction), stridor, or abscess should the Fastrach be used with blind ETT insertion. In all of the aforementioned conditions, blind manipulation is contraindicated. The LMA is inserted blindly into the pharynx, forming a low-seal around the laryngeal inlet (Fig. 49-22). The special design features of the Fastrach, specifically, include a rigid, anatomically curved conduit that is wide enough to accept an 8.0 ETT with an epiglottic elevating bar to facilitate the blind passage of the special ETT (Fig. 49-23). As with all LMAs, the

Figure 49-20. Esophageal trachea Combitube in the tracheal position. This figure demonstrates the ventilatory pattern achieved when the Combitube is placed in the trachea. Tracheal positioning of the Combitube is rare as greater than 97% of the time the Combitube will enter the esophagus when placed blindly. (Modified from Wissler RN: *The esophageal-tracheal Combitube*. *Anesthesiol Rev* 1993;20:147-151, with permission.)

Fastrach is placed blindly and the cuff is inflated. Once ventilation is confirmed, the ETT can be blindly passed via the LMA conduit into the trachea. The blind intratracheal placement must be confirmed with P_{ETCO_2} , an EDD, or by FOB. The LMA can be kept in place until airway stability is achieved. Once successful, ETT placement through the LMA is verified, the LMA can be deflated and removed using a push device to help keep the ETT in place. If intubation is not successful, ventilation can occur via the LMA between attempts.

Passage of a FOB through the LMA or Fastrach has a much higher chance of success and is nearly 100% successful in most series.¹⁴ A 6.0 mm ID cuffed ETT (a nasal RAE tube is most suitable due to its additional length) may be passed over the fiberoptic bronchoscope and through the shaft of the Nos. 3- and 4-sized LMA whereas a 7.0-mm ID cuffed ETT will only fit through the shaft of the No. 5-sized LMA. Subsequently, if a larger ETT is required, the 6.0- or 7.0-mm ID cuffed ETT can be exchanged for a larger ETT using an airway exchange catheter (AEC).¹⁴ The various sized ETTs that fit through all sized LMAs and the FOBs that fit through these ETTs are displayed in Table 49-6. Alternatively, and preferably, when the glottic chink is expected to be of normal size, the authors recommend using the newer blue intubating LMA (ILA-by Cookgas, Mercury Medical, Clearwater, Fla.). A large size of 4.5 will allow passage of an 8.0 or 8.5 ETT (Fig. 49-21).

Generally, the largest FOB that will fit through the ETT is best to maximize the ability of passing the ETT through a normally sized adult glottis. The possibility of the ETT to hang up at the glottis is more common with use of the pediatric-sized FOB. However, if the patient has a small glottic chink, then a smaller FOB and ETT is better. If a 4.0 or less mm OD FOB is used with either the 6.0- or 7.0-mm ID ETT, the lungs can be continuously ventilated around the FOB while contained within the ETT by passing the FOB through the self-sealing diaphragm of a bronchoscopy elbow adapter. The distal and proximal ends of

Figure 49-21. Cookgas Intubating Laryngeal Airway (ILA). The Cookgas ILA has several benefits over other LMAs for emergency airway use: **A**, 15-mm airway connector ridges facilitate easy removal for fiberoptic airway management and improved tube seal upon replacement. **B**, Oval-shaped hypercurved airway ventilation tube resists kinking. In addition, the relatively large internal diameter accommodates large-sized adult endotracheal tubes (ETTs): 2.5 ILA allows 6.5 ETT; 3.5 ILA allows 7.5 ETT; and 4.5 ILA allows 8.5 ETT. Furthermore the relatively short length of ventilation tube facilitates fiberoptic intubation. **C**, The auxiliary airway hole improves airflow and prevents suction effects from drawing up the epiglottis inside the airway tube. **D**, The keyhole-shaped airway outlet directs both FOB and ETTs toward the laryngeal inlet, and is anatomically engineered to align with the glottic chink. **E**, The mask ridges move against posterior larynx improving anterior seal. **F**, Recessed front improves posterior pharyngeal fit and ILA stability. Available through Mercury Medical, Clearwater, Fla.

the bronchoscopy elbow adapter are connected to the ETT and ventilatory apparatus, respectively. Figure 49-24 shows the use of the bronchoscopy elbow adapter, 6.0-mm ID ETT and LMA for the continuous ventilation FOB intubation technique for both a nasal RAE and standard 6.0-mm ID ETTs. With a 4.0-mm OD FOB/6.0-mm ID ETT combination, the space available for ventilation around the FOB corresponds to a 4.5-mm ID ETT.

The LMA, as a ventilatory device and/or intubating conduit, can be placed into the ASA DA algorithm in three different places. These are (1) on the “awake intubation” limb of the algorithm as a conduit for FOB guided tracheal intubation, (2) on the “anesthetized” limb as both a life saving ventilatory device, and (3) as a conduit for FOB assisted tracheal intubation.

Rigid Bronchoscope

A rigid bronchoscope is a straight, metal, lighted tube capable of visualizing the large airways with ventilatory capacity through the associated ventilating side port (Fig. 49-25). The rigid bronchoscope is effective in cases of large airway masses

Figure 49-22. LMA insertion. With the neck extended and the head flexed, flatten the deflated cuff against the hard palate and advance until resistance is met. Once in place, inflate the cuff enough to achieve an adequate seal. (Images courtesy of LMA North America, Inc., San Diego.)

Figure 49-23. Fastrach LMA.

and bleeding. In the ASA DA algorithm, the application of the rigid bronchoscope is recommended as an emergency airway tool in the CNI-CNV situation, especially when LMA ventilation has failed or its use is not feasible. Similarly, the Bainton pharyngolaryngoscope (Figs. 49-26, 49-27) is a straight blade with a shallow vertical portion at the proximal end and incorporates a tubular distal portion (with an intraluminal light source

protected from secretions and obstruction); a tracheal tube with an inner diameter of 8 mm or smaller, optionally with the adapter removed, is easily passed through the tube of the blade without significantly obstructing the view.

Surgical Airway

Transtacheal Jet Ventilation

Transtacheal jet ventilation (TTJV) is another method of gaining emergency ventilation in a “cannot intubate-cannot ventilate” patient. The technique consists of palpating the cricothyroid membrane and advancing a 14-gauge catheter through the membrane and into the trachea with the needle tip pointed proximally 30 to 45 degrees caudad from the axis of the neck (Fig. 49-28). Once the catheter is in the trachea, its transtacheal position must be verified by attaching a syringe to the catheter and attempting to aspirate air. If air is not aspirated, the catheter may not be in the trachea and should be removed. After air aspiration has occurred, the needle stylet is withdrawn, and the hub of the intravenous catheter is connected to a transtacheal jet ventilation system (Fig. 49-29).

The TTJV system must have 25 to 50 pounds per square inch (psi) of pressure to allow flow down the small-bore (14-gauge) catheter. The natural airway must be maintained during exhalation; occasionally, some jaw thrust is required. Transtacheal jet ventilation can maintain oxygenation and adequate ventilation for more than 40 minutes.²⁵ Indeed, TTJV can take place while an alternative form of airway establishment is performed, such as fiberoptic bronchoscopy intubation.

Cricothyroidotomy - Percutaneous

The same technique described for TTJV is used to place a thin-wall (14-G or larger) needle into the trachea. Once the needle is confirmed intratracheal, a wire is passed through the needle

Table 49-6. Relevant Diameters of the Different Sized Laryngeal Mask Airways (LMAs), Endotracheal Tubes (ETTs), and Fiberoptic Bronchoscopes (FOBs) That Fit into the ETTs

LMA MFR	Size	Patient Weight (kg)	LMA Internal Diameter (ID mm)	Cuff Volume (mL)	Largest ETT Inside LMA (ID mm)	Largest FOB Inside ETT (mm)
Classic	1	<6.5	5.25	2-5	3.5	2.7

Cookgas ILA (Mercury Medical, Clearwater, Fla.)

Figure 49-24. A patient can be continuously ventilated during fiberoptic intubation using the laryngeal mask airway (LMA) as a conduit for the fiberoptic bronchoscope (FOB). By passing a 4.0-mm OD fiberscope through the self-sealing diaphragm of a bronchoscopy elbow adaptor and the tip of a cuffed 6.0-mm ID endotracheal tube (ETT) to the level of the grille on the LMA, ventilation can occur around the FOB but within the lumen of the ETT; the deflated cuff of the ETT inside the shaft of the LMA makes a tight enough seal to permit positive-pressure ventilation. Once the FOB is passed well into the trachea, the 6.0-mm ID ETT is pushed over the FOB into the trachea until the adaptor of the ETT is against the adaptor of the LMA (From Benumof JL: Laryngeal mask airway and the ASA difficult airway algorithm. *Anesthesiology* 1996;84:686-699, with permission.)

Figure 49-25. Rigid bronchoscope with ventilating side port, optic guide, and several sizes shown.

Figure 49-26. Bainton pharyngolaryngoscope. Scale drawing of the Bainton pharyngolaryngoscope. (From Bainton CR: A new laryngoscope blade to overcome pharyngeal obstruction, *Anesthesiology* 1987;67:767, with permission.)

into the trachea using the Seldinger technique (Fig. 49-28). Maintaining the guidewire several centimeters into the trachea, the cricothyrotomy site is dilated. Then, using the Seldinger technique, the cricothyrotomy tube is advanced, confirmed to be intratracheal and secured in place. Of note, whenever a formal tracheostomy can be performed, it is favored over the emergency cricothyroidotomy to prevent the subglottic stenosis frequently seen with cricothyrotomy.

Figure 49-27. Schematic of intubation technique with Bainton pharyngolaryngoscope. **A**, Tubular portion fits within the pharyngeal space. Tip of blade elevates epiglottis to permit laryngeal view. **B**, ETT without an adapter (stylet optional) is inserted into tubular portion of blade and advanced into larynx. ETT cuff is inflated. **C**, syringe and stylet are removed from ETT and pharyngolaryngoscope is withdrawn from mouth. Right hand of operator stabilizes ETT as blade is elevated over proximal end of ETT and cuff pilot tube. (From Bainton CR: A new laryngoscope blade to overcome pharyngeal obstruction, *Anesthesiology* 1987;67:767, with permission.)

Cricothyroidotomy - Open

Cricothyroidotomy is the emergency surgical airway of choice (versus tracheostomy) primarily due to the ease of determining anatomic landmarks (Fig. 49-30). The thyroid cartilage is stabilized and an incision is made through the skin and subcutaneous tissue overlying the cricothyroid membrane. The membrane is then opened with a stab incision and an endotracheal tube or cricothyrotomy tube is inserted and placement confirmed in the usual fashion.

Tracheostomy

Tracheostomy is less desirable in emergency airway scenarios than cricothyroidotomy because it is slower, requires additional steps, and has greater potential for bleeding. Optimally, a transverse skin incision is made in midline position (for cosmetic and healing purposes). However, in emergency situations with

Figure 49-28. This figure demonstrates a 14-gauge angiocatheter passing through the cricothyroid membrane at an angle approximately 30 degrees caudad from the skin. After achieving this position, the metal stylet is withdrawn and a syringe is applied to the catheter to confirm intratracheal position; aspiration of air is the expected end point if the 14 gauge catheter is truly in the tracheal lumen. (From Benumof JL, et al: *Transtacheal ventilation*. In Benumof JL (ed): *Clinical procedures in Anesthesia and Intensive Care*. Philadelphia, Lippincott-Raven Publisher, 1992, p. 199, with permission.)

novice surgeons, a vertical incision can be made in the neck (to minimize bleeding and avoid the anterior jugular veins) overlying the trachea and the cricoid cartilage (Fig. 49-31). Next, skin and subcutaneous tissue are divided with a scalpel through the platysma, the strap muscles, and potentially the thyroid isthmus. Once the first few tracheal rings are exposed, a horizontal incision is made between the first and second tracheal rings and the tube is introduced into the trachea. Percutaneous placement of a tracheostomy tube can be performed but is recommended under bronchoscopic guidance as to reduce the chance of paratracheal insertion and to document real time intratracheal position of the needle, wire, dilators, and the tracheostomy tube.

Blind Intubation Techniques

Generally, blind intubation techniques are rarely used as a "first-line" method and typically, in fact, are employed when other safer techniques have failed. Some techniques include the frequently used blind nasal approach (in awake, spontaneously ventilating patients) and techniques that are typically relegated

to anesthetized patients (including light wand, esophageal-tracheal Combitube, and retrograde wire). The blind nasal technique, being the most commonly employed blind technique, is described here in some detail.

Blind Nasal Intubation

Positioning, preparation, and topical anesthesia for a blind nasal intubation are the same as for fiberoptic bronchoscopy. For a blind nasal intubation, the patient should be spontaneously ventilating and, if possible, awake and cooperative. The ETT is placed in the already dilated and anesthetized nasal passage, and the airway expert's ear is placed near the 15-mm connector end of the endotracheal tube to listen for breath sounds. As the

ETT is passed down the nasal passage and toward the glottic aperture, the airway sounds from the patient will become much louder than previously noted. At this point, the airway expert should ask the patient to pant or take some deep breaths (both maneuvers tend to open the glottic aperture). During each inhalation, the ETT should be advanced. With this maneuver, the ETT can be essentially sucked into the larynx.

It is occasionally beneficial to use a flexible-tipped type of ETT known as an Endotrol tube. The Endotrol tube gives the intubator the ability to flex the ETT anteriorly while advancing the tube (Fig. 49-32). Clinical end points alerting the physician that the ETT is inside the patient's trachea are (1) the patient is no longer able to speak, (2) increased secretions are heard in the ETT, and (3) frequently, coughing is elicited as the ETT passes down the larynx advancing into the trachea. Following placement of the ETT, however, its position must be confirmed just as with other methods of intubation. In this case, an end-tidal CO₂ monitoring device is recommended.

Figure 49-29. This figure demonstrates the equipment used for pressurizing the already placed transtracheal catheter. (1) Wall oxygen pressure quick disconnect device. (2) Green Chemtron O₂ hose. (3) NPT hose barb connector. (4) Bird regulator gauge (0 to 50 psi). (5) NPT air hose connector. (6) High pressure self-coiling air hose. (7) Jet injector valve. (8) NPT hose barb connecting the injector valve to clear soft flexible tubing (9). (10) Hose barb connecting to the clear tubing with a standard Becton/Dickinson male Luer lock connector. (11) Transtracheal ventilation intravenous catheter with standard hub. (From Benumof JL, Scheller MS: *The importance of transtracheal jet ventilation in the management of the difficult airway*. *Anesthesiology* 1989;71:769-778, with permission.)

Intubation Using a Light Wand

The light wand is a rediscovered technique for intubating the trachea using a blind approach. The light wand is typically relegated to elective use in anesthetized patients, but it can also be a useful adjunct in the "cannot intubate-cannot ventilate" patient. The light wand was first described by Macintosh and Richard²⁶ in 1957. Several commercial versions of the light wand are now available. All are similar devices comprising a lighted stylet over which an ETT fits.

The patient is anesthetized, and the ETT with lighted stylet is passed into the oropharynx. Pulling the tongue out can frequently facilitate passing the light wand into the trachea. Once the ETT passes through the cords and enters the larynx, it produces a jack-o-lantern effect because of transillumination (Fig. 49-33). This effect is very prominent when the room lights are dimmed, but it can be difficult to appreciate in the bright lights of the CICU. Once the light wand is in the larynx, the endotracheal tube is advanced, and the stylet is withdrawn. At this point, confirmation that the ETT is in the larynx must be accomplished using end-tidal CO₂ monitoring or other technique.

Retrograde Wire Intubation

The retrograde technique of intubation was first described by Waters in 1963.²⁷ Waters employed a Tuohy needle passed in a cephalad direction through the cricothyroid membrane. An

Figure 49-30. Surgical cricothyroidotomy. Horizontal skin incision, incision of cricothyroid membrane, dilation of the opening, and introduction of a ventilation tube. (From Biro P, et al: *Transtracheal access and oxygenation techniques*. *Acta Anesth Scand* 1998;42:169, with permission.)

Figure 49-31. Tracheostomy. **A**, Transverse incision made usually for elective tracheostomy but a vertical incision allows for less bleeding when emergent procedure done. **B**, The strap muscles are separated and **(C, D)** thyroid isthmus retracted caudally. **E**, After the second tracheal ring is cleaned off, an inferiorly based flap is developed in the tracheal wall and sutured to the skin to allow easy access to the trachea while tract matures. (Neifeld JP *Head and Neck in Greenfield LJ, et al. (eds): Surgery: Scientific Principles and Practices. Philadelphia Lippincott-Raven Publishers, 1997, p 644, with permission.*)

Figure 49-32. Flexible tipped (Endtrol) nasotracheal tube. The flexible tipped nasotracheal tube can greatly aid blind nasal tracheal intubation. By pulling the ring, the endotracheal tube (ETT) flexes more anterior, this helps direct the tip around the soft palate and into the laryngeal inlet. (See inset). (From Ward CF, Salvatierra CA: *Special intubation techniques for the adult patient*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 154, with permission.)

epidural catheter was then threaded through the Tuohy needle, and the catheter was retrieved from the oropharynx using a plastic dressmaker's hook. Next, both the tube and the catheter were pulled through the vocal cords into the trachea by pulling on the catheter from the cricothyroid membrane. In 1967, Powell and Ozdil²⁸ introduced a wire-through-the-needle retrograde technique; in their modification, the wire was placed through the Murphy sidehole. This wire placement allowed the endotracheal tube to pass farther through the cords than it can when the wire passes out the tip of the endotracheal tube.²⁸ Other modifications of these techniques have been described,²⁹ but the basic technique remains the same. Indeed, the Cook Critical Care (Bloomington, Ind.) division has developed a commercially available emergency retrograde intubation kit.

Fiberoptic Bronchoscopy

Fiberoptic bronchoscopy (FOB) intubation can be performed in awake patients who are spontaneously breathing and in anesthetized or apneic patients. The technique for awake nasal

Figure 49-33. Transillumination of the larynx with light wand. This diagram demonstrates the jack-o'-lantern effect caused by transillumination of the soft tissues on the neck when the light wand enters the larynx. The left panel demonstrates the position of the light wand upon entry into the laryngeal inlet. The middle panel demonstrates this view from the anterior orientation and the right panel shows a side view of the light wand in position to cause transillumination of the anterior structures. (From Ward CF, Salvatierra CA: *Special intubation techniques for the adult patient*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 175, with permission).

fiberoptic intubation is described here in detail; FOB intubation of the anesthetized patient is only briefly described. There are many recipes for accomplishment of FOB intubation. Success with any of these techniques requires appropriate patient selection, sufficient patient preparation, and adequate endoscopist experience and skill (Table 49-7).

Patient Selection

Indications for fiberoptic bronchoscopy intubation are (1) situations in which alignment of the oral pharyngeal and laryngeal axes is difficult or ill-advised (e.g., cervical spine injury or neck fixed in a halo brace) and (2) any situation in which direct laryngoscopy is predicted to be difficult (i.e., HMD <6 cm, Mallampati class III or IV; see Fig. 49-5), especially in patients with a small mouth opening and in temporomandibular disease. Contraindications to FOB intubation include massive oropharyngeal bleeding or life-threatening airway obstruction, which would not allow time for adequate topicalization and severe hemodynamic instability, which similarly would not allow sufficient preparation or FOB intubation time.

Relative contraindications to FOB intubation are copious secretions and friable tissues that cannot be managed with antisialagogues and careful manipulation of the FOB. Tumors, abscesses, and maxillofacial trauma are all good indications for fiberoptic intubation, provided that the endoscopist can avoid the tumor, pus, and blood and see the entire way into the trachea.

Patient Preparation

Positioning for FOB

The patient is placed in a sitting position, nasal cannula oxygen is administered, and pulse oximetry and other monitoring devices are applied. The sitting position allows secretions to run down into the esophagus and out of the bronchoscopic view.

Additionally, gravity helps direct the fiberoptic bronchoscope toward the larynx as compared with the supine position, where gravity tends to favor the posterior esophageal orifice.

Intravenous Analgesia, Sedation, and Antisialagogue

Patients should receive an antisialagogue (glycopyrrolate, 0.2 mg) and sedation before the start of the procedure. Opiates, benzodiazepines, and neuroleptic drugs have all been used successfully. Low-dose opiates alone (fentanyl, 1 to 4 $\mu\text{g}/\text{kg}$) are sufficient in patients not tolerant of opiates. Midazolam should not be routinely used because it causes some patients to become hyperalgesic and uncooperative. Fentanyl provides adequate sedation and analgesia, both of which are useful while topicalization is occurring. Dexmedetomidine can also be used as it provides excellent sedation, decreases the opioid requirement, and does not depress ventilation.

Local Anesthesia and Vasoconstriction

The following description of mucosal topicalization and vasoconstriction can be used for any blind technique, not just FOB intubation. The patient should receive phenylephrine (Neo-Syneprine) or oxymetazoline (Afrin) nasal spray in both nares before initiation of topicalization. Then the patient is asked to report which nares allows for better air flow. This will identify the nares that should be intubated and primarily topicalized. However, both nares should be anesthetized to block the superior laryngeal nerve (SLN) on both sides and thus anesthetize the supralaryngeal structures (as described subsequently).

Next the nasopharynx, oropharynx, base of the tongue, and larynx are anesthetized. The nasopharynx is anesthetized with 4% cocaine or 4% lidocaine with Neo-Syneprine. For nasopharyngeal anesthesia, 4% cocaine provides intense vasoconstriction and has a more rapid onset and longer duration than lidocaine.

Table 49–7. Causes of Failure to Intubate with Fiberoptic Bronchoscope

Cause of Failure	Comments and Solutions
Patient Selection Factors	
Massive bleeding	Unable to see adequately is a relative contraindication to FOB. Small amounts of bleeding can be controlled with frequent suctioning. A vasoconstrictor added to topical agents helps limit bleeding.
Uncooperative patient	Patient will not hold still and/or is very belligerent. Rare problem in elective surgery, but may occur in trauma and emergency situations.
Patient too unstable	Does not allow time to properly anesthetize airway.
Patient Preparation Factors	
Inadequate topical anesthesia	Be patient, take time to topicalize properly. Dry the mucosa (glycopyrrolate) and suction secretions from the oropharynx so that topical anesthesia can get to the mucosa to work. Anesthetize the nose, nasopharynx, oropharynx, larynx, and trachea. Nerve blocks, used by some, are not usually necessary when proper anesthetization is performed.
Presence of secretions or small amounts of blood	Treat with proper suctioning, use of an antisialagogue (glycopyrrolate) and a vasoconstricting agent (Neo-Syneprine), or use cocaine. Attach O ₂ to suction port of FOB, blowing secretions away.
Patient desaturates during FOB	Patient should be wearing nasal prongs or mask O ₂ during FOB whenever significant right-to-left shunt is present. Also, endoscopist can attach O ₂ to the suction channel of the FOB and instruct patient to pant during intubation.
Endoscopist Experience Factors	
Inability to navigate normal anatomy	Most common problem of novice is too little practice with airway models and mannequins before attempting to intubate patients.
Distorted anatomy due to tumors or abscess	These are excellent indications for using an FOB, because intubation with direct laryngoscopy may be difficult. However, the endoscopist must be well grounded in normal anatomy before negotiating abnormal anatomy in a difficult intubation. Use of a small ETT may help in these circumstances.
Inability to visualize cords due to a large floppy epiglottis	Have patient say “Ahh” and/or “pant like a puppy.” (If patient is anesthetized, helper should apply jaw thrust or pull the tongue forward.)
Fogging of objective	Use a dilute detergent (Hibiclense) to wipe the FOB lenses before use, and warm the FOB before use.
Inability to advance tube into trachea	Inadequate topical anesthesia—perform nerve block or use more topical. Large discrepancy between ETT and FOB—use the largest FOB that will fit easily through the ETT yet still allow easy removal with proper lubrication. Hung up at glottic opening—pull back the ETT and rotate 90 to 180 degrees either right or left to allow the ETT to pass through the cords more easily.
Inability to remove the FOB	Beware that the FOB may exit the Murphy eye of the ETT. This can be avoided if the FOB is threaded through the ETT before attempting intubation. Some endoscopists place the lubricated ETT through the naris into the nasopharynx blindly and then pass the FOB through the ETT. This technique has greater risk that FOB might exit the Murphy eye. Also, be sure that the FOB is well lubricated with silicone before placing it through the ETT.

ETT, endotracheal tube; FOB, fiberoptic bronchoscope.

The toxic dose of cocaine is 3 mg/kg, whereas the toxic dose of lidocaine is 7 mg/kg when used with vasoconstriction.

Cocaine is applied to each nare using Krause forceps (Fig. 49-34) or a cotton-tipped applicator. The nares are painted first, and then the applicator is passed down the nasopharynx. Advancing the applicator into the pyriform fossa also blocks the superior laryngeal nerve (SLN). This nerve innervates the epiglottis, aryepiglottic folds, and mucous membranes of the laryngeal structures down to the false cords. When the applicator can be inserted without causing discomfort, a soft 34 French nasal airway is passed. If the patient tolerates this maneuver, topicalization of the nasopharynx is complete.

While the nasopharynx is being anesthetized, the oropharynx and larynx can be simultaneously anesthetized by spraying a fine mist of 4% lidocaine via a DeVilbiss nebulizer. The DeVilbiss

sprayer can be modified by connecting it to a low-flow O₂ source after removing the squeeze bulb, thus providing a continuous source of aerosolized lidocaine (Fig. 49-35). The patient should be asked to “pant like a puppy” so as to entrain the aerosolized lidocaine into the trachea as well. When the DeVilbiss sprayer can enter the oropharynx without causing the patient to gag, oropharyngeal and base of tongue anesthesia is adequate for FOB intubation. Provided that the patient has breathed enough lidocaine mist into the airways, the trachea is usually adequately anesthetized at this point as well.

Some endoscopists prefer performing nerve blocks of the glossopharyngeal nerve (at the palatoglossal arch) (Fig. 49-36) and the superior laryngeal nerve (externally, where it crosses the superior cornu of the hyoid) (Fig. 49-37), and administering transtracheal lidocaine (Fig. 49-38).³⁰ These maneuvers are not

Figure 49-34. Superior laryngeal nerve block by external approach ("topicalization"). Posterior view of the nasopharyngeal area showing the perforating branches of the superior laryngeal nerve. Krause forceps are used with gauze soaked in local anesthetic fluid at the level of the pyriform sinus. (From UCI Department of Anesthesia D.A. Teaching aids (with permission).

Figure 49-35. Continuous oxygen flow atomizer apparatus. Oxygen tubing is connected from an oxygen tank to the bulb attachment site of a DeVilbiss atomizer. A hole is cut in the oxygen tubing near the attachment site. Oxygen is allowed to flow into the tubing and out of the cut hole until a finger is applied covering the hole; then oxygen flows to the nebulizer and a fine mist of local anesthetic is emitted. The size and velocity of the spray is directly related to the flow of oxygen through the tubing. (Reproduced with permission from Benumof JL: *Anesthesia for Thoracic Surgery*, Philadelphia, WB Saunders, 1987, pp 241-243; with permission).

necessary for FOB aided or blind nasal intubation techniques in properly topicalized patients (i.e., following above recipe). However, if awake laryngoscopy is planned with either a normal RDL or a Bullard laryngoscope, the deep pressure receptors may still be active causing the patient to gag. When pressure-inducing laryngoscopic devices are used to intubate awake patients, supplemental glossopharyngeal nerve blocks should also be performed (see legend in Figure 49-36 for instructions).

Figure 49-36. Glossopharyngeal nerve (lingual branch) block. The tongue is pushed medially with a tongue depressor, and a 3-inch spinal needle is inserted into the base of the anterior tonsillar pillar 0.5 cm lateral to the base of the tongue and advanced 0.5 cm deep. After negative aspiration, 2 mL of local anesthetic is injected. Both sides are injected for adequate block of the gag reflex. (From Mulroy MF: *Regional Anesthesia: An Illustrated Procedure Guide*, 3rd ed. Lippincott Williams and Wilkins, 2002, p 229, with permission.)

Technique of Fiberoptic Intubation

Awake Nasal Technique

The largest ETT that will fit the patient's nasal passage should be used; most adults can accept an 8.0 ETT. If the patient's naris can be easily dilated with a 34 French soft nasal airway, an 8.0 ETT will almost always fit. This is because the external diameter of a 34 French soft nasal airway is approximately 11.0 mm, whereas that of an 8.0 ETT is approximately 10.5 mm.

Following topical anesthesia, the FOB (with an already loaded ETT) (Fig. 49-39) is inserted into the patient's naris. Alternatively, an ETT can be placed in the naris to serve as an introducer, and the fiberoptic bronchoscope can then be placed through the endotracheal tube and into the nasal passage. The advantage of the first technique is to eliminate the possibility that the FOB will exit the Murphy eye of the ETT because the ETT is preloaded on the FOB. The advantage of the second technique is that the ETT serves as a dilating airway and a guide for the FOB. When the FOB exits the ETT, it is frequently aiming right into the laryngeal aperture.

When manipulating the FOB, it is useful to remember that small movements at the end of the FOB result in very large changes in the view. Regardless of the technique chosen to introduce the FOB into the naris, the endoscopist next advances the FOB under direct vision until the epiglottis or the laryngeal aperture is identified. The FOB should never be advanced blindly because structures that are not clearly identified may be damaged. Once the glottic opening or the epiglottis is in view (Fig. 49-40), the FOB is maneuvered around the epiglottis, through the vocal cords, and into the trachea. The FOB is then

Figure 49-37. Superior laryngeal nerve block. The 23- or 25-gauge needle is introduced onto the superior border of the lateral wing of the thyroid cartilage or caudad to the greater cornu of the hyoid bone. After negative aspiration deep to the thyrohyoid membrane, 2 to 3 mL of local anesthetic are injected into the space below the membrane. (From Norton ML: *Atlas of the Difficult Airway: Topical and Regional Anesthesia of the Upper Airway*, Mosby Publishing, 2002, p 91, with permission.)

advanced further down the trachea to a position just above the carina. At this point, the ETT is threaded over the FOB through the larynx and into the trachea.

If the ETT does not advance easily, it may be hung up at the arytenoids or at the laryngeal aperture. This problem can be due either to a size discrepancy between the internal diameter of the ETT and the outer diameter of the FOB because the ETT is simply too large for the glottis. Often, rotating the ETT 90 to 180 degrees either clockwise or counterclockwise will facilitate passage of the ETT through the glottic aperture.

If the ETT will not pass despite the use of these maneuvers, the ETT and FOB should be removed together as a unit, and a smaller ETT used. If secretions become a problem during

Figure 49-38. Transtracheal injection (topical subglottic anesthesia—recurrent laryngeal nerve distribution). A 20-gauge IV catheter is introduced through the cricoid membrane. Once tracheal entry is confirmed by air aspiration, 4 mL of topical anesthetic is injected as the patient inspires; the inward air flow carries the solution down the trachea, and the cough reflex will spread it up to the undersurface of the vocal cords. (From Mulroy MF: *Regional Anesthesia: An Illustrated Procedure Guide*, 3rd ed. Lippincott Williams and Wilkins, 2002, p 230, with permission).

bronchoscopy, they can be removed by flushing saline down the working channel of the FOB or passing oxygen through it, providing the additional benefit of increasing the FiO_2 in spontaneously breathing patients.

Once the ETT is positioned approximately 3 to 4 cm above the carina, the FOB is removed. If it becomes difficult to remove the FOB, the nasal passage may be narrow and may be crimping the ETT, or the FOB may have passed out the Murphy eye. If this occurs, the fiberoptic bronchoscope and the ETT must be removed as a unit, and the procedure begun again.

Oral Technique

The FOB can be advanced through the oropharynx in both awake, spontaneously ventilating patients, and those who are asleep and being ventilated with a mask or LMA. The sedation and local anesthesia preparation is the same as that required for a nasal intubation (details described above).

With oral intubation in a spontaneously ventilating patient, the FOB is advanced into the airway through a rigid plastic Ovassapian oral airway intubator (Fig. 49-41, A). The oral intubation can be more difficult in some patients because the FOB must take a more acute bend at the oropharynx to be directed toward the larynx (compared with the more gentle curvature required for the nasal intubation).

When FOB-assisted intubation is performed in patients under general anesthesia, concomitant ventilation can be achieved using an LMA, Intubating Fastrach LMA, or the Patil intubating mask with self-sealing diaphragm (Fig. 49-41, B), along with the Ovassapian oral airway intubator, as described by Rogers and Benumof.³¹ Entry into the glottis is generally easier with an LMA-FOB-assisted intubation compared with an intubating mask-FOB-assisted technique.

Figure 49-39. Fiberoptic bronchoscope with endotracheal tube (ETT) threaded over the insertion end of the FOB. The 15-mm airway connector has been removed, and the ETT is secured to the body of the FOB with a piece of tape. The distal (insertion) end of the FOB is lubricated with a silicone-based fluid, the cuff of the ETT is deflated. The tip of the FOB can only be flexed in one plane. To maneuver the FOB in other planes, the scope itself must be longitudinally twisted. (From Zupan J: *Fiberoptic bronchoscopy in anesthesia and critical care*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 258, with permission.)

Emergency Airway Management Complications

Complications of emergency airway management are numerous. However, four life-threatening emergency airway complications that must be avoided in the management of airways of critically ill patients are: (1) failure to intubate/ventilate the “difficult airway,” (2) unrecognized esophageal intubation, (3) aspiration of gastric contents, and (4) hemodynamic compromise.

Failure to Intubate or Ventilate

Failure to maintain a patent airway for more than a few minutes can lead to brain damage or death, and is the single most common cause of anesthesia-related morbidity and mortality.¹ CICU patients in cardio-respiratory failure are at an even higher risk because they are starting out with a more compromised hemodynamic and respiratory status than elective patients in the operating room. Furthermore, difficulty can occur because proper equipment and help may be missing. The ASA DA algorithm was developed by a task force of academic clinicians with the goal of reducing airway related catastrophes. Although not specifically created for emergency situations, the ASA DA algorithm provides logical guidance for emergency airway management of the CNI-CNV situation (as reviewed in detail previously).

Unrecognized Esophageal Intubation

An esophageal intubation is not an error of commission; it is an error of omission (that is failure to recognize it). Once the airway is secure, confirmation of placement and ventilation

Figure 49-40. View of the larynx and carina via an FOB. This figure demonstrates the normal anatomy of the larynx (A) and the view obtained from a fiberoptic bronchoscope positioned just above the laryngeal inlet (B). After passage of the FOB through the vocal cords and down the trachea the carina comes into view (C). The tracheal cartilages are c-shaped and are joined posteriorly with a membrane. This anatomy allows for identification of the various portions of the tracheal bronchial tree. (From Zupan J: *Fiberoptic bronchoscopy in anesthesia and critical care*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 258, with permission.)

must occur immediately. Depending on the patient's underlying condition, confirmation of ETT position can be complicated and can lead to disastrous results if not properly verified. Endotracheal tube confirmation techniques can be characterized as direct and indirect methods.

Direct Confirmation of Intratracheal Position

Direct vision of the endotracheal tube passing through the cords is considered "the gold standard." The only foolproof techniques for confirming an endotracheal position are seeing the tube pass through the cords and looking through the endotracheal tube and visualizing the tracheal rings with an FOB, or in penetrating neck trauma, the trachea may be exposed and the tube can be placed inside under direct vision.

Indirect Confirmation of Intratracheal Position

All of the usual clinical end points are indirect methods and error-prone including: auscultating equal bilateral breath sounds, observing symmetrical chest rise, and fogging of the ETT. Two specific indirect methods for determining ETT position are used for all emergency intubations. These include $P_{ET}CO_2$ measurement and the esophageal detector device (EDD).

The $P_{ET}CO_2$ can be detected by capnography or by a portable calorimetric device made by Nellcor Puritan Bennett called the Easy Cap II. These devices are good predictors of esophageal intubation in patients with normal cardiovascular status. However, in code situations with little or no cardiac output, very little blood will traverse the pulmonary circulation and consequently very little CO_2 will be exhaled with each breath and be available to be detected. Indeed, $P_{ET}CO_2$ has been used to quantify the efficacy of CPR.

Conversely, patients with high levels of CO_2 in their stomach (from $NaHCO_3$ or soft drinks) can give a false positive test on the first couple breaths. After six breaths, esophageal/gastric CO_2 levels drop. Barring these two relatively rare events, end tidal CO_2 measurement is a reliable indication of ETT position.

Recently, an esophageal detector device has been described by Wee.³² The Wee esophageal detector device (comprised of an Ellicks evacuator applied to the supposed "tracheal" tube) has proven to be highly sensitive and specific for detection of esophageal intubation (Fig. 49-42). If the tube is in the esophagus, the deflated bulb fails to re-expand when released because suction applied to the esophageal wall causes the mucosa to close in on and obstruct the ETT. In contrast, when the tube is in the trachea, air flows out of the lungs into the trachea and reinflates the bulb because the tracheal rings keep the airways from collapsing around the ETT.

Extubation or Endotracheal Tube Change in the Difficult Airway

Extubation of the trachea or tube change in the ICU or CICU patient with a known difficult airway should be considered a high-risk endeavor and should be performed over a jet stylet ETT changer, as described by Bedger and Chang.³³ If there is any difficulty placing the new ETT, ventilation can be performed using the jet stylet according to the method of Goskowitz and associates.³⁴

Aspiration of Gastric Contents

The severity of gastric aspiration is a function of the volume, pH, and nature of the material aspirated. Patients at high risk for aspiration either should receive a rapid-sequence induction

Figure 49-41. The oral airway intubator and the intubating anesthesia mask. The oral airway intubator (A) has a channel large enough to pass an 8.0-mm endotracheal tube (ETT). The intubating anesthesia mask fits over the patient's face as a normal mask does and is equipped with the usual 15-mm airway connector. Additionally, there is an intubating port with self-sealing diaphragm through which a fiberoptic bronchoscope and previously threaded ETT may pass (B). The scope passes via the intubating port through the intubating oral airway and then into the trachea. The ETT (previously threaded over the bronchoscope) is then advanced into the trachea. The bronchoscope is withdrawn, the endotracheal tube is grasped near the patient's mouth, and the anesthesia mask is removed with care not to pull the ETT out the trachea in the process. (From Zupan J: *Fiberoptic bronchoscopy in anesthesia and critical care*. In Benumof JL (ed): *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia JB Lippincott Co, 1992, p 261, with permission.)

Figure 49-42. Collapsed self-inflating bulbs (SIBs) were connected simultaneously to tracheally and esophageally placed tubes. The SIB connected to the tube in the trachea instantaneously reinflated, while the SIB connected to the tube in the esophagus remained collapsed. (From Salem MR, Wafai Y, Joseph NJ, et al: *Efficacy of the self-inflating bulb in detecting esophageal intubation. Does the presence of a nasogastric tube or cuff deflation make a difference?* *Anesthesiology* 1994;80:42-48, with permission.)

or should undergo an awake, topical anesthesia intubation technique.³⁵

The purpose of the rapid sequence induction (with cricoid pressure) is to seal the airway with a cuffed endotracheal tube as soon as possible after the loss of airway reflexes. A rapid-sequence induction is used when contraindications to a blind nasal intubation are present and when the risk of aspiration of gastric contents is high (bowel obstruction, obesity, hiatal hernia). Death can occur when the concern for a full stomach supersedes more important issues such as difficult airway and severe hypovolemia.

Hemodynamic Compromise

Patients in the CICU who are in respiratory failure may be hovering on the edge of cardiopulmonary arrest from the primary process. Also, they may be at risk from the elevated circulating catecholamines, which increase myocardial O_2 consumption and SVR (except in the rare circumstance of concomitant anaphylaxis, sepsis, or drug overdose). Furthermore, elevated catecholamines and $Paco_2$ (if respiratory failure present) sensitize the myocardium to ventricular ectopy.

More importantly, the elevated catecholamines tend to support the patient's BP before intubation. Therefore, the cardiovascular system of the critically ill patient frequently requires some exogenous catecholamine or vasopressor support during or following intubation. This support can come in

the form of pharmacologic therapy or intravascular volume expansion.

Hypotension following emergent intubation occurs secondary to lysis of endogenous catecholamine output and due to the heart-lung interactions of positive pressure ventilation (especially in hypovolemic patients).

Causes of Preinduction Increases of Catecholamines

Before induction and intubation of trauma patients, a hyperadrenergic state exists serving to buoy the patient's blood pressure. Several factors promote this hyperadrenergic state through increased endogenous catecholamine elaboration: (1) stress (fear of dying and dyspnea), (2) pain, (3) elevated $Paco_2$ (ventilatory failure), (4) pump failure, and (5) hypovolemia and hemorrhage.

Causes of Hypotension Following Induction and Intubation

Following induction/intubation the BP frequently falls in patients with respiratory failure (especially following a rapid sequence induction). The hypotensive response can be attributed to four factors.

Loss of Consciousness (Decrease in Sympathetic Tone)

All intravenous (IV) induction drugs such as etomidate, ketamine, propofol, and sodium pentothal (STP) lead to a loss of consciousness and thereby a loss of preinduction stress, fear, and anxiety mediated catecholamine production. Loss of this catecholamine elaboration can cause the BP to drop.

Direct Myocardial Depression and Vasodilation

Some IV drugs cause direct myocardial depression (e.g., thiopental, propofol, ketamine) and decreased SVR (thiopental and propofol). Etomidate is associated with very little myocardial depression. Ketamine causes some myocardial depression but its sympathomimetic effect can sometimes buoy the blood pressure (providing the patient is not already secreting the maximal amount of endogenous catecholamines).

Decreased Right Ventricular (RV) Preload and Increased RV Afterload

Positive pressure ventilation (PPV) will decrease venous return to the right heart and thus decrease preload and increase RV afterload (when alveolar pressure is greater than pulmonary capillary pressure). These changes in turn decrease filling of the left heart, tending to decrease stroke volume. These effects are especially pronounced when the patient is intravascularly volume depleted.

Decreased $Paco_2$

Hyperventilation will blow off the previously elevated $Paco_2$, resulting in a further decrement in the stimulus for catecholamine release. The combination of hypovolemia with now decreased endogenous catecholamine elaboration along with mechanical factors inhibiting cardiac output (positive pressure ventilation) can lead to catastrophic hypotension.

Techniques to Limit Hypotension Following Intubation

Avoid using a RSI technique when not necessary. A patient with an obvious difficult airway and full stomach should be intubated awake unless he or she becomes uncooperative or grossly unstable. Use small doses of induction drugs when required.

The airway is expected to be difficult to intubate, maintain spontaneous ventilation with cricoid pressure in particularly debilitated patients (i.e., those with pericardial tamponade). Pretreat with a fluid load (except in the case of myocardial ischemia related to high preload). Have vasopressors drawn up available for administration and do not hyperventilate following intubation.

Anesthesia Induction Drugs for Rapid-Sequence Intubation

For emergent intubations, a rapid-sequence technique is the preferred mode for intubating the trachea. However, the stable patients anticipated to have a difficult airway should undergo intubation using an awake technique. Selection of the correct hypnotic drug for rapid-sequence anesthesia induction can be problematic.

Drug or Dosage: What is the Important Factor?

It has been frequently said that more soldiers were killed in World War II by pentothal than by bullets. Indeed, Halford³⁶ wrote a compelling negative critique of the use of pentothal following the Pearl Harbor experience. In the same volume of *Anesthesiology*, however, appeared a case report by Adams and Gray³⁷ (and an accompanying editorial) revealing that pentothal was not the lethal factor but rather the *dosage* that was typically administered to the traumatized patient.

In general, severely ill patients should not receive pentothal or propofol for induction. If the patient is comatose upon arrival of the airway expert to the resuscitation scene, no drug other than oxygen and possibly a neuromuscular blocking drug is required until the patient's blood pressure and heart rate indicate that he or she can tolerate hypnotic agents.

Specific Drugs for Anesthesia Induction

Etomidate

An imidazole derivative, etomidate provides remarkable hemodynamic stability in critically ill patients. Thus, it is the induction drug of choice for hemodynamically unstable patients. The standard induction dose for etomidate is 0.2 to 0.3 mg/kg IV. In stable patients with ischemic heart disease and valvular disease, etomidate does not cause significant alteration in hemodynamic parameters.³⁸ Like any drug that causes loss of consciousness, however, etomidate can lead (indirectly) to hypotension in patients who are maintaining their cardiovascular system via a high resting catecholamine state. In repeat doses, etomidate can cause adrenal suppression. Etomidate is metabolized primarily in the liver, with the majority of metabolites excreted via kidneys (85%) and bile (13%); only 2% is excreted unchanged.³⁹

Ketamine

Ketamine, a phencyclidine derivative, is a unique dissociative anesthetic that produces amnesia and intense analgesia. The standard induction dose for ketamine is 2 to 5 mg/kg IV, or 5 to 10 mg/kg IM. When very small doses (0.5 to 2 mg/kg) of ketamine are used, respiration and airway reflexes usually remain intact. Larger doses can cause a release of endogenous catecholamines that often leads to hypertension and tachycardia. Ketamine does, however, cause myocardial depression. Thus, in cardiomyopathy patients or in patients with hypovolemia and baseline maximal endogenous sympathetic tone, ketamine may

still lead to hypotension. Ketamine is a bronchial smooth muscle relaxant,⁴⁰ making it suitable for use in asthmatic patients. Recovery from ketamine can be associated with hallucinations. Ketamine is metabolized in the liver by the microsomal enzymes to metabolites, which are then altered to the glucuronide form and excreted into the urine.

Thiopental

A derivative of barbituric acid, sodium thiopental is the standard intravenous induction drug used by many anesthesiologists. The standard induction dose in stable patients is 4 to 6 mg/kg. The induction dose in hemodynamically unstable patients must be significantly decreased (i.e., 0.25 to 0.5 mg/kg in patients with congestive heart failure or following trauma). The major side effects of thiopental are dose-dependent depression of respiration and hypotension secondary to a combination of cardiac depression and systemic vasodilation. Hypotension with thiopental and other induction agents can be life-threatening in volume-depleted patients. Lack of analgesic properties makes barbiturates incomplete general anesthetic agents.

Propofol

Propofol, an alkylphenol derivative, is a relatively new hypnotic agent that appears to have several advantages over thiopental for certain procedures.⁴¹ Emergence from brief anesthesia with propofol is extremely rapid because it is cleared more rapidly from the brain than thiopental. This is due to propofol's larger volume of distribution and high clearance from the blood (clearance actually exceeds hepatic blood flow). Propofol has intrinsic antiemetic properties, and patients can emerge from anesthesia hungry, euphoric, and, occasionally, in a noticeably amorous mood.

Despite these benefits, propofol is relatively contraindicated in hemodynamically unstable patients. The hemodynamic side effects of propofol are similar to those of thiopental. Propofol causes irritation and discomfort during intravenous administration. These effects are reduced by administering the drug into larger veins, using a rapidly running IV, and pretreating with intravenous lidocaine (0.5 mg/kg) or fentanyl (2 µg/kg). A typical induction dose of propofol (2 mg/kg) may be followed by a continuous infusion (100 to 200 µg/kg/min) for maintenance of anesthesia. The induction and maintenance doses of propofol (like pentothal) must be decreased in the unstable patient. Propofol is metabolized in the liver by conjugation to glucuronide and sulfate and is eventually excreted via the kidneys.

Clinical Scenarios

When called to the bedside of a patient for a "code blue," the airway expert must first determine whether the patient is truly in full cardiopulmonary arrest or in cardiopulmonary distress with impending arrest, the so called pseudocode. Several specific clinical examples of "pseudocode" are provided in this section.

True "Code" (Full Cardiopulmonary Arrest)

In the patient in full arrest, no drugs are necessary; however, oxygen, suction, proper preparation, and patient positioning are important. Management begins with implementation of the ABCs (airway, breathing, and circulation): apply cricoid pressure, open the airway, mask ventilate, and use a direct

laryngoscopic technique to intubate the trachea with a styletted endotracheal tube.

Following intubation, endotracheal position is verified using both clinical signs—symmetric chest movement, equal bilateral breath sounds, fogging of the endotracheal tube—and the more reliable devices for documenting endotracheal positioning: end-tidal CO₂ with a typical device (Nellcor, Easy Cap) or with an infrared measuring device (available in the operating room and some CICUs and ICUs). Alternatively, a fiberoptic bronchoscope or Wee esophageal detector device can confirm tracheal positioning. The airway expert must be sure to attach the endotracheal tube securely to the patient's maxilla following intubation, and should be cautious when manipulating the patient's head or body. This is the time during emergency airway management when medical personnel let their guard down (because the airway is secured), and someone may inadvertently pull the endotracheal tube out of the trachea while reaching over to move the patient for some other manipulation. The ETT should be secured at 21 cm from the upper incisors in normal adult females and at 23 cm in normal adult males. Finally, a chest radiograph should be ordered and reviewed to verify that the ETT is resting in the midtracheal position (see Fig. 49-43).

Pseudocode (Cardiopulmonary Arrest Imminent)

The pseudocode is characterized by the anesthesiologist's being called *stat* for a “code blue” to the CICU, ICU, or ward and finding upon arrival that the patient is still ventilating and has a pulse and blood pressure. The patient may or may not be in need of definitive emergency airway management. The airway expert must first decide whether intubation is indeed necessary, and if so, how urgently intubation must be performed,

and whether the patient is in the optimum setting. While these issues are being decided, the airway expert should apply oxygen to the patient, listen to the patient's chest with a stethoscope, and (if necessary) assist ventilation with a bag-mask device. Next, the anesthesiologist or airway expert should ask members of the patient's primary team what history has led to this event. The patient should also be interviewed regarding significant past medical problems, drug allergies, and current medications, including monoamine oxidase inhibitors (MAOs) and cardiac, pulmonary, or diuretic medications. The airway expert should then verify that the 10 prerequisites for safe airway management (described earlier) are available and should proceed with guidelines provided in the next section.

Airway Management Guidelines for Specific Clinical Scenarios

Several frequently encountered clinical scenarios occur on the ward, in the emergency room, and in critical care units. Each scenario has several specific and identifiable management points. Although the scenarios presented here represent patients who are in cardiopulmonary failure but have not yet gone into full arrest, improper or delayed therapy can lead to full arrest.

Ventilatory Failure Due to Airway Compromise

The airway expert should always be prepared to use transtracheal jet ventilation (TTJV) or to perform an emergent cricothyroidotomy for the patient who has a compromised airway. Clinical signs of airway compromise are stridor, chest retractions, CO₂ retention, and, ultimately, hypoxia. Airway compromise can occur secondary to tumor, foreign body, trauma, epiglottitis, laryngeal edema associated with anaphylaxis or drug allergy, and postoperative complications. Common postoperative causes of stridor include bleeding into a fresh surgical wound following neck surgery (carotid endarterectomy, thyroid, or parathyroid surgery) and soft tissue swelling following operations on the neck (i.e., anterior cervical discectomy) and massive blood transfusion.

For the stridorous patient with impending airway obstruction, the primary directive should be to maintain airway patency and spontaneous ventilation until the airway is secured (i.e., a partial airway obstruction should not be transformed into a complete airway obstruction). Therefore, a controlled awake technique with topical anesthesia and using a fiberoptic bronchoscope or direct vision is the recommended approach. Blind techniques are not recommended because they may cause complete airway obstruction. Furthermore, emergency airway management in a patient with a suspected difficult airway or with stridor should be performed in the presence of another physician (preferably a surgeon) with particular expertise in obtaining a surgical airway.

Respiratory Failure Due to Gas Exchange Problems (Shunt)

Primary pulmonary parenchymal problems, such as aspiration pneumonia, *Pneumocystis* pneumonia, adult respiratory distress syndrome, and sepsis, cause a large and variable right-to-left transpulmonary shunt. Affected patients typically exhibit signs of air hunger, have a high minute ventilation with a rapid shallow breathing pattern, and are ideally managed via a blind nasal intubation technique. Such a patient tends to suck the endotracheal tube into the trachea as it is placed carefully through the

Figure 49-43. Anatomic distances for endotracheal tube positioning. The usual satisfactory position of the endotracheal tube in a 70-kg adult male (23 cm from the upper incisors). This position allows the tip of the endotracheal tube to be 3 to 4 cm above the carina. In the normal adult male patient, distance between the vocal cords and the carina is 10 to 15 cm, and that between the dental line and the vocal cords, 12 to 15 cm. (From Bogdonoff DL: *Airway considerations in the management of patients requiring long-term endotracheal intubation*. *Anesth Analg* 1992;74:276.)

anesthetized nares. The patient may not require quite as much topical anesthesia and analgesia as a patient who presents for an elective operation because of the air hunger. When time allows, however, proper anesthesia induction and patient preparation are humane and can be the critical difference leading to success in securing the airway in such a patient.

Congestive Heart Failure

Congestive heart failure has many etiologies. The patient who has respiratory insufficiency attributable to CHF has, by definition, inadequate cardiac output and invariably manifests a high resting catecholamine state. The high sympathetic output serves to maintain what little cardiac reserve and vascular tone the patient has. One can occasionally temporize the patient with pulmonary edema with high-flow oxygen and medical therapy. If the patient requires intubation, however, consideration should be given to initiating support with inotropic agents and invasive monitoring before commencing airway management. Furthermore, only very small doses of sedative hypnotics should be administered.

Alternatively, a blind nasal intubation with careful topical anesthesia is a very acceptable technique in the patient with CHF. It is essential, however, to take the time to carefully anesthetize and prepare the patient so that he or she does not become more distressed and increase catecholamine output even further, leading to ventricular or supraventricular dysrhythmias.

If renal failure is the etiology of CHF, consideration should be given to the qualitative platelet defect that accompanies renal failure and the increased risk of nasal bleeding. Renal failure is not a contraindication to a nasal technique, provided that anesthetization of the airway is careful and complete.

Congenital Heart Disease

The maneuvers used to intubate the trachea in a patient with congenital heart disease can significantly alter the pathophysiologic expression of that disease. The airway expert must consider not only the effects of the drugs used on heart rate, rhythm, preload, afterload, and contractility but also the relative effects on pulmonary vascular resistance versus systemic vascular resistance and the resultant pulmonary versus systemic blood flow.⁴² Some lesions typically cause a predominant left-to-right shunt, whereas others cause a right-to-left shunt. Several lesions (i.e., hypoplastic left heart, transposition of the great vessels) can cause either shunt, depending on the patient's specific anatomy (caliber of the pulmonary vessels, size of an atrial septal defect, relative ventricular outflow obstruction, etc.) and physiologic state. Table 49-8 shows the common congenital lesions and the hemodynamic manipulations that should be attempted.

Lesions that increase pulmonary blood flow are said to cause a left-to-right shunt. Emergency airway manipulations for patients with such lesions are designed to limit the pulmonary perfusion and to increase systemic perfusion. This goal is achieved through manipulating the pulmonary and systemic vascular resistance (PVR and SVR). If the PVR/SVR ratio is increased, less blood will flow to the lungs. Increasing PVR promotes the shunting of blood away from the lungs. The goal in these patients is not to increase PVR, but rather to avoid manipulations that decrease PVR. Maneuvers that decrease PVR include any that cause high FiO_2 , hypocarbia, alkalosis, low mean airway pressure, and abolition of sympathetic stimulation.

In patients with diminished pulmonary blood flow, anesthetic manipulations should be designed to improve flow through the pulmonary vasculature. Pulmonary blood flow can be promoted and right-to-left shunting reduced by decreasing the right heart to left heart pressure ratio. This can be done by maintaining a high FiO_2 , promoting hypocarbia (through hyperventilation), eliminating acidosis, maintaining a low mean airway pressure, and achieving a normal or slightly elevated SVR. In the case of a fixed pulmonary outflow obstruction (such as tetralogy of Fallot), changes in systemic vascular resistance may alter pulmonary blood flow more than similar changes in pulmonary vascular resistance. In a patient with a tetralogy of Fallot, infusion of phenylephrine frequently reduces intracardiac shunting and increases blood flow through the pulmonary system, improving oxygenation.

Anesthetic drug-induced depression of cardiac contractility is not always detrimental in congenital heart disease. Obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS) with infundibular left ventricular outflow obstruction can be exacerbated by tachycardia and hypovolemia as well. This is in contrast to patients who suffer from aortic stenosis or pulmonic stenosis at the valvular level, in whom contractility must be maintained to eject blood out of the stenotic valves. Drugs used for induction and for hemodynamic support should be selected according to the recommendations in Table 49-8.

Valvular Heart Disease

Just as in congenital heart disease, anesthetic drug administration and emergency airway management in valvular heart disease can have a significant impact upon the patient's baseline physiology.⁴⁶ Other chapters in this textbook have more completely addressed the pathophysiology of the various valvular lesions, and the subject will not be duplicated here. Nevertheless, a brief overview of the basic physiology and important hemodynamic goals suggested for safe emergency airway management are provided (Table 49-9).

Aortic stenosis (AS) is the most common cardiac valvular abnormality. The pathophysiology results from obstruction of the left ventricular outflow at the valvular level, which leads to concentric hypertrophy of the left ventricular muscle. The left ventricular end-diastolic pressure (LVEDP) is generally elevated to promote filling of the hypertrophied left ventricle. Similarly, sinus rhythm is critical because left atrial contraction is required to fill the stiff left ventricle. Myocardial contractility is typically preserved and is very important for stability in patients with AS. Hemodynamic goals include maintaining a low heart rate to give the ventricle a longer time to fill and to increase the relative diastolic time, which is when the coronary arteries are perfusing the hypertrophic left ventricle. Preload should be higher rather than lower, and SVR must be maintained on the relatively high side to augment coronary artery blood flow. Also, it must be recognized that the resistance that the left ventricle ejects against in AS is at the valvular level and is not related to the SVR.

Patients with aortic insufficiency (AI) typically have volume overload physiology; stroke volume and ejection fraction are generally maintained through preload reserve and afterload reduction. The hemodynamic goals here are to maintain the heart rate in a relatively higher range to keep left ventricular preload on the higher side and to minimize SVR to help promote forward flow. Contractility should be maintained but not increased.

Table 49–8. Anesthesia Induction Considerations for Patients with Congenital Heart Disease*

	<i>Pathophysiologic Expression of Disease</i>			
	Right-to-Left Shunt	Left-to-Right Shunt	Right Ventricular Obstruction	Left Ventricular Obstruction
<i>Lesions responsible</i>	ASD (late) TGV Tetralogy of Fallot† Tricuspid atresia	ASD (early) AV canal PDA‡ TAPVR vsd	Pulmonary stenosis	Coarctation of the aorta Aortic stenosis§
<i>Hemodynamic goals</i>				
Heart rate	↔, ↓†	↔	↓	↔, ↓, §
Rhythm	Sinus	Sinus	Sinus	Sinus
LV Preload	↑	↑	↑	↑
SVR	↑↑	↓↓	↔	↓, ↑, §
PVR	↓↓	↑↑	↓	↔
Contractility	↔	↔↑	↔	↔
<i>Induction drug considerations</i>	R-to-L shunts are increased by decreasing SVR (large induction dose of sodium pentothal) or by increasing PVR (excessive positive-pressure ventilation, hypoxia, acidosis, hypercarbia)	Avoid pulmonary vasodilators; maintain on lower FiO ₂ ; and avoid myocardial depressants. (If chest open, hypotension can be aided by surgically applied PA obstruction)	Fairly fixed RV output. Will be made worse by increasing the PVR, or by decreasing the perfusion pressure to the hypertrophic RV (do not decrease the SVR or contractility)	Strong ventricle and necessarily so (do not decrease the contractility) For coarctation of aorta, may decrease SVR. For AS, keep rate slower and SVR high

*ASD, atrial septal defect; AV, arteriovenous; PA, pulmonary artery; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; RV, right ventricular; SVR, systemic vascular resistance; TAPVR, totally anomalous pulmonary venous return; †, slightly increased; ↑↑, significantly increased; ↓, slightly decreased; ↓↓, significantly decreased; ↔, maintained stable without need for increase or decrease; TGV, transposition of the great vessels; VSD, ventricular septal defect.

†If dynamic RV obstruction operative, limit tachycardia.

‡Occasionally, right-to-left shunt (hypoplastic left heart).

§Recommendations for coarctation of the aorta and aortic stenosis are the same except where indicated (HR and ↑ SVR recommendations apply to aortic stenosis).

Mitral stenosis (MS) is another valvular lesion with specific implications for choice of anesthesia induction drug. Patients with MS have a dilated left atrium and an under-filled but physiologically normal left ventricle. Patients with baseline normal sinus rhythm can manifest acute congestive heart failure if they lapse into atrial fibrillation. Thus such patients should not be made anxious during airway manipulations. Hemodynamic goals for MS include reducing the heart rate, thus allowing time for blood to flow from the dilated volume-overloaded left atrium through the stenotic mitral valve and into the relatively empty left ventricle. Normal sinus rhythm should be maintained (if the patient is in this rhythm). Left ventricular preload must be kept as elevated as possible without causing pulmonary edema.

Mitral regurgitation (MR) is the final valvular lesion with significant hemodynamic considerations for induction of anesthesia for emergency airway management. Patients with this lesion have left ventricular volume overload physiology. The heart rate should be maintained in the higher range, and left ventricular preload should be elevated during anesthesia induction. The SVR should be kept low, however, to help the left ventricle to empty blood in a forward direction rather than retrograde through regurgitant mitral valves. Contractility should be

maintained. Pharmacologic methods of increasing the heart rate (with atropine, epinephrine, isoproterenol) should be available in case the rate decreases with the manipulations used to control the airway.

Asthma

Patients with reactive airways disease are frequently encountered in the CICU. The asthmatic patient presents several difficult problems that simultaneously impinge on emergency airway management. These patients may be very distressed and agitated, may be moving very little air, and may have wide swings in blood pressure owing to the effects of the transmitted pleural and intra-abdominal pressures on the cardiovascular system. Furthermore, a very significant problem for the anesthesiologist or airway expert is the specter of unrecognized esophageal intubation resulting from the difficulty of hearing breath sounds in asthmatic patients during an acute attack. Therefore, a rigid direct laryngoscopic technique is recommended in the asthmatic patient. Visualization of the cords is superior to a blind technique because not only is it difficult to hear breath sounds transmitted, but also the chest wall excursions may be so minimal that the airway expert may not hear much flow in and out of the ETT during the blind technique.

Table 49–9. Anesthesia Induction Considerations for Patients with Valvular Heart Disease*

	Aortic Stenosis	Aortic Insufficiency	Mitral Stenosis	Mitral Regurgitation
<i>Pathophysiology</i>	Concentric hypertrophy	Dilated LV, volume overloaded Stroke volume and ejection fraction maintained with preload reserve	Dilated LA, ↑PAP, empty and protected LV May manifest as dyspnea, may be secondary to increased cardiac output (pregnancy or sepsis)	Dilated LA and LV, volume overloaded LV failure may be underdiagnosed because of regurgitant flow to LA despite severely decreased forward stroke volume
<i>Hemodynamic goals</i>				
Heart rate	↓↓	↑	↓↓	↑
Rhythm	NSR	—	Frequently in AF But, NSR→AF = ↓ BP	—
LV Preload	↑	↑	↑	↑
SVR	↑	↓	↔	↓
PVR	↔	↔	↓	↓
			(these patients may have severe PA HTN)	
Contractility	↔↑	↔↑	↔	↔↑
<i>Induction considerations</i>	Avoid myocardial depression, maintain CA perfusion, pressure (↑SVR, ↑BP) Be prepared to perform cardioversion if an arrhythmia occurs (CPR is futile) Treat hypotension with phenylephrine (Etomidate is good induction choice)	Minimize myocardial depression and keep the patient fast, full, and vasodilated. A PAC is useful to measure filling pressures and cardiac output. Dobutamine is a reasonable support drug at anesthesia induction.	Avoid tachycardia (No pavulon, etc. Conduction through the AV node may dramatically increase ventricular HR) Do not decrease contractility Inadequate sedation can precipitate extreme anxiety and tachycardia Consider esmolol to treat tachycardia	Isolated MR rare. Usually secondary to papillary muscle dysfunction or RHD. MVP is most common cause of <i>trivial</i> isolated MR. Keep the patient fast, full, and vasodilated Have several ways on hand to increase heart rate

AI, aortic insufficiency; AV, atrioventricular; BP, blood pressure; CA, coronary artery; CHF, congestive heart failure; CPR, cardiopulmonary resuscitation; HR, heart rate; HTN, hypertension; LA, left atrium; LV, left ventricle; MR, mitral regurgitation; MVP, mitral valve prolapse; NSR, normal sinus rhythm; PAC, pulmonary artery catheter; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; RF, rheumatic fever; SBE, subacute bacterial endocarditis; SVR, systemic vascular resistance; ↑, slightly increased; ↑↑, significantly increased; ↓, slightly decreased; ↓↓, significantly decreased; ↔, maintained stable without need for increase or decrease.

If a rigid, direct laryngoscopic technique is selected, ketamine is the ideal induction drug, because it provides some hemodynamic stability and, most importantly, bronchial dilation.⁴³ If the asthmatic patient also has a difficult airway, fiberoptic bronchoscope intubation should be used.

Airway Management for Cardioversion

Direct-current cardioversion is commonly employed in the CICU setting. Synchronized cardioversion is used to convert supraventricular and ventricle arrhythmias to sinus rhythm. When the patient is hemodynamically stable and has an arrhythmia of long duration that does not respond to drug therapy, cardioversion can be performed electively.

Cardioversion is painful, and thus, a light general anesthesia is required to allow the patient to undergo the procedure without remembering it or experiencing the pain. Thiopental,

methohexital, propofol, etomidate, and midazolam have all been used successfully for cardioversion.^{44–46} When cardioversion is performed electively, the patient should have fasted 8 hours before the procedure and should be monitored with pulse oximetry, blood pressure, and ECG.

Anesthesia should not be induced until the cardiologist is ready to administer the countershock. At this time, the patient is preoxygenated and given small, incremental doses of anesthetic drug until no longer responsive. Gail and colleagues⁴⁶ have demonstrated that a continuous slow injection of anesthetic drugs is superior to intermittent injections and that patients tend to require less drug and to suffer fewer hemodynamic effects with this technique. Both propofol and methohexital are superior to midazolam in their ability to provide rapid anesthesia onset and rapid recovery. Most authorities recommend removal of the mask immediately before countershock, so that no one is

touching the patient. However, in patients with significant right-to-left shunting the airway expert can keep the mask on the patient's mouth by holding only the plastic mask with one gloved hand, thereby keeping the rest of his or her body completely away from the patient. This technique ensures that the patient will not breathe any room air during the application of the countershock.

Often, more than one shock is required for restoration of normal sinus rhythm, and additional doses of intravenous medication may be required. Following the production of normal sinus rhythm, the patient is allowed to resume spontaneous ventilation, and the mask should be held in place until the patient awakens and has control of the airway and gag response. No muscle relaxants should be used, and intubation is not required unless the patient is prone to aspiration or has a full stomach.

If the cardioversion is performed on an emergent basis, it must be remembered that the patient has not fasted, and intubation of the trachea may be appropriate. Furthermore, in hemodynamically unstable patients, a drug devoid of myocardial depressor or vasodilator effects, such as etomidate, is superior to thiopental, propofol, or midazolam.

Conclusion

Emergency airway management in patients in the CICU is fraught with danger for the patients, because on average they tend to be sicker than patients in elective cases and because proper equipment and expert help may be difficult to obtain in a timely manner.

The morbidity and mortality of emergency airway manipulation in these settings can be decreased by carefully preparing the patient and physician for the planned manipulation, and by developing alternative plans before the initiation of airway management. Thinking ahead helps one avoid the four major complications of emergency airway management: failed intubation/lost airway, unrecognized esophageal intubation, aspiration of gastric contents, and hemodynamic compromise. A common theme developed throughout this chapter and supported by the literature is to maintain spontaneous ventilation and to use an awake intubation technique in any patient recognized to have a difficult airway.

Mechanical Ventilation in the Cardiac Care Unit

Daniel Baram, Paul Richman

CHAPTER 50

Introduction
Impact of Positive Pleural Pressure on Hemodynamics
Indications for Mechanical Ventilation
Managing Gas Exchange and Oxygen Delivery

Delivery of Mechanical Ventilation
Complications of Mechanical Ventilation
Ventilation of ARDS and Obstructive Airways Disease

Introduction

Mechanical ventilation is a common indication for intensive care unit (ICU) admission. This chapter will provide an overview of mechanical ventilation: its indications, basic physiology, ventilator settings, and issues that arise in caring for patients on mechanical ventilation.

Understanding mechanical ventilation requires a review of normal breathing. Ventilation occurs when fresh gas enters the alveolus, carbon dioxide diffuses from the blood across the alveolar-capillary membrane, and the carbon dioxide is exhaled. Oxygenation occurs simultaneously as oxygen diffuses from the inhaled gas into capillary blood. Total ventilation is divided into alveolar ventilation, that portion which participates in gas exchange, and dead-space ventilation, that portion that does not reach a functioning alveolar unit and is exhaled unchanged.

The functional residual capacity (FRC) is the resting volume at which the elastic recoil pressure of the lung inward equals the elastic recoil pressure of the chest wall outward, alveolar and mouth pressure are both zero, and there is no airflow. FRC increases with low lung elastic recoil pressure (such as in emphysema) and decreases when lung recoil pressure is high (such as in pulmonary edema or fibrosis).

Inspiratory muscles lower pleural pressure, generating a negative alveolar pressure while mouth pressure remains constant. Gas follows the pressure gradient and enters the lung. Expiration occurs when the lung returns to FRC with the relaxation of the inspiratory muscles although expiratory muscles can be used to speed the flow of gas out of the lung or to reduce lung volume below FRC down to residual volume.

Tidal volume is the volume of gas entering and leaving the lung during a respiratory cycle. It is determined by the pressure gradient from airway to alveolus and the mechanical properties of the lung and airways. Modern ICU ventilators deliver tidal volume by applying positive pressure to the airway. Negative pressure devices that lower the pressure outside of the chest wall, akin to the iron lung of historical note, are still used for some patients with chronic respiratory failure, but these devices are rarely used in the acute setting.

The history of mechanical ventilation is replete with famous figures in pulmonary physiology, anesthesia, and surgery.¹ Ventilators have been used in the operating room since the end of

the 1900s, but widespread use in respiratory failure began in the 1950s treating patients with paralysis from polio. Advances in oxygen delivery and blood gas analysis allowed the treatment of patients with increasingly complex pulmonary and chest wall diseases over the next decade. Modern ventilators continue to advance with improvements in reliability and responsiveness and increasing ability to control all phases of the inspiratory cycle.

Impact of Positive Pleural Pressure on Hemodynamics

The complex interactions between the cardiac and pulmonary systems are well known to the cardiologist. Lowering of alveolar and pleural pressure during normal spontaneous breathing augments venous return, explaining the varying split of the S₂ heart sounds and the variation in right ventricular murmurs with inspiration. Analogously, the Valsalva maneuver, sustained forced expiration against a closed glottis raising pleural pressure, lowers cardiac output and left ventricular size accentuating the murmur of hypertrophic cardiomyopathy; release of the Valsalva restores venous return accentuating right-sided murmurs.

Transitioning from negative pressure in the pleura to positive has important hemodynamic consequences affecting both the right- and left-sided cardiac circulations.² A complete review of this topic is beyond the scope of this chapter, but understanding basic cardiopulmonary interactions allows the reader to predict the impact of positive pressure breathing on a given patient's condition.^{3,4}

Positive alveolar pressure affects blood circulation in two important ways:

1. A portion of the alveolar pressure is transmitted to the pulmonary capillaries and veins, as increasing alveolar volume compresses the pulmonary capillary. The extent of transmission is dependent on lung elastance; more compliant lungs distend more easily, increasing stretch of the alveolar wall and increasing transmission of pressure. Increased capillary pressure has two net effects. Blood already within the capillary and pulmonary veins is ejected forward into the left atrium, increasing left ventricular preload acutely. The increased pressure acts as increased afterload for the right ventricle, decreasing left ventricular preload during the next cardiac cycle.

2. Rise in alveolar pressure distends the lung raising pleural pressure. Using the analogy of a balloon being inflated within a box, pleural pressure reflects distention of the lung up against the chest wall. The extent of transmission of alveolar pressure to the pleura is dependent on both chest wall and lung compliance; index of transmission = (lung compliance)/(lung compliance) + (chest wall compliance) defines this relationship. The lower the chest wall compliance compared to lung compliance, the more pressure is transmitted. Patients with stiff lungs and a normal chest wall have smaller increases in lung volume and therefore pleural pressure changes little; conversely, patients with normal lungs and stiff chest walls have lungs that push against the stiff chest wall, raising pleural pressure more steeply.⁵⁻⁷

A rise in pleural pressure directly affects right ventricular preload and left ventricular afterload. Venous return is affected by central venous pressure as described by Guyton, and this determines right ventricular preload. Blood drains from the systemic veins down the pressure gradient from the mean systemic pressure down to central venous pressure; any increase in central venous pressure reduces the gradient, lowering venous return. Pleural pressure is also a determinant of left ventricular afterload. Increased intrathoracic pressure ejects blood out of the thoracic aorta; this decreases afterload and facilitates left ventricular emptying. This can also be expressed as decreased myocardial work, which is determined in large part by transmural pressure.

Decrease in preload and afterload can occur cyclically during inspiration or can be continuous. For instance, patients ventilated with positive pressure breathing with positive end-expiratory pressure (PEEP) of zero have the normal negative pleural pressure at end-expiration that becomes positive during inspiration. Patients treated with continuous positive airway pressure (CPAP) continue to breathe unassisted spontaneously (i.e., lower their pleural pressure with each breath), but the baseline pressure is shifted upwards resulting in a continual hemodynamic effect. Often patients on mechanical ventilation receive positive inspiratory pressure on top of PEEP, thereby having cyclic decreases in preload on top of an already reduced baseline.

Manipulation of pleural pressure offers therapeutic options when patients are in the cardiac care unit, and it is important to remember these hemodynamic effects when initiating or withdrawing mechanical ventilation or adjusting settings. Patients who are preload dependent frequently develop hypotension after intubation, for instance those with hypovolemia, right ventricular infarction, pulmonary hypertension, or aortic stenosis; great care should be taken when initiating mechanical ventilation in patients with pericardial tamponade because deterioration in to pulseless activity (PEA) has been documented. Alternatively, the decrease in preload and afterload from intubation is beneficial for patients with congestive heart failure.

The interplay of breathing and hemodynamics offers an opportunity to determine preload responsiveness in critically ill patients. Combining the models of Guyton and Starling, Magder and colleagues showed that careful interpretation of the central venous pressure waveform during spontaneous breathing can differentiate those patients who are on the ascending portion of their Starling filling curves, thereby correctly predicting which patients will increase their cardiac output with a fluid challenge.^{8,9} Similarly patients with large swings in arterial blood

pressure with positive intrathoracic pressure are preload dependent and likely responsive to fluid.¹⁰ A thorough review of this topic has been published.¹¹

Indications for Mechanical Ventilation

The most common reason for mechanical ventilation in the cardiac care unit (CCU) is cardiogenic pulmonary edema. The underlying cardiac pathology may be a cardiomyopathy, valvular disease, or tachyarrhythmia. Whatever the cause, the resulting respiratory insult is the same: increased left atrial pressure and imbalance in Frank-Starling forces across the lung capillary membrane. This results in transudation of fluid into the lung interstitium and flooding of the alveoli. The lungs become stiff, and gas exchange is impaired across the thickened capillary membrane. In addition, the bronchi become edematous, so that airway narrowing may complicate the picture. All this leads to ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch causing severe hypoxemia, and increased work of breathing causing ventilatory failure and CO₂ retention. Excess work of breathing increases the oxygen demand by the diaphragm, further stressing the heart. In this state, the goals of mechanical ventilation are to improve gas exchange and reduce the patient's work of breathing. Settings for mechanical ventilation should reflect these dual goals.

Other indications for mechanical ventilation in the CCU include:

- Loss of upper airway reflexes and/or aspiration pneumonia. This may be due to cardiac arrest, cardiogenic shock, or the need for heavy procedural sedation
- Acute and/or chronic pulmonary disease
- Concomitant neuromuscular disease

Finally, nosocomial and iatrogenic complications in the CCU may result in respiratory failure and the need for mechanical ventilation. These include pulmonary embolism, hospital-acquired pneumonia, critical illness polyneuropathy, and pneumothorax after placement of a central venous catheter.

Managing Gas Exchange and Oxygen Delivery

Oxygenation

The paramount goal of mechanical ventilation is to assure an adequate PaO₂ (arterial pO₂), such that hemoglobin saturation (SaO₂) is comfortably above 90%. It is important to recognize however that SaO₂ is only one of three factors whose product determines O₂ delivery to the tissues, the other two being cardiac output and the concentration of hemoglobin, as described by the equation:

$$O_2 \text{ delivery} = SaO_2 \times C.O. \times [Hgb] \times \text{constant}$$

From this it is clear that an increase in cardiac output from 5.0 to 6.0 liters/min or a rise in hemoglobin from 8 to 10 mg% will have a greater impact on O₂ delivery than a rise in O₂-hemoglobin saturation (SaO₂) from 92% to 98%. Further, once SaO₂ is >92%, the patient is on the "flat portion" of the hemoglobin-O₂ saturation curve, such that small changes in PaO₂ will not greatly affect the SaO₂. For both of these reasons, keeping SaO₂ in the range of 92-95% is a reasonable goal when adjusting ventilator settings.

Importantly, the 3 factors in the equation above can interact with each other; for example increasing the intensity of

mechanical ventilation to improve SaO_2 may over-pressurize the thorax, reduce venous inflow to the right ventricle and impair cardiac output. Excessive red blood cell transfusion to achieve a “normal” hemoglobin concentration is also ill advised, as it will increase blood viscosity and may impair C.O. Careful attention to these interactions will guide the clinician in choosing interventions to improve O_2 delivery to tissues.

The measurement of O_2 saturation by pulse oximetry (SpO_2) is a good estimate of SaO_2 in most situations, though it also records carboxyhemoglobin. When blood concentration of carbon monoxide is high (in heavy smokers or smoke-inhalation victims) the SpO_2 overestimates SaO_2 .

In the mechanically ventilated patient, the two main parameters that affect the PaO_2 are the FiO_2 (fraction of O_2 in inspired air) and the mean airway pressure. A moderate increase in FiO_2 is often adequate to improve the PaO_2 in patients with respiratory failure due to mismatching of ventilation and perfusion in the lung (V/Q mismatch). This situation occurs commonly in patients with inhomogeneous airway diameter due to obstructive lung disease or early interstitial lung edema in patients with CHF.

Severe hypoxemia however may be refractory to increases in FiO_2 when it is due to pulmonary “shunting” in which a significant fraction of the cardiac output passes through a lung capillary bed that is not aerated (not exposed to gas). This commonly occurs in patients with consolidated pneumonia, massive pulmonary edema or atelectasis due to airway obstruction or compression of lung tissue. In these scenarios, even FiO_2 levels approaching 100% will be unsuccessful in treating the cyanosis, just as in patients with an intra-cardiac shunt. Fortunately, there are alveoli at the margins of consolidated or atelectatic lung regions that can be “recruited” to function as gas exchange units if a high distending pressure is maintained. These higher airway pressures are commonly achieved by applying positive end-expiratory pressure (PEEP), which exerts its beneficial effect on PaO_2 by preventing the collapse of recruitable lung units during exhalation. The effect of PEEP on cardiac output is complex, as it reduces both RV preload and LV afterload. The result may be either beneficial or deleterious, depending on the patient's volume status and lung compliance.^{12,13} This is detailed in the preceding section.

Ventilation

Alveolar ventilation is the process by which the lungs excrete CO_2 , and is thus inversely proportional to PaCO_2 . So called “minute ventilation” (Ve) is the total volume of air exhaled per minute, and is the sum of alveolar ventilation (Va) and ventilation of the pulmonary “dead space” (Vd), which is the volume of exhaled air that did not participate in gas exchange at the alveolar membrane:

$$\text{Ve} = \text{Va} + \text{Vd}$$

Elevated dead space may be present chronically, as in patients with emphysema, or acutely as in a patient who has suffered a pulmonary embolism. In either case however, if dead space is stable over time, control of minute ventilation will control alveolar ventilation and thus will regulate PaCO_2 . Ve is measured as the product of respiratory rate (RR) and tidal volume (TV). Thus adjusting these two ventilator parameters will regulate PaCO_2 . An important caveat to this is that patients on mechanical ventilation regulate their own RR via respiratory drive mechanisms, unless heavily sedated or paralyzed; therefore raising or

lowering the ventilator “set” rate will not necessarily change the patient's actual RR or alter PaCO_2 .

The chief reason to control alveolar ventilation or PaCO_2 is to regulate pH. Marked acidosis can impair cardiac contractility and responsiveness to vasopressors^{14,15}; marked alkalosis reduces the threshold for ventricular arrhythmias in susceptible patients.¹⁶ However mild derangements in pH (0.10 to 0.15 units either way) are generally harmless. Thus strict control of pH by adjusting Ve is often unnecessary, particularly if it requires harmful increases in the intensity of alveolar ventilation (see section on ARDS, below). Inadequate levels of Ve will however cause respiratory acidosis (low pH, high PaCO_2), stimulating the patient's respiratory drive; in experimental studies this may divert up to 30% of cardiac output to the respiratory muscles.¹⁷ Conversely, excessive Ve causes respiratory alkalosis (high pH, low PaCO_2) which suppresses respiratory drive and can cause a patient to be apneic during a weaning trial, thereby prolonging the use of mechanical ventilation.

Delivery of Mechanical Ventilation

There is a rapidly expanding menu of options when delivering mechanical ventilation. Terminology is complicated by proprietary names entering bedside usage and by the retention of historical abbreviations that were nonideal. Although nomenclature standardization has been proposed, it has not reached universal usage, causing confusion at the bedside.^{18,19} Another source of confusion is that different ventilators may require entry of a setting in different ways; for example, inspiratory time may be entered in seconds (e.g., 1.5 seconds) or as a percentage of cycle time (e.g., 25% of 6 seconds) or a ratio of inspiration to expiration (e.g., 1:3 of 6 seconds).

Despite the rapid increase in options, there are little randomized controlled data showing a benefit to a particular style of ventilation. There are significant differences in comfort and muscle unloading depending on the mode selected, but no mode has been shown superior in regards to patient outcome.^{20,21} Ventilator setting in most ICUs remains dependent on local expertise and the model of mechanical ventilator available. Improved understanding of the available modes allows finer control over ventilation and a better understanding of how a change in patient status will affect the setting. Most important to the patient is whether ventilation is assured, the respiratory muscles are effectively unloaded, and whether the tidal volume and end-expiratory volume are appropriate for the disease.

Mechanical ventilators allow manipulation of nearly every aspect of inspiration; expiration however, is not controlled except for airway pressure (PEEP). Usually discussed first is the pattern of breathing, or mode. A mode will allow different types of breath: each with its own name, options, and settings. These issues will be introduced in this chapter but full discussion requires a textbook and is beyond the scope of this chapter.²²

Most breaths on mechanical ventilation can be classified as either mandatory or spontaneous. The ventilator exerts more control during mandatory breaths; settings include when to start the breath, what to control during the breath, and when the breath ends. Common mandatory breaths include: volume control, pressure control, and demand-flow volume control.

A hallmark of mandatory breaths is the required setting of inspiratory time. During spontaneous breathing, the ventilator does not control inspiratory time but rather supports the inspiratory efforts. Common spontaneous breaths include pressure support and unsupported.

Some ventilators allow breaths that are not easily classified as mandatory or spontaneous. One example is volume-assured pressure support, which is a hybrid with spontaneous breathing that converts to mandatory if a tidal volume target is not reached.²³ Another example is biphasic positive airway pressure (BIPAP) in which there are two asynchronous cycles as the ventilator maintains a background pattern of varying positive pressure breathing interspersed with patient effort.²⁴

Mode

Generally the first decision in ventilator setting is the mode. The most common modes are continuous mandatory ventilation (CMV), intermittent mandatory ventilation (IMV), and spontaneous ventilation (CPAP).¹⁸ CPAP, standing for continuous positive airway pressure, describes a mode which is continuously spontaneous and therefore never mandatory. The name is intrinsically confusing, as the acronym CPAP also signifies a therapy for sleep apnea, a type of mask, and delivery of positive airway pressure. It is also inaccurate as airway pressure is not constant (when used in conjunction with pressure support) or necessarily positive as CPAP can be set to zero. Despite attempts at renaming, CPAP remains entrenched in bedside and ventilator manufacturer usage.

CMV allows only mandatory breaths, the shape and size is determined by the settings described below. There is a minimum set rate. Patients can increase ventilation by “triggering” additional breaths; the ventilator senses either a drop in airway pressure across a closed inspiratory valve or inspiratory flow from a bias flow circuit. Regardless if the breath is time-triggered (i.e., at the minimum set rate) or patient-triggered (i.e., above the minimum set rate), every breath is mandatory and largely controlled by the ventilator.

CPAP allows only spontaneous breaths. There is no minimum set rate; each breath is started and stopped by the patient, and the patient breathes at the tidal volume and respiratory rate determined by their drive and respiratory mechanics. The ventilator can mimic unassisted breathing or can provide “support” during each breath; the level of support can vary from minimal support, to low levels of support to overcome the inherent added work of the ventilator, to higher levels of support that can actually be sufficient to essentially take over the entire work of breathing except for the initial trigger. It is important to remember that the ventilator is adjusting the inspiratory flow continuously over the breath to allow a spontaneous breath; it is not that the ventilator is just standing by passively. The ability of the ventilator to mimic unsupported breathing has improved significantly over the last decade; prior ventilators had high levels of imposed work that are much lower today.

IMV delivers a set number of mandatory breaths delivered per minute. Patient triggering above this set rate delivers spontaneous breaths. As such, IMV requires setting of two distinct parameters: a full description of the mandatory breaths and the level of support to deliver during spontaneous breaths. Careful attention to both the mandatory and spontaneous breaths is needed to appropriately adjust the amount of ventilatory support delivered to the patient. Most ventilators attempt

to synchronize the mandatory breaths with patient effort so a patient trigger may yield a mandatory or a spontaneous breath. This can lead to instability in the respiratory center as identical phrenic nerve output results in different tidal volumes. During IMV, patients may be performing more work during the mandatory breaths than during the spontaneous ones.²⁵

Mandatory Breaths

Volume Control

Volume control is a mandatory breath in which the ventilator delivers a preset flow rate over a set time to generate the set tidal volume. Some ventilator manufacturers use the term “volume control” to include breaths with demand flow; in this chapter these breaths will be discussed after pressure control as they are akin to pressure control than volume control.

Flow is predetermined and set during these breaths. Some ventilators require inspiratory flow to be constant (“square”); others allow different shapes such as decelerating (“ramp”). After normalization for inspiratory time, the impact of changing shape is likely small.^{26,27} Although certain ventilators appear to have different setting requirements, delivery of a volume control breath includes these presets: flow, volume, and time. Inspiratory time is determined by the time required to deliver the set volume at the set flow rate and shape.

It is easiest to understand volume control by first imagining the patient as being totally relaxed. Flow is delivered through the airway into the lung. A tidal volume of 500 mL in a normal-sized adult should result in a rise of airway pressure of 10 cm H₂O. A component of this pressure is related to resistance; a component is related to elastance (or stretch of the chest wall and lung). Other forces such as inertia are generally not clinically relevant. Patients with high resistance (such as asthma or an obstructed endotracheal tube) or low elastance (such as congestive heart failure or pneumonia) require a larger change in pressure to deliver the set tidal volume.

Maintaining an inspiratory hold, or “plateau,” at the end of the breath allows partitioning of the airway pressure. There is no inspiratory flow during the plateau so resistive forces fall to zero; airway pressure now reflects only the elastic recoil force of the lung and chest wall. This allows bedside analysis of an elevated airway pressure.

The plateau pressure reflects end-inspiratory stretch of the alveolus; this is always lower than the peak airway pressure because this includes the pressure required to overcome resistance. In patients where the resistance is predominantly in the large airways or endotracheal tube, the alveoli are protected from the peak airway pressure; in diseases where the resistance is heterogeneously distributed into smaller airways, alveoli at the ends of low resistance bronchi are likely exposed to nearly the peak airway pressure shown on the ventilatory screen.

If the patient breathes during volume control, this lowers airway pressure. As the flow during the breath is set, effort from the patient generates some inspiratory flow and the ventilator needs to push less hard. The stronger the patient effort, the closer to zero the pressure curve becomes. If the patient effort would have generated a higher flow than that set, the ventilator in effect becomes a brake limiting flow, resulting in negative airway pressure. Attempts to lower airway pressure by lowering inspiratory flow often lead to increasing patient effort and dyssynchrony.

It should be clear that volume control requires careful attention to flow rate settings. Settings need to satisfy the patient's

need for airflow and maintain an appropriate inspiratory time to allow expiration. Practitioners at the bedside need to readjust flow settings to changing patient effort such as occurs during awakening from sedation.

Pressure Control

Pressure control describes a mandatory breath in which the ventilator maintains the set airway pressure for a given inspiratory time. Maintaining positive airway pressure inflates the lung. Analogous to volume control, the pressure volume relationship is determined by the mechanics; therefore in patients with normal mechanics a low inspiratory pressure will generate an adequate tidal volume, but patients with poor mechanics will require a higher pressure.

Adjustment of tidal volume during pressure control requires careful attention to the inspiratory flow-time curve. If inspiratory flow is continuing at the end of the breath, prolonging inspiratory time will increase tidal volume; if flow has stopped, alveolar pressure equals airway pressure, resulting in an inspiratory plateau, and an increase in inspiratory pressure is needed to increase tidal volume. Patients with low resistance and low compliance have very short time constants and therefore tolerate short inspiratory times.

Pressure control will generally have a lower peak airway pressure than volume control because flow rate decreases over time, making the gradient from peak to plateau smaller. For a given tidal volume, pressure control and volume control yield the same alveolar pressures. As noted under volume control, limiting peak pressure is not as crucial as limiting alveolar pressure unless there is marked heterogeneity in airway resistance.

A more important difference between pressure control and volume control is how it adapts to varying patient effort. Patient effort generates inspiratory flow, which the ventilator must meet and exceed to raise airway pressure to the target; increasing effort requires increasing flow and results in increasing tidal volume. Whereas patient effort during volume control results in the patient doing work the ventilator would have done, during pressure control any patient work is additive to ventilator work.

One caveat to pressure control is that volume is not assured so a rapid worsening in mechanics will lead to an abrupt rise in Paco_2 . As all ventilators have alarms that monitor low exhaled tidal volume, this concern is perhaps overstated.

Demand-Flow Volume Control

This mandatory setting is available under various trade names on newer ventilators. It combines the assurance of a set tidal volume with the comfort and responsiveness of pressure control. The ventilator delivers pressure-controlled breaths, slowly titrating the inspiratory pressure to achieve the set tidal volume.

Settings are tidal volume and inspiratory time. Demand-flow volume control adjusts to patient effort. Increasing patient effort will result in larger tidal volumes for a given airway pressure. Although there is a set tidal volume target, the actual tidal volume on a given breath varies based on the inspiratory pressure, mechanics, and patient effort.

Over time, the ventilator adjusts the pressure to the target. For example, a patient with pneumonia will require lower inspiratory pressures to maintain the desired tidal volume as the lung improves. If the patient had been receiving the set tidal volume and now has increasing effort, the ventilator will gradually reduce the inspiratory pressure on subsequent breaths to

re-establish the desired tidal volume. Provided stable respiratory drive, the patient and ventilator will interact and establish an equilibrium sharing the respiratory work.

This option for ventilatory support is increasingly replacing traditional volume control. Demand-flow, improved patient interaction, and avoiding the need to preset flow rate are significant advantages.

Spontaneous Breaths

Unsupported

On IMV and CPAP, the ventilator can adjust inspiratory flow to match the effort of the patient. The target is to maintain a constant airway pressure during the inspiratory and expiratory phase. As the ventilator is using feedback to adjust flow, there is inherent delay and the resulting breath is not exactly like a patient breathing atmospheric pressure. There is an imposed work from the cumulative delays in pressure sensing and flow controllers present primarily at the initiation of inspiration and expiration. Improvements in ventilator design have significantly reduced this imposed work, such that breathing on CPAP is now much easier on a modern ventilator than one built 10 to 20 years ago.

Pressure Support

During spontaneous breathing, the ventilator can raise the target airway pressure during the inspiratory cycle, delivering "pressure support." The ventilator transitions from PEEP to a higher inspiratory target when patient effort is detected; this higher pressure is maintained until a predetermined signal that the breath is ending. This signal is typically defined as a reduction in inspiratory flow.

Initially designed as a means to overcome the imposed work of the ventilator and the endotracheal tube, pressure support can be titrated from zero (i.e., unsupported) to that sufficient to deliver full support, referred to as PSVmax. Pressure support allows precise titration of the support provided, although it is important to remember that the percentage of support given varies with the total amount of work required. Therefore a pressure support level of 10 may be full ventilatory support for a patient with normal lungs, but may only provide a small percentage of support for a patient with stiff lungs who required inspiratory pressures of 30 to deliver a tidal volume on volume control.

Patient ventilator interactions on pressure support vary depending on patient mechanics. In patients with low static compliance, lowering pressure support below PSVmax results in increasing patient work to maintain tidal volume; raising support above PSVmax results in increased tidal volume and continued minimal work. In patients with obstruction, raising pressure support increases tidal volume and decreases respiratory drive; these often contribute to diminished ability for the ventilator to sense patient effort, so-called failed triggers.

Initial Ventilator Settings

Any attempt to provide a simple algorithm to properly set a ventilator is doomed to failure because there are such a multitude of variables. Rather this section will highlight some considerations in selecting initial settings. The patient should then be carefully reassessed and each setting titrated.

1. **Oxygenation:** it is customary in many centers to deliver 100% oxygen in the first moments of ventilation until the ABCs of resuscitation are ensured. Provided the endotracheal is in place and secure and ventilation is occurring, most patients

can be rapidly titrated downward. FiO_2 above 60% is toxic, though generally 50% is considered safe. Though many patients are hypoxemic at time of intubation, most will tolerate reduced FiO_2 as their hypoxemia reflects ventilatory failure that should improve with mechanical ventilation.

- Patients who remain hypoxemic on 100% FiO_2 are manifesting shunt. Those with bilateral infiltrates may benefit from rapid titration upward of PEEP to decrease intrapulmonary shunt.²⁸ Patients with intracardiac shunt will not respond to ventilation and need manipulation of hemodynamics to minimize right-to-left shunting. Patients with unilateral infiltrate and pulmonary shunting are difficult to oxygenate; options may include nitric oxide inhalation or use of gravity to increase blood flow to the better ventilated lung.
2. Minute ventilation: at time of intubation many patients are deeply sedated or paralyzed and are unable to set their respiratory rate or control their minute ventilation. Patients with severe metabolic acidosis or with high dead space will require a high minute ventilation to maintain pH. Though normal minute ventilation is 5 to 6 L/min, some patients require a fourfold increase or more. Another indication for initial high minute ventilation includes tricyclic and salicylate overdose. Hypercapnic patients due to respiratory depression, such as narcotic overdose, do not require increased minute ventilation because carbon dioxide rapidly corrects after initiation of normal ventilation.
 3. Tidal volume: mean initial tidal volume settings have fallen from the historical 15 mL/kg/IBW to below 10 mL/kg/IBW.²⁹ Patients with small, fibrotic, diffusely infiltrated or compressed lungs may require a lower tidal volume. As discussed below, a tidal volume of 6 mL/kg/IBW reduces mortality in patients with ARDS.
 4. Respiratory rate: selection of minute ventilation and tidal volume will typically determine the set rate. Patients who will remain paralyzed or deeply sedated require the clinician to precisely titrate rate; otherwise selecting a low backup rate may avoid diaphragmatic atrophy by requiring patient trigger.³⁰
 5. Mode: Patients with acute respiratory failure or hemodynamic instability benefit from full ventilatory support. This can be delivered as mandatory breathing, high level pressure support³¹ or both. This is little data showing an advantage of CMV versus IMV as an initial setting.³²

Non-Invasive Ventilation

Acute decompensation of two chronic conditions, CHF and COPD, may result in critical hypoxemia or intolerable work of breathing that is reversible over the course of hours. In these situations, gas exchange and work of breathing may be temporarily assisted by means of so-called non-invasive positive-pressure ventilation (NPPV) without the use of mechanical ventilation via an endotracheal tube.³³⁻³⁵ The patient interface for NPPV is most commonly a mask with a silicone rim strapped to the patient's head to provide a tight seal over the nose and mouth; occasionally a nasal mask or nasal cushions covering the nares may be sufficient. NPPV can be applied in a variety of ways: the airflow generator may be a standard ventilator with separate inspiratory and expiratory tubing, or a simpler pressure generator that provides controlled airflow to a set pressure via a single tube (in this case a "bias flow" allows exhaled gas to be flushed out through an opening near the mask).

The simplest form of NPPV is constant positive airway pressure (CPAP) whereby a steady supra-atmospheric pressure is applied to the airway to recruit collapsed alveoli and improve oxygenation. This is most often successful in rescuing patients with pulmonary edema and a normal PaCO_2 . More commonly, the NPPV machine algorithm delivers variable flow to achieve a higher airway pressure in inspiration than in exhalation, termed "bilevel" pressure ventilation. This non-invasive mode provides mechanical assistance to a patient who cannot perform enough alveolar ventilation to excrete CO_2 , due to COPD or neuromuscular weakness for example. In such patients with impending respiratory failure due to a reversible condition, NPPV can provide a "bridge" of mechanical assistance and improved oxygenation until the acute decompensation is corrected. This may allow the patient to avoid the morbidity associated with intubation and mechanical ventilation. Prospective trials have demonstrated that judicious use of NPPV prevents the need for mechanical ventilation in up to 75% of acute COPD exacerbations and 50% of acute CHF decompensations.³⁶⁻³⁹

Because NPPV mask ventilation cannot reliably provide controlled alveolar ventilation it should not be used in patients with florid respiratory failure. In fact it is contraindicated in this circumstance, as it may lull the provider into a false sense of security while the dyspneic patient deteriorates with a mask covering his face. In addition, the mask interface applies pressure not only to the airway, but also the esophagus, which may result in gastric distension, vomiting inside a closed mask and a disastrous aspiration. Patients with impaired mental status are particularly at risk. Obtundation is a therefore a relative contraindication to NPPV; its use should be restricted to patients who are fairly alert and can protect their airway. Another important caveat is that a hemodynamically compromised patient on NPPV may deteriorate to point of cardiac arrest with an unprotected airway, converting a planned intubation into an emergent "code" situation.^{40,41}

Monitoring should include visual observation of their work of breathing, and an ABG performed 1-2 hours after initiating NPPV to ensure that CO_2 retention is not occurring. It has been recommended that patients who do not improve in the first 2-4 hours should be considered for prompt endotracheal intubation.⁴²

Discontinuing Mechanical Ventilation

The term "weaning" from mechanical ventilation implies a gradual process. In general, this is not necessary, as mechanical ventilation can be stopped promptly when the cause of respiratory failure has improved. Use of the word "weaning" has thus declined in favor of the term "liberation" from the ventilator. Ironically, in fact, it is often the physician who must be "weaned" from the belief that a patient still requires mechanical ventilation. An important recent finding is that a protocol mandating daily tests of the patient's ability to breathe off the ventilator will shorten the mean duration of mechanical ventilation by 1 to 2 days. This is significant, since the risk of nosocomial pneumonia, with its attendant 20% to 50% mortality, increases with the duration of ventilation.

Historically, physicians in the CCU have been concerned that a "weaning" trial may increase the O_2 demand by the respiratory muscles (by 15% to 25%), increase cardiac afterload and lead to a catecholamine release, which together may precipitate ischemia in patients with unstable coronary disease.^{43,44} It is thus

conventional to keep a ventilated patient sedated to avoid stress and the potential risk of hypoxemia, until ischemia has resolved or revascularization accomplished. Of note, however, studies in mixed MICU-CCU patients have found that acute troponin I elevation or ST segment deviation occurs only rarely during ventilator liberation trials.⁴⁵

Once the CCU patient's condition has stabilized, the process of liberation from the ventilator requires the few brief assessments. First, the patient must be reasonably awake, able to clear secretions, and protect the airway. This may be a problem in obese patients who have received continuous sedative infusions. It has been shown that the pharmacokinetics of the short-term sedatives, such as midazolam and propofol, change after 48 hours of continuous infusion in such patients; clearance of the drug from adipose stores in the body is slow. It is often a distressing surprise to stop the sedative infusion before a liberation trial, only to find the patient remains deeply sedated for greater than 24 hours.

Secondly, the patient must be able to oxygenate at moderate settings for FiO_2 and PEEP. A general rule of thumb is that the oxygen saturation should be above 92% on an FiO_2 less than 50% with a PEEP 5 cm H_2O or less. Thirdly, the patient should be hemodynamically stable.

Once these conditions have been met, many clinicians use "weaning parameters" to predict whether extubation will be successful before removing the endotracheal tube. Multiple parameters have been studied; the most common method is to place the patient on spontaneous unassisted ventilation (CPAP) for 30 to 60 minutes and record the ratio of respiratory rate to tidal volume (f/TV). A cutoff value less than 105 yields an 86% positive predictive value and 82% negative predictive value for extubation success.⁴⁶ However, a recent study showed that when the f/TV ratio is incorporated into a weaning protocol, the time to extubation is delayed.⁴⁷ Though controversial, "weaning parameters" such as the f/TV ratio may be useful parameters to guide clinical judgment about when to extubate a patient.^{48,49,50}

A number of ventilator settings have been used to wean patients from mechanical ventilation, including CPAP with pressure support titration, SIMV titration, and single or multiple daily trials of spontaneous breathing via a T-tube or CPAP. The latter has been consistently associated with a shorter duration of mechanical ventilation in multiple studies, and is the method most often used in modern ventilator liberation protocols.

Since it is not possible to predict extubation success with 100% accuracy, some patients (approximately 10% to 15%) will require reintubation for recurrent respiratory failure in the first 24 hours after extubation. Therefore close observation for 12 to 24 hours after extubation is essential. This should include frequent monitoring of vital signs and arterial O_2 saturation and physical examination. The latter may reveal postextubation stridor, indicating laryngeal and subglottic edema. In the pediatric population, this has been successfully treated with nebulized dexamethasone, an approach which has been extrapolated to adults. Factors such as traumatic intubation, a history of self-extubation, and a prolonged period of ventilation predispose patients to postextubation stridor. Patients at risk of this complication can be identified by measuring the magnitude of tidal volume "leak" after deflating the endotracheal tube cuff. Treatment with prophylactic IV corticosteroids may reduce the incidence of this complication in a high-risk population.

Monitoring of Patients on Mechanical Ventilation

Radiology

It has been routine to obtain daily portable chest radiographs for patients intubated on mechanical ventilation, though some studies suggest that it may be safe and cost-efficient to change this practice.⁵¹⁻⁵⁴ Chest radiographs have utility in monitoring fluid status, evaluating for ventilator-associated pneumonia, and confirming the proper location of a patient's tubes and lines.⁵⁵ However, portable films are limited and differ from routine chest radiographs. Standard radiographs are taken in the standing position, shot from posterior to anterior, and can be obtained with higher energy because such analysis of a portable chest radiograph requires recalibration.

Radiographs should be carefully inspected in regard to indwelling lines and catheters; in fact, these account for most of the new diagnoses in most studies. Endotracheal tubes (ETT) should be located approximately 2 cm from the carina. Remember that the tip of the ETT changes with head position: in orally intubated patients, the ETT tip moves up when the head is flexed and vice versa; in nasally intubated patients the opposite occurs. If inserted too far, typically the ETT will move into the right mainstem where it may occlude the right upper lobe bronchus; therefore atelectasis of the left lung or right upper lobe should prompt careful inspection of the ETT location. Correct location of venous catheters and aortic balloon pumps should be ascertained on every film. Additionally, care should be taken to ensure there are no retained guide wires or other foreign bodies within the chest.

Fluid status can be assessed on a chest radiograph. Bilateral effusions and bilateral infiltrates suggest pulmonary edema; additional signs include cardiomegaly and width of the vascular pedicle.⁵⁶ Vascular redistribution and Kerley B lines are less specific on portable films as many are taken in a supine or semi-recumbent position.

Chest radiographs are less sensitive and specific for pneumonia as classic findings of lobar consolidation are uncommon in ventilator-associated pneumonia. Consolidation and atelectasis are difficult to distinguish, especially on a single film. Persistent opacities, especially in the right clinical context, are more likely to be infectious. Left lower lobe atelectasis, recognized as a triangular density behind the heart, is extremely common in patients who are obese or with cardiomegaly.

It is important for clinicians to be aware of the differences in detecting pneumothorax in the ICU.⁵⁷ Though even a small pneumothorax is readily detected on an upright film, moderate and large pneumothoraces can be easily overlooked on a portable chest x-ray. Air will collect in the most superior aspect of the chest; in a supine patient this is at the anterior costophrenic angle. A "deep sulcus" sign signifies air pushing the diaphragm downward. Lung marking may still be present as the lung will be seen posterior to the air collection. Useful findings for pneumothorax include subcutaneous air, mediastinal shift, and abnormal sharpness in the margins of the heart, aorta, or mediastinum. In the case of suspected pneumothorax, obtaining a truly upright or decubitus film may be useful. Similarly, pleural effusions can be quite large before they become evident; posterior layering effusion appears as a general graying over the lung that usually becomes less evident at the apex. Bedside ultrasound allows localization of pleural effusion and facilitates drainage procedures.^{58,59}

Though transportation to the scanner can be challenging and at times impossible, computed tomography (CT) scan is extremely useful to visualize the lung, pleura, and mediastinum.^{60,61}

Pneumothorax can be definitively diagnosed and the chest tube placement facilitated. Effusions can be evaluated for loculations, pleural enhancement, and size. CT imaging of acute respiratory distress syndrome (ARDS) has significantly advanced our understanding of the physiology of this disease.⁶¹ Many patients will demonstrate unexpected pulmonary infiltrates, though this can lead to difficulty when trying to evaluate for pneumonia. CT scanning is very useful in evaluating for pulmonary embolism because ventilation-perfusion scanning is extremely challenging to interpret in the mechanically ventilated patient.

Ventilator Alarms and Waveform analysis

Careful monitoring of airway pressure and flow provides invaluable information during mechanical ventilation. These monitors are essentially continuous pulmonary function tests and will provide assessment of mechanics, be early warning signs of complications, and allow tracking of a patient's course.

The most basic monitor is airway pressure. It is continuously monitored and displayed on most ventilators, and alarms are set to monitor for both high and low pressure. Loss in airway pressure suggests a leak, commonly signifying a ventilator circuit disconnect or patient extubation. Other potential causes include a rupture in the balloon cuff of the endotracheal tube, poor mask seal during noninvasive ventilation, or incorrectly set tidal volume.

Sudden rise in airway pressure implies a change in airway resistance or compliance. Airway resistance may signify an obstructed endotracheal tube, patient biting of the tube, airway secretions, or blockage along the ventilator circuit, such as a clogged heat-moisture exchanger. Sudden drop in pulmonary compliance may indicate a tension pneumothorax or advancement of the endotracheal tube down the right mainstem bronchus, or "air trapping" from dynamic hyperinflation.

Many ventilators now provide graphic displays that provide more information than simple readout of peak airway pressure. Common waveforms that are monitored include airway pressure versus time and airflow versus time; other options include pressure-volume and flow-volume curves. Full analysis of these curves is beyond the scope of this chapter, but these graphs are invaluable in determining the physiologic cause of a patient's respiratory failure or while troubleshooting an acute problem.

During standard volume control, airflow is preset, so little is gained analyzing the inspiratory phase of the flow-time curve. Similarly, during pressure control the inspiratory pressure waveform is preset. Expiratory flow-time curves are useful regardless of the ventilatory settings because they reflect patient expiration. Patients should have a nearly linear expiratory flow curve; scooping or decelerating curves indicate airway resistance. Patients who continue to show exhalatory airflow as the next breath is initiated are likely air-trapping.

Work of Breathing

Assessment of the work of breathing is crucial in evaluating a patient. Patients with high workload are more likely to require mechanical ventilation until mechanics improve. Patients in respiratory failure with a normal workload should be evaluated for neuromuscular weakness or excessive sedation because the respiratory failure is not explained by mechanics.

Ventilator work is defined as the change in airway pressure related to tidal volume or $\int P \, dv$. Work is expressed as joules per liter, though it may also be useful to express joules per breath

or joules per minute. Low compliance, high airway resistance, and high minute ventilation all result in increased work. When patients are relaxed, ventilator work is the change in airway pressure during the tidal volume. Patient work is more difficult to measure. Monitoring of esophageal pressure only captures work performed across the lung and does not include work across the chest wall. Expiratory work is even more difficult to calculate; patients with obstructive airway disease perform significant expiratory work because the ventilator only assists in inspiration.

Most patients are not fully relaxed during mechanical ventilation, and many patients continue to work during a mandatory breath. In fact, many patients "resting" on the ventilator are working harder breathing than the physicians caring for them. Simply triggering a ventilator can require significant work, especially in patients with airway obstruction.

Though patient work may be difficult to quantify, bedside clinical examination can identify patients performing significant work. Signs of high work include agitation, tachypnea, hypertension, tachycardia, nasal flaring, accessory muscle use, and intercostal retractions, just as in patients who are not intubated. Signs of respiratory distress in ventilated patients are commonly attributed to anxiety and treated with benzodiazepines. Care must be taken to fully evaluate the cause of the distress. Often adjustment of the ventilator settings can relieve this distress, reducing the need for sedation.

Complications of Ventilation

- Sedation/delirium: Causes, Treatment, Complication, Daily wake-ups
- VAP: diagnosis, prevention, treatment
- Prolonged mechanical ventilation
- Tracheotomy

Complications of Mechanical Ventilation

Ventilator-Associated Pneumonia (VAP)

Attributable mortality from VAP may be as high as 30%.^{62,63} This feared complication is the main rationale for trying to limit the duration of ventilation. Risk factors include advanced age, severity of illness, immunosuppression, the use of heavy sedation, colonization of the upper airway by pathogens and long duration of ventilation. Recently an association has been recognized with the presence of an infected "biofilm" inside the endotracheal tube, which is now the target of preventative interventions.^{64,65} The reader is referred to excellent recent reviews of this topic.⁶⁶⁻⁶⁸

Barotrauma and "Volutrauma"

Expiratory airflow in the diseased lung is non-homogeneous leading to focal air-trapping. The parenchyma may rupture, allowing air to track medially along the bronchovascular sheath, leading to pneumomediastinum and ultimately free rupture into the pleural space. Tension pneumothorax may occur when rapid accumulation of air pressurizes one hemithorax and compresses the central veins, causing shock. This is evident at the bedside: a patient who develops sudden shock, absent air entry and distension on one side and contralateral shift of the trachea should undergo prompt needle decompression, even before a confirmatory chest x-ray.

Many experts prefer the term "volutrauma," since it is now understood that ventilation with large tidal volumes causes

sequential inflation-deflation cycles in regions of atelectatic lung, resulting in shear injury and contributing to the lung pathology (see “ARDS” below)

Hemodynamic Compromise

This occurs most commonly at the initiation of mechanical ventilation in a volume-depleted or otherwise pre-load dependent patient, as detailed elsewhere in this chapter

Oversedation

As noted above, this complication is due to the well-intentioned use of rapid-acting sedatives by continuous infusion. After 24-48 hours, these drugs demonstrate prolonged elimination times, especially in the obese patient, which delays weaning. It is preventable by a brief daily interruption all continuous sedative infusions.^{69,70}

Respiratory Muscle Weakness

This problem, though rare in patients ventilated for <72 hours, is more common when patients are paralyzed or heavily sedated for long periods. Suppression of respiratory drive leads to alterations in diaphragmatic muscle fibers that are associated with respiratory muscle weakness.⁷¹ The problem may be compounded by malnutrition and the use of medications that cause myopathy such as corticosteroids and aminoglycosides.

Airway injury/stenosis: The incidence of clinically important laryngeal injury and subglottic stenosis is <2% with the use of modern low-pressure endotracheal tubes cuffs. However, re-intubation, shock and hyperactivity in the ventilated patient place the patient at risk. Careful monitoring to keep endotracheal tube cuff pressure <30 cmH₂O is recommended to avoid this complication⁶⁷

Ventilation of ARDS and Obstructive Airways Disease

Acute Respiratory Distress Syndrome

The acute respiratory distress syndrome (ARDS) was first described in 1967 and is now recognized as the development of non-cardiogenic pulmonary edema as a response to either a pulmonary or nonpulmonary injury.^{72,73} Disruption of the alveolar capillary membrane leads to surfactant inactivation, hyaline membrane formation, and alveolar flooding. Frequently seen in the setting of multiorgan failure and sepsis, it can also present as a single organ system failure.

Diagnostic criteria from an international consensus require (1) acute onset in the proper clinical setting, (2) arterial hypoxemia, (3) bilateral radiographic infiltrates, and (4) that it is not explained by increased hydrostatic pressure (e.g., heart failure).^{74,75} Though these criteria have been proven useful in designing clinical trials, there are significant issues regarding sensitivity and specificity.⁷⁶⁻⁷⁸

Problematic in the CCU is the exclusion of patients with elevated left atrial wedge pressure. ARDS has been well described after myocardial infarction.⁷⁹ If ARDS occurs after a large myocardial infarction and the patient then develops acute heart failure, ARDS is still present. Though patients with uncomplicated congestive heart failure often respond fully to diuretics, patients who develop pulmonary edema during acute illness may remain tachypneic and hypoxemic despite

maximum diuresis, suggesting a “noncardiogenic” component to their edema.

Increasingly, it is recognized that ventilatory strategies play an important role in the development of ARDS, prompting the term “ventilator-induced lung injury.” Animal models have clearly demonstrated that ventilation of normal lungs with high tidal volume leads to lungs with histopathologic changes identical to ARDS; ventilation of injured lungs with a normal tidal volume yields the same results. During ARDS much of the lung does not participate in ventilation, such that delivering what would generally be considered a normal tidal volume is too large and contributes to lung injury. Large randomized studies have proved the importance of reducing tidal volume and current recommendations are for selecting a tidal volume of 6 mL/kg/IBW.⁸⁰ In mild ARDS, increasing respiratory rate can compensate for the reduced tidal volume, but in severe cases, quite extreme hypercapnia and acidemia may need to be tolerated. It is crucial to allow this “permissive hypercapnia,” because there is a mortality benefit to reducing tidal volume; there is no proven benefit to maintaining a normal pH.⁸¹

Initially ARDS was considered a “stiff lung” that showed reduced static compliance, poor oxygenation, and abnormal x-rays. In fact, an ARDS lung that is forced open under high pressure will function normally and appear normal on a CT scan; if allowed to collapse fully, it again becomes stiff and oxygenates poorly.⁸² This cycling between airless (or derecruited) and ventilated (or recruited) is thought to contribute to ventilator-induced lung injury. ARDS is perhaps better considered an abnormally derecruitable lung, and most patients with ARDS will improve their oxygenation with raised airway pressure because applying high airway pressure will recruit collapsed lung units.^{61,82,83}

Open-lung strategies have been developed that capitalize on the concept that the lung functions more normally when aerated. The lung will continue to function well provided airway pressure does not fall below a critical closing pressure. Lungs that have been recruited in this manner will oxygenate well; several strategies have been devised for ventilation (i.e., carbon dioxide removal) while maintaining an open lung.⁸⁴

Maintaining high PEEP throughout the cycle will optimize arterial oxygenation; care must be taken to carefully follow tidal volume and peak inspiratory pressure as the lung is already quite full even before inspiration begins. Controlled studies have shown high PEEP strategies to be safe but did not reduce mortality over more conservative PEEP approaches.⁸⁵

High frequency oscillators (HFO) or jet ventilators offer a means to excrete carbon dioxide with extremely small tidal volumes.⁸⁶ Using this approach requires (1) opening the lung through the application of high airway pressure and (2) delivering rapid breaths often at a rate of 180 to 300 (3 to 5 Hertz) with a controlled I:E ratio. Tidal volumes of just 100 to 200 mL at 3 to 5 Hertz can maintain adequate arterial blood gases through a variety of physiologic mechanisms. Once the lung is fully opened, gradual reductions in airway pressure are tolerated. This mode requires dedicated ventilators, deep patient sedation, and careful monitoring. Studies suggest improved patient outcome, but larger randomized studies are required to prove mortality benefit.⁸⁷⁻⁸⁹

Another open-lung approach is airway pressure release ventilation (APRV).^{90,91} Two separate dyssynchronous actions contribute to ventilation. First, there are brief intermittent

decompressions that allow carbon dioxide removal; the expiratory time is kept very short (often 0.5 second) to prevent alveolar derecruitment. Second, the patient is allowed to spontaneously ventilate; lung compliance is improved as the lung is recruited and the patient is able to maintain an acceptable tidal volume. A major advantage of APRV is the avoidance of the deep sedation commonly required with HFO, but there is no proven mortality benefit over conventional ventilation.^{84,92}

It is important to identify patients with ARDS. Studies have shown high variability in diagnosing it across ICUs and across hospitals.^{74,78,93} Patients with bilateral infiltrates who are hypoxemic should be evaluated. Patients with shock are likely to have a component of ARDS, even if they also have cardiogenic pulmonary edema. Once ARDS is identified, ventilatory strategy dictates reducing the tidal volume to 6 cc/kg/IBW and titrating PEEP to improve oxygenation; another option is to transition to an open-lung strategy.⁸⁰ The clinician must understand that the patient may remain in respiratory failure for several days, requiring heightened awareness regarding nutrition, minimizing nosocomial complications, attention to patient comfort and sedation, and discussion with the family.

COPD and Asthma

Many patients with cardiac disease have coexistent asthma and chronic obstructive pulmonary disease (COPD). Patients with severe chronic disease and those with acute exacerbations require careful attention while on mechanical ventilation. The clinician must be aware that increasing flow into the lung is only beneficial provided the air can get back out. Obstructive airways manifest primarily during expiration and mechanical ventilators assist inspiration. Patients are at risk for hyperinflation with attendant risks of reduced preload and pneumothorax.⁹⁴ Most dramatic are patients with status asthmaticus; though management is similar to that of COPD, severe status is a true emergency that may benefit from consultation with a pulmonologist.⁹⁵

Patients with airway obstruction require attention to expiratory time. Unfortunately, ventilators do not display this important parameter. Though normally a patient can exhale a standard tidal volume in under 2 seconds, patients with COPD require longer. For example, a patient with severe COPD with an FEV₁ of 0.6 L can only exhale 600 mL in 1 second; when sedated on a ventilator, expiratory flows are lower. If this patient is given a tidal volume of 800 mL with an expiratory time of 2 seconds, it is predictable that the patient will not return to FRC and develop hyperinflation. Breath stacking or “dynamic hyperinflation” increases elastic recoil pressure such that the patient may reach an equilibrium that permits expiration of 800 mL in 2 seconds, but at the expense of increased intrathoracic pressure or “auto-PEEP.” If equilibrium is not reached, either the ventilator will stop delivering tidal volume due to reaching the high pressure limit or pneumothorax develops.

Hemodynamically, autoPEEP acts identical to PEEP, decreasing preload and venous return. AutoPEEP is also similar to set PEEP in that hyperinflation increased inspiratory work because the respiratory system is less compliant as it nears total lung capacity. AutoPEEP differs from PEEP in that alveolar pressure is above airway pressure at the beginning of inspiration; this results in an imposed work of trigger that needs to be overcome with each inspiratory effort.^{96,97}

Though expiratory time is not reported, many ventilators do report inspiratory time to expiratory time ratios (I:E). Simple

arithmetic shows the limitation of exclusively focusing on I:E ratio. A patient breathing at 10 breaths/min (i.e., each breath lasts 6 seconds) with an I:E ratio of 1:2 has an inspiratory time of 2 seconds and expiratory time of 4 seconds. A patient breathing at a rate of 20 breaths/min (i.e., each breath lasts 3 seconds) cannot have 4 seconds to exhale, even with an I:E ratio of 1:100.

Optimizing expiratory time requires control of the respiratory rate and short inspiratory time. Inspiratory time during mandatory breaths (i.e., CMV and IMV) is set. During standard volume control, inspiratory time is determined by tidal volume and air-flow and increasing flow rate will shorten inspiratory time. In pressure settings, generally the I-time can be set in seconds. If a patient has a set rate of 12/min and the I:E ratio is deemed appropriate, the ventilator will not shorten the inspiratory time if the patient begins to breathe more rapidly; therefore the I:E ratio will become inappropriately high (with insufficient exhalatory time) even if the ventilator allows “setting of the I:E ratio.”

Patients with obstructive airways often receive bronchodilators, such as inhaled β_2 -agonists and anticholinergics.⁹⁸ These medications can be delivered from a meter-dosed inhaler with an adapter or from a nebulizer.^{99,100} Both of these delivery systems are inefficient at times, delivering less than 10% of the expected dose with much of the drug depositing in the ventilator circuit or endotracheal tube. As bronchodilators are generally safe and inexpensive, the dose is commonly increased. There remains significant uncertainty regarding how much, if any, drug is actually delivered. Careful attention to aerosol delivery can significantly increase drug delivery; factors to consider include bypassing the humidifier, distance of the nebulizer from the Y connector, and ventilator settings.^{101,102} These issues take on greater significance when delivering drugs with a narrow therapeutic window or high cost.

Emergency Dialysis and Ultrafiltration

Nand K. Wadhwa

CHAPTER 51

Indications for Renal Replacement Therapy
Principles and Technical Aspects of Renal Replacement Therapy

CRRT Compared with IHD
Ultrafiltration for Decompensated Heart Failure
Conclusion

MANAGEMENT OF critically ill patients with acute kidney injury (AKI) in the intensive care unit (ICU) often necessitates emergency dialysis for optimization of volume and metabolic status.¹ AKI often develops as one of the manifestations of multiple organ failure¹⁻⁴ and is an independent risk factor for mortality.⁵⁻⁷ Despite technological advances in renal replacement therapy (RRT) and improved delivery methods, the in-hospital mortality rate associated with AKI ranges from 35% to 80% in critically ill patients.^{1-5,8-11} This may be in part explained by the fact that presently no effective pharmacologic therapy exists for AKI and that RRT is only a supportive therapy for AKI. However, timing of initiation and dose and modality of RRT may affect the outcomes.¹²⁻¹³ This chapter describes the different modalities of RRT and addresses the basic principles regarding selection of different RRT for management of patients with renal failure and/or volume overload in the cardiac intensive care unit (CICU).

Indications for Renal Replacement Therapy

In a multinational study, the prevalence of AKI requiring RRT in the ICU was reported at 5.7%.¹ More importantly, there is an increasing need for dialysis in the CICU as highlighted in a recent study from the ADHERE registry stating that 91% of the patients hospitalized for acute decompensated heart failure (ADHF) had some degree of renal failure, with 64% having at least moderate renal failure and that 14% of them required initiation of RRT.¹⁴

The basic goals for management of patients with AKI are maintenance of fluid and electrolyte balance, avoidance of nephrotoxic agents (i.e., aminoglycosides, radiocontrast agents, etc.), maintenance of adequate nutrition, and appropriate dosing of medications according to the renal function.¹⁵ When conservative therapy fails to achieve optimal fluid and metabolic control, dialysis is initiated. The most widely accepted indications for RRT in patients with AKI are: (1) fluid overload refractory to diuretics; (2) hyperkalemia (usually serum potassium >6.5 mEq/L); (3) severe metabolic acidosis (arterial pH <7.1); (4) signs of uremia, such as pericarditis, neuropathy, or unexplained altered mental status. However, there is a wide disparity among nephrologists regarding the timing of initiation of dialysis based on concentrations of blood urea nitrogen (BUN) or serum creatinine and/or urine output in the ICU.¹⁶⁻¹⁹

Principles and Technical Aspects of Renal Replacement Therapy

There are multiple modalities of dialysis that are included under RRT and are summarized in Table 51-1. The comparison of solute removal and main features of various techniques are summarized in Table 51-2. These modalities mainly differ in the principles of solute removal and rate of solute removal. Solute removal during dialysis occurs by three mechanisms: (1) passive diffusion of solutes between the plasma and the dialysis fluid along their concentration gradient; (2) convection (i.e., dragging of the solutes along with the plasma water across the filter membrane); and (3) adsorption of solutes to the filter membrane. Each modality will be discussed in the following sections.

Table 51-1. Modalities of Renal Replacement Therapy

Intermittent Therapies	Hybrid Therapies	Continuous Therapies
Hemodialysis (HD)	Sustained	Slow continuous
Peritoneal dialysis (PD)	low-efficiency dialysis (SLED)	ultrafiltration (SCUF)
Ultrafiltration (UF)	Extended daily dialysis (EDD)	Continuous hemofiltration: (CHF) - CAVH, CVVH
Hemofiltration (HF)		Continuous hemodialysis: (CHD) - CAVHD, CVVHD
		Continuous hemodiafiltration: (CHDF) - CAVHDF, CVVHDF
		Continuous cyclical peritoneal dialysis (CCPD)

CAVHD, Continuous arteriovenous hemodialysis; CVVHDF, Continuous venovenous hemodialysis; CAVHF, Continuous arteriovenous hemofiltration; CVVHF, Continuous venovenous hemofiltration; CAVHDF, Continuous arteriovenous hemodiafiltration; CVVHDF, Continuous venovenous hemodiafiltration.

Table 51–2. Comparison of Solute Removal and Main Features of Renal Replacement Therapies

	IHD	SLED/EDD	SIUF/SCUF	C-HF/CVVHF	C-HD/ CVVHD	C-HDF CVVHDF	CCPD
Duration hr	3-4	8-12	8- Continuous	Continuous	Continuous	Continuous	Continuous
Access	Blood access	Blood access	Blood access	Blood access	Blood access	Blood access	Peritoneal access
Solute removal	Diffusion	Diffusion	Convection	Convection	Diffusion	Both	Diffusion
Blood flow rate mL/min	250-400	100-200	50-100	100-300	100-200	100-300	—
Dialysate flow rate mL/min	500-800	100	0	0	9-34	9-34	2 L every 2 hr exchange
Replacement fluid L/day	0	0	0	24-96	0	24-48	0
Fluid removal L/day	0-4	0-4	0-5	0-4	0-4	0-4	0-4
Effluent L/day	—	—	0-5	24-100	12-52	36-100	24-28
Effluent saturation %	15-40	60-70	100	85-100	100	85-100	60-70
Urea clearance mL/min	180-240	75-90	3.5	14-69	8-36	21-69	10-14

Data from Daugirdas JT, Blake PG, Ing TS: Handbook of Dialysis, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2007.

IHD, Intermittent hemodialysis; SLED, slow sustained extended dialysis; EDD, extended daily dialysis; SIUF, slow intermittent ultrafiltration; SCUF, slow continuous ultrafiltration; C-HF, continuous hemofiltration; CVVHF, continuous venovenous hemofiltration; C-HD, continuous hemodialysis; CVVHD, continuous venovenous hemodialysis; C-HDF, continuous hemodiafiltration; CVVHDF, continuous venovenous hemodiafiltration; CCPD, continuous cyclical peritoneal dialysis.

Intermittent Hemodialysis (IHD)

IHD is the dialytic modality of choice in hemodynamically stable patients with AKI needing RRT. Typically it is performed 3 days a week, but may increase to daily if necessary, with each session lasting for 3 to 4 hours. Solute is removed primarily by passive diffusion of small solutes such as urea and creatinine from the plasma into the dialysate, down their favorable concentration gradient. In contrast, bicarbonate diffuses from the dialysate into the plasma during metabolic acidosis. Blood (250 to 400 mL/min) and dialysate (500 to 800 mL/min) flow at high rates through the dialyzer in a countercurrent fashion, thus removing small solutes at a substantial rate (180 to 240 mL/min for blood urea nitrogen). The constant flow of new blood with high solute concentration and new dialysate with low solute concentration maximizes the rate of diffusive loss by maintaining a high concentration gradient between the two compartments. The net effect is that the loss of small solutes is much greater than that of fluid. On an average, up to 4 L of fluid are removed during each session of HD, thus limiting convective removal of solutes, with diffusion being the main mechanism for solute removal during IHD.

Slow Low-Efficiency Dialysis or Extended Daily Dialysis (SLED/EDD)

Solute removal during SLED/EDD also occurs mainly by diffusion. In comparison to IHD, blood flow rates (100 to 200 mL/min) and dialysate flow rates (100 mL/min) are much lower in SLED/EDD, with each session lasting for 8 to 12 hours. Hence, the rate of solute removal is much slower in SLED/EDD compared with IHD, which minimizes hemodynamic instability due

to the dialysis procedure itself. However, fluid removal during SLED/EDD is similar to IHD, but can be increased depending upon the volume status and hemodynamic stability of the patient.

Peritoneal Dialysis (PD)

PD uses a highly permeable natural peritoneal membrane for dialysis. This modality is mainly used as continuous cyclical PD (CCPD) in the ICU setting but can also be used on intermittent (IPD) basis. Solute removal during PD also occurs mainly by diffusion, driven by the osmotic gradient. Solute clearance depends upon the exchange volume and the dwell time (the time during which the fluid is present in the peritoneal cavity). For example, with an exchange time of 2 hours (which includes fill time of 5 to 10 minutes, dwell time of 90 minutes, and drain time of approximately 20 to 30 minutes) and an exchange volume of 2 L, approximately 24 L of fluid will be exchanged daily. If the daily net fluid removal is 4 L, total daily drained dialysate will be 28 L (24 L + 4 L). Given the urea concentration in the drained dialysate is about 60% to 70% of that in the plasma in a patient with average peritoneal membrane transport, the urea clearance would be approximately in the range of 16.8 to 19.6 L/day (0.6 to 0.7×28 L). This clearance is somewhat lower and may not be sufficient in a critically ill, catabolic patient.

Continuous Renal Replacement Therapies (CRRT)

The concept of continuous dialysis was introduced in the 1960s, but only recently has this modality become well established in the ICU.²⁰ Solute removal is achieved either by convection,

diffusion, adsorption, or a combination of these methods depending upon the prescription. It is the therapy of choice in critically ill patients who are hemodynamically unstable and are in need of dialysis. The therapy is intended to run 24 hours a day. Depending on the mechanism of solute removal, CRRT are sub-classified into continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), continuous venovenous hemodiafiltration (CVVHDF), and slow continuous ultrafiltration (SCUF).

CVVH uses convection for solute removal with ultrafiltration rates (fluid removal rate) on an average of 1 to 4 L/hr. Fluid balance is achieved by replacing the ultrafiltrate with a physiologic electrolyte-based replacement solution, which can be infused either before or after the dialyzer. Solute removal in CVVH is regulated by the characteristics of the membrane and on the site of replacement solution administration, either predialyzer (predilution hemofiltration) or postdialyzer (postdilution hemofiltration). For the same effluent flow rate, clearance in predilution hemofiltration mode is less than that in postdilution hemofiltration. However, because of the dilution of blood by the replacement fluid before entering the dialyzer, much higher filtration fractions (larger effluent flow rate and replacement fluid rate) are feasible in predilution hemofiltration.²¹ By contrast, CVVHD uses only dialysate and hence, removes solute by diffusion. The dialysate flow rates (9 to 34 mL/min)²² in this modality are significantly lower than the dialysate flow rates in IHD and SLED/EDD. CVVHDF, as the name implies, uses both dialysate and replacement fluid and thus uses both diffusive and convective clearance.²³ Finally, SCUF does not use either dialysate or replacement fluid and is primarily used for optimization of volume status in patients that are hemodynamically unstable. Hence, CRRT techniques differ in the mechanism of solute removal. Despite the difference in the mechanism of solute clearance to achieve metabolic control, no study to date has clearly demonstrated improved clinical outcomes based on the different modality of CRRT.

The CRRT modalities can be performed using either an arteriovenous or venovenous circuit. Pump-driven venovenous circuits are better because they allow for higher solute clearance and also eliminate the need for arterial cannulation.²⁴ A prospective study comparing two consecutive groups of patients with AKI treated with either CVVHD (25 patients) or CAVHD (continuous arteriovenous hemodialysis, 28 patients) revealed a greater amount of hourly ultrafiltrate (mean, 590 mL versus 424 mL; $P < 0.001$) with CVVHD, but urea and creatinine clearances were not significantly different between the two groups. The major advantage of CVVHD was the substantial decrease in the number of access-related complications (2 versus 10; $P < 0.025$). Therefore the use of venovenous circuit is preferred over arteriovenous circuit.²⁴

CRRT Compared with IHD

CRRT is superior to IHD for the management of patients with AKI, particularly in patients that are hemodynamically unstable. The gradual removal of fluid and solute during CRRT enhances hemodynamic stability, which allows for increased salt and water removal and aggressive nutritional support. Furthermore, enhanced clearance of inflammatory mediators, particularly with hemofiltration in patients with concomitant sepsis, might provide additional benefits.²⁵⁻²⁷

However, to date no study has shown a survival benefit with CRRT when compared with IHD. This might be in part explained by the fact that most of the studies comparing IHD and CRRT have been nonrandomized observational studies or retrospective case series in which analysis was confounded by variations in disease severity among treatment groups.²⁸⁻³² In a multicenter study, conducted at four academic medical centers in Southern California, Mehta and colleagues³³ randomized 166 patients with AKI to IHD or CRRT. In the primary intention-to-treat analysis, 28-day all-cause mortality was 59.5% in patients that were randomized to CRRT compared with 41.5% in patients randomized to IHD ($P < 0.02$). However, unbalanced randomization had resulted in more patients with significantly higher APACHE III scores and a higher prevalence of liver failure in the CRRT group, both of which are associated with increased mortality. Adjustment for this imbalance in randomization using multivariate techniques yielded an adjusted odds of death associated with CRRT of 1.58 (95% CI 0.7 to 3.3). Similarly, Swartz and colleagues³⁴ used multivariate regression to adjust for severity of illness in 349 patients and reported that the adjusted risk of death associated with CRRT was 1.09 (95% CI 0.67 to 1.80) compared with IHD, which suggests neither a benefit nor a hazard associated with modality of dialysis. Since then, two meta-analyses^{35,36} comparing CRRT and IHD have shown improved outcomes with CRRT, but these results have not been supported by any of the randomized trials. In aggregate, after randomization of more than 700 patients, no survival benefit can be ascribed to modality of dialysis therapy.

Several studies³⁷⁻³⁹ have reported that despite the absence of a survival benefit, CRRT is associated with improved recovery of renal function compared with IHD. The analyses used in these studies, however, only considered recovery of renal function in surviving patients, and did not adjust for differences in mortality between the treatment groups. Reanalyzing the data using an end point that combines both mortality and nonrecovery of renal function demonstrated no apparent difference in outcome between groups.⁴⁰ Similarly, no difference in recovery of renal function was observed in three recent randomized trials.⁴¹⁻⁴³ Thus current data do not suggest improved recovery of renal function with CRRT. Although SLED has similar hemodynamic effects and metabolic control as CRRT,⁴⁴ currently no study has compared outcomes between SLED and other modalities.

In summary, current data suggest that survival and recovery of renal function are similar with both IHD and CRRT. In the majority of patients, selection of modality should therefore be based upon local expertise and available resources. In selected patients, CRRT may provide enhanced hemodynamic stability, and better management of volume status and nutritional requirements. It also provides for better preservation of cerebral perfusion in patients with brain injury or fulminant liver failure.⁴⁵

Optimal Timing for Initiation of RRT

In its early use, IHD was initiated only once advanced signs and symptoms of uremia and volume overload had set in.⁴⁶⁻⁴⁷ Despite control of these symptoms, no reduction in mortality was demonstrated. This led to the concept of "prophylactic" IHD.⁴⁸ Three retrospective studies reported that early (defined as BUN less than 93 to 150 mg/dL) versus late initiation of dialysis (BUN greater than 160 to 200 mg/dL) was associated with improved survival (43% to 75% for early dialysis versus 12% to 58% for late dialysis).^{49,50} Another prospective study of 18 patients reported

better survival (69% versus 20%) with early initiation of dialysis (BUN <60 versus 150 mg/dL).⁵¹ Similarly, using the Program to Improve Care in Acute Renal Disease (PICARD) database, a multicenter observational study for AKI, Liu and colleagues¹³ reported that patients in the “high” BUN group at time of initiation of dialysis had slightly lower survival rates at 14 and 28 days despite having a reduced burden of organ failure when compared with patients in the “low” BUN group. This result was not confirmed by another prospective study of 34 patients with AKI, which showed no difference in mortality among patients who started dialysis at BUN of 60 mg/dL or later at 100 mg/dL.⁵²

In relation to the timing of CRRT and clinical outcomes, three nonrandomized studies have reported improved outcomes, including improved survival with early versus late initiation of therapy.^{13,53–55} In a retrospective study of 100 consecutive patients treated with CVVH in a single shock trauma unit, survival was 39% among patients who were initiated on CVVH with BUN less than 60 mg/dL compared with 20% in patients with BUN greater than 60 mg/dL at the time of initiation of RRT.⁵³ Similarly, two other studies involving patients who developed AKI following cardiac surgery demonstrated higher survival rates in patients in whom CVVH was initiated when urine output was less than 100 mL within 8 hours after surgery, despite diuretic administration, compared with patients in whom therapy was withheld until objective laboratory criteria for dialysis, such as higher levels of serum creatinine, BUN, and potassium, were present.^{54–55}

In summary, no recommendations on the timing of initiation of RRT are possible beyond those defined by the conventional criteria for usual indications for RRT. General clinical practice is to start RRT when the BUN reaches 80 to 100 mg/dL, even though no consensus exists and practice patterns vary widely. The optimal timing for initiation of RRT in patients with AKI will require an adequately powered prospective randomized trial.

Optimal Dose of RRT in the ICU

Currently, no evidence-based recommendations exist regarding the optimal dialysis dose in AKI. Two components that affect the dosing of IHD include (1) the dose delivered during each treatment and (2) the frequency of treatment. No prospective studies have evaluated the impact of the dose of IHD per treatment on a fixed treatment schedule (e.g., three times per week). One retrospective study, evaluating the outcome of 844 critically ill patients with AKI requiring RRT,⁹ showed no correlation between delivered dose of dialysis and outcomes in patients with either very low or very high severity scores of illness. However, in patients with intermediate severity of illness, improved survival was observed in patients in whom the delivered dose of dialysis was above the median Kt/V_{urea} (K is the dialyzer urea clearance in mL/min, T is the duration of dialysis treatment in minutes, and V is the total body water in liters) of more than one. Similarly, Schiffl and colleagues evaluated the impact of the frequency of IHD on outcomes in 160 patients with AKI who were assigned to either daily or every other day IHD.⁵ Compared with alternate day dialysis, daily dialysis was associated with a significant reduction in all-cause mortality 14 days after the last hemodialysis session (from 46% to 28% [$P = 0.01$]). In addition, fewer hypotensive episodes were observed with daily hemodialysis and more rapid resolution of AKI (mean 9 days versus 16 days) was seen. However, the delivered dose in the alternate day dialysis group was significantly lower than the “acceptable and adequate dose” of dialysis. Thus, rather than

comparing an “adequate” with an “enhanced” dosing strategy, the increased mortality in the every-other-day group might have resulted from “inadequate” therapy.

Similarly, the relationship between patient outcomes and dosing of CRRT has been assessed in three randomized controlled trials.^{12,56,57} In the first study, 425 patients with AKI were randomly assigned to receive CVVH with ultrafiltration rates of 20, 35, or 45 mL/kg/hr.¹² Using an intention to treat analysis, survival 15 days after discontinuation of CVVH was 41% in the lowest dose arm compared with 57% and 58% in the intermediate and highest dose arms, respectively ($P < 0.001$). In the second trial, 106 oliguric patients were randomly assigned to early high-volume CVVH, early low-volume CVVH, or late low-volume CVVH.⁵⁶ At 28 days, survival was similar for all three groups (74%, 69%, and 75%, respectively). In the third study, 206 patients from a single center were randomly assigned to either CVVH (with a hemofiltration rate of 25 ± 5 mL/kg/hr) or CVVHDF (with a hemofiltration rate of 24 ± 6 mL/kg/hr plus 18 ± 5 mL/kg/hr of dialysate flow).⁵⁷ Survival after 28 days was 39% in the CVVH group and 59% in the CVVHDF groups ($P = 0.03$).

The Veterans Affairs/National Institutes of Health Acute Renal Failure Trial Network study which was designed as a multicenter study evaluating the effect of dialysis intensity on patient outcome comparing IHD in hemodynamically stable patients with either CVVHDF or SLED in hemodynamically unstable patients. The two dosing regimens were: 1) intensive therapy: hemodialysis and SLED were administered six times per week with a target Kt/V of 1.2 to 1.4 per treatment, while CRRT was provided with an effluent flow rate of 35 mL/kg per hour; 2) less intensive therapy: hemodialysis and SLED were given three times per week, while CRRT was provided with an effluent flow rate of 20 mL/kg per hour.⁵⁸ The rate of death from any cause by day 60 was 53.6% with intensive therapy and 51.5% with the less intensive therapy (odds ratio, 1.09; 95% confidence interval, 0.86 to 1.40; $P = 0.47$). Furthermore no significant differences occurred in in-hospital mortality, duration of RRT or recovery of renal function. The Randomized Evaluation of Normal versus Augmented Level of RRT (RENAL) conducted in Australia and New Zealand was designed to randomly assign patients with severe acute kidney injury who required intensive care to CVVHDF at a total effluent flow rate of either 25 or 40 mL/kg per hour.⁵⁹ In both treatment groups, 44.7% of patients died in the first 90 days after randomization (odds ratio, 1.00; 95% confidence interval, 0.81 to 1.23; $P = 0.99$). Overall, similar rates of recovery of kidney function were observed in both groups.

In summary, we can conclude from these studies that at least a delivered dose of Kt/V urea of 1.2 to 1.4 per IHD treatment session should be provided when given three days a week in a stable patient. The goal of therapy for CRRT should be to provide a total effluent flow rate of at least 20–25 mL/kg per hour in patients who requires intensive care.

Goals of RRT/Monitoring Parameters

The basic goals of management of patients admitted to CICU are the maintenance of fluid and electrolyte balance and hemodynamic stability in the presence of compromised heart performance. Hemodynamic instability has a marked effect on kidney function irrespective of the etiology and type of heart failure, and often results in AKI or worsening of preexisting kidney disease.

When IHD is initiated, initial treatment should be aimed to decrease BUN slowly, with a target urea reduction ratio of

less than 40%, especially if the predialysis BUN is greater than 125 mg/dL. This is done since rapid removal of solutes in the acute setting may result in dialysis dysequilibrium syndrome, causing altered mental status, seizures, and/or coma.⁶⁰⁻⁶² The patient should initially be hemodialyzed daily for 3 days with a gradual increase in the dose of HD. Subsequent HD sessions should provide a goal Kt/V of at least 1.2 per session. Adequacy of dialysis can also be assessed by urea reduction rate (URR) of at least 65% after each HD treatment. Dialysis should be continued as long as clinically necessary. One does not need to start CRRT or PD slowly, since they do not cause dialysis dysequilibrium syndrome because both modalities lead to slower removal of solutes when compared with IHD.

RRT for ESRD Patients in the ICU

End-stage renal disease (ESRD) patients on chronic maintenance dialysis are often admitted to the CICU for cardiac complications including acute coronary events. Most of these patients can usually tolerate IHD even in the presence of some hemodynamic instability with concomitant use of appropriate vasopressors. Daily dialysis may be needed in some patients to provide optimal metabolic and volume control. However, for patients who are hypercatabolic and hemodynamically unstable, CRRT is the modality of choice. Before initiation of CRRT in patients with ESRD, most of the centers place an acute dialysis catheter in the internal jugular vein or the femoral vein, even in patients with a functioning permanent arteriovenous access, such as an arteriovenous fistula or graft, due to safety issues. However, at Stony Brook, we regularly use the permanent AV access by using an angiocath⁶³ since temporary vascular access is associated with thrombosis of the cannulated vein and catheter-related infections.^{64,65} ESRD patients receiving continuous ambulatory peritoneal dialysis (CAPD) are usually switched to continuous cycler peritoneal dialysis (CCPD) in the ICU. If a patient on PD develops communication between the pleural cavity and the peritoneal cavity following cardiac surgery or develops compromised respiratory status requiring mechanical ventilation, IHD or CRRT should be considered. In addition, in a hypercatabolic patient, IHD or CRRT are preferred to PD due to better fluid and metabolic control.

Ultrafiltration for Decompensated Heart Failure

Heart failure (HF) affects approximately 4.9 million people in the United States and accounts for an estimated 1 million hospital admissions each year and remains the single most common admitting diagnosis in the United States for patients older than 65 years.⁶⁶ Hospitalizations for acutely decompensated heart failure (ADHF) have increased from 399,000 in 1979 to 1,100,000 in 2005, just in the United States.⁶⁷ An estimated \$12.7 billion is spent each year on inpatient management of ADHF. Despite advances in treatment, the number of deaths due to heart failure has steadily increased and an estimated 300,000 patients die of heart failure each year.⁶⁸

Heart failure involves impairment in the ability of the heart, particularly the left ventricle, to fill with or eject blood in amounts adequate to meet the body's metabolic needs. Decreased cardiac output leads to renal hypoperfusion, which causes activation of the renin-angiotensin-aldosterone system (RAAS) that further leads to increased fluid retention. This vicious cycle, if allowed

to continue, results in an approximately 50% risk of death at 1 year following initial hospitalization for HF. Clearly, removal of the excess volume is associated with improved prognosis. In one study, patients with New York Heart Association (NYHA) class IV heart failure and evidence of volume overload had improved survival with optimization of volume status.⁶⁹

Diuretics are currently the mainstay of therapy aimed at acutely reducing pulmonary capillary wedge pressure and leading to a negative fluid balance. All loop diuretics reduce sodium chloride reabsorption in the thick ascending limb of the loop of Henle.⁷⁰ The efficacy of the loop diuretics is dose-dependent and is determined largely by the rate at which the diuretic is delivered to its site of action. Loop diuretics are highly protein-bound and therefore enter the urine primarily by tubular secretion in the proximal tubule rather than by glomerular filtration.⁷⁰

Patients with HF respond less effectively to a given dose of diuretic than normal subjects. This is due to decreased delivery of the diuretics to the kidney since renal blood flow is reduced and also due to increased renal sodium reabsorption via RAAS. In addition, intestinal absorption of the diuretic may also be delayed.⁷¹ Moreover, in patients on chronic loop diuretics, distal tubular hyperplasia may inhibit diuresis via increase in the activity and number of Na⁺/Cl⁻ cotransporters.⁷² Besides questions regarding optimal dosing, dosing intervals, goal of diuresis, and the potential toxicities of these drugs have not been studied in placebo-controlled randomized clinical trials. This is particularly relevant since, although useful, diuretics have many undesirable side effects including promotion of potassium and magnesium wasting that may provoke arrhythmias, exacerbation of glucose intolerance, and the activation of the RAAS. In addition, overdiuresis can induce renal dysfunction, which has been associated with poor long-term outcomes.⁷³⁻⁷⁵ More importantly, poor response to diuretics may contribute to high rates of readmission for HF as observed in the Acute Decompensated Heart Failure National Registry (ADHERE). Despite the use of intravenous diuretics in almost 90% of the patients admitted with ADHF, 42% of patients were discharged home with unresolved symptoms, which might have contributed to the high rates of readmission for HF.⁷⁶

In an attempt to find better treatment for HF, studies have been performed to compare the efficacy of ultrafiltration with diuretic therapy in the treatment of ADHF. UF is a safe and reliable means for removing excess fluid. It removes water and non-protein-bound small- and medium-sized solutes through a semipermeable membrane.⁷⁷ In the RAPID-CHF study, 40 patients admitted with acute decompensated heart failure were either randomized to the usual care or usual care and UF. In the UF group, patients received 8 hours of UF treatment in addition to the usual care, resulting in greater average volume removal and weight loss at 24 and 48 hours.⁷⁸ In the study by Costanzo and colleagues, UF was initiated early on (within hours of admission) in 20 patients with ADHF who had clinical evidence of volume overload along with either diuretic resistance or presence of renal insufficiency. UF was continued until the patients' congestive symptoms were relieved, resulting in aggressive fluid elimination (approximately 8.6 L) and improvement in clinical signs and symptoms that lasted for 90 days following UF treatment.⁷⁹ Similarly in the UNLOAD study, a prospective clinical trial, 200 heart failure patients with at least two signs of volume overload were randomized to either UF therapy or intravenous diuretics. At 48 hours, the UF group demonstrated a significantly greater amount of weight loss (5 kg versus 3.1 kg; $P = 0.001$) and

larger net fluid loss (4.6 L versus 3.3 L; $P = 0.001$), compared with the diuretic group. More importantly, at 90 days, UF resulted in lower readmission rates for HF (18% versus 32%; $P = 0.037$), decreased length of hospital stay among patients that required readmission (1.4 days versus 3.8 days; $P = 0.022$), and lower rates of unscheduled visits (21% versus 44%; $P = 0.009$). However, no differences were observed in serum creatinine between the two groups.⁸⁰ Similarly, Marenzi and colleagues removed 4880 ± 896 mL (range 4300 to 7000 mL over 9+3 hours) by UF in 24 patients with NYHA class IV refractory heart failure and reported a significant increase in the cardiac output and stroke volume at the end of UF and also reported continued improvement even 24 hours after UF.⁸¹ Moreover, both right and left heart pressure decreased in equal ratio with UF.⁸²⁻⁸⁵ Additionally, UF has been shown to improve exercise tolerance and mechanical lung function, and also has been shown to reset the neurohumoral activation, thereby restoring response to diuretics.^{81,86-89} The improvement in both exercise tolerance and pulmonary function with UF has been reported to persist even 6 months after treatment.^{84,90}

In conclusion, studies have shown that ultrafiltration is an effective method of fluid removal in patients with ADHF, with advantages that include adjustable rate of fluid removal, predictable UF volume, and no major effect on serum electrolytes. In addition, it might also decrease the neurohormonal activity, thus inhibiting the vicious cycle of fluid and salt retention. It is not clear whether UF provides an additional advantage in patients who respond adequately to standard intravenous diuretics. In addition, given the relatively small body of data, it is not possible to assess the safety of ultrafiltration in terms of catheter-related infections, thrombosis of veins, and long-term outcomes.

At our center, we perform UF in patients with ADHF who are diuretic-resistant. We perform UF using the PRISMA M100 set with AN69 hemofilter (Gambro) (Fig. 51-1). The vascular access consists of a double-lumen catheter placed in the internal jugular vein or an angiocath placed in peripheral vein. We prefer to use the internal jugular vein in these patients because most of these patients have underlying chronic renal dysfunction¹⁴ and preservation of the peripheral veins is essential for future placement of permanent dialysis access. The blood flow rates are maintained at 50 to 100 mL/min. The ultrafiltration rate is

usually maintained between 300 to 800 mL/hr while maintaining systolic blood pressure at least greater than 80 mm Hg. Anticoagulation includes continuous heparin infusion at 500 units/hr. We allow for a maximum of 5 L of fluid removal over a period of 8 hours in a day. Blood pressure and heart rate are recorded every 30 minutes. The patient undergoes daily ultrafiltration for 8 hr/day until the patient becomes clinically euvolemic.

Conclusion

In the CICU, dialysis is needed for management of patients with ESRD, AKI, and/or acute decompensated heart failure. Patient survival and recovery of renal function are not affected by IHD or CRRT. However, CRRT is the modality of choice in hemodynamically unstable patients since it allows for better management of volume status and nutritional needs. Management of AKI is different from that of ESRD, and the RRT prescription should incorporate the unique characteristics of each patient. The close collaboration among nephrologists, cardiologists, and intensivists would allow for better management of patients in the ICU and may improve outcomes.

Cardiocerebral Resuscitation, Defibrillation, and Cardioversion

Gordon A. Ewy

Etiology of Ventricular Arrhythmias	Mechanical Devices for Resuscitation
Three Phases of Ventricular Fibrillation	Postresuscitation Dysfunction
Defibrillation	Postresuscitation Care
Cardiocerebral Resuscitation for Cardiac Arrest	Ending Resuscitative Efforts
Bystander Responder Critical	Techniques of Defibrillation
Hemodynamics of Cardiac Arrest	Electrical Cardioversion of Atrial Arrhythmias
Cardiopulmonary Resuscitation	Conclusion
Considerations in Resuscitation Research	

SUDDEN DEATH is a leading cause of mortality in developed countries and accordingly an important public health problem.^{1,2} Although out-of-hospital cardiac arrest is the major cause of sudden death, in-hospital cardiac arrest is also a significant concern. Fortunately, the incidence of ventricular fibrillation (VF) occurring in hospitalized patients with and after an acute coronary syndrome is decreasing because of more aggressive revascularization that decreases ischemia and limits infarct size, the use of β -adrenergic blockers that reduce ischemia, and the correction of hypomagnesemia and hypokalemia—electrolyte abnormalities that predispose to ventricular arrhythmias.² Despite this trend, ventricular fibrillation is still one of the many medical emergencies that the physician must be able to manage.

Although ventricular arrhythmias are always secondary to some abnormality, they are classified as *primary* because of the sudden onset of ventricular fibrillation or pulseless ventricular tachycardia and *secondary* when the cardiac arrest follows prolonged hypotension from cardiogenic, septic, or hemorrhagic shock or from respiratory arrest. This chapter addresses primary cardiac arrest.

The approach to the therapy of ventricular fibrillation both in and out of hospital depends upon its duration. Therefore this chapter begins by reviewing this important and relatively new concept, delineating the electrical, circulatory, and metabolic phases of untreated ventricular fibrillation.³

A major portion of this chapter will deal with cardiocerebral resuscitation (CCR), a more effective approach to the therapy of unexpected or primary cardiac arrest that is so new that many of its tenets have yet to be incorporated into national and international guidelines.⁴⁻⁸ A review of national and international guidelines for cardiopulmonary resuscitation (CPR) and advanced cardiac life support (ACLS) for primary cardiac arrest is not appropriate because significant portions of even the 2005 guidelines are currently out of date.⁹ Traditional CPR should be

reserved for respiratory arrest—a review of which is beyond the scope of this chapter.

Etiology of Ventricular Arrhythmias

The most common causes of ventricular tachycardia and fibrillation are acute myocardial infarction, chronic ischemic heart disease with decreased ventricular function, valvular heart disease that results in significant myocardial dysfunction, and cardiomyopathies (dilated, hypertrophic, arrhythmogenic right ventricular dysplasia [ARVD], and neuromuscular disorders).² Other causes include myocarditis, infiltrative cardiomyopathies, end-stage chronic kidney disease, and congenital heart disease in adults who had postoperative correction of their defect(s). Normal ventricular function does not rule out a cardiac cause of near syncope, frank syncope, or cardiac arrest because there are a number of arrhythmias that can produce such symptoms. Genetic identification is now possible for some conditions that predispose to serious cardiac arrhythmias, such as long QT syndrome, short QT syndrome, Brugada syndrome, and idiopathic ventricular tachycardia. Other conditions such as electrolyte disturbances and toxic agents that can cause ventricular tachycardia, VF, and sudden death must be identified clinically. Stress cardiomyopathy is a newly recognized entity of myocardial dysfunction that occurs predominantly in women following severe emotional stress that may result in ventricular dysfunction, hypotension, shock, and even ventricular fibrillation—an explanation for emotionally induced sudden death.

Three Phases of Ventricular Fibrillation

Some of the recent changes in the approach to the therapy of ventricular fibrillation (VF) are based on the three-phase, time-sensitive model of untreated VF articulated by Weisfeldt and

Becker.³ This model helps to explain why some of the previous approaches to and recommendations for the therapy of VF are ineffective.

The first, or electrical phase (Fig. 52-1) of untreated VF, lasts for 4 or 5 minutes. During this time the most important therapeutic intervention is prompt defibrillation. Although the heart is fibrillating, the myocardium has neither used up all of its energy stores nor undergone serious cellular damage and is therefore able to respond to the electrical defibrillation and generate a perfusing rhythm. This is why implantable cardioverter-defibrillators (ICDs) are so effective and why automated external defibrillators (AEDs) have been employed successfully in patients with out-of-hospital cardiac arrest in airplanes and airports, casinos, and in communities where prompt defibrillation was possible.¹⁰⁻¹² However, even in the electrical phase of VF, the earlier the defibrillation, the greater the chance that it will result in a perfusing rhythm and therefore survival.

The second or circulatory phase (see Fig. 52-1) of untreated VF lasts for a variable period of time, originally estimated to be from about minute 5 to about minute 10 of untreated VF (but probably extends from minute 5 to about minute 15). During this circulatory phase of ventricular fibrillation, the continued lack of myocardial perfusion during the continued uncoordinated myocyte contractions of untreated VF results in declining amplitude and frequency spectrum of the electrocardiographic fibrillation waveforms, declining myocardial energy stores, and the accumulation of toxic metabolites.^{13,14} Defibrillating during this circulatory phase without first improving myocardial perfusion by chest compressions usually results in pulseless electrical activity (PEA) or asystole. A critical intervention during this second or circulatory phase of VF cardiac arrest is restoring myocardial blood flow by the generation of adequate coronary perfusion pressure with chest compressions not only before but also immediately after direct current shocks.⁴ Chest compressions during the circulatory phase of VF increase the amplitude and the frequency spectrum of the fibrillation waveforms and improve the chances of restoring a perfusing rhythm following defibrillation. Chest compression immediately after the electrical shock provides perfusion to the energy-starved poorly contracting myocardium, increasing its chance of recovery and allowing it to develop enough strength or force of contraction to generate a perfusing rhythm. The third or metabolic phase (see Fig. 52-1) of VF follows the circulatory phase. Survival in this phase, in the absence of hypothermia, is unusual.

Electrical phase Minute 0 to minute 4 or 5
Circulatory phase Minute 4 or 5 to minutes 10 to 15
Metabolic phase After minutes 10 to 15

Figure 52-1. Three-phase, time-sensitive model of untreated ventricular fibrillation. During the electrical phase, the most important intervention is prompt defibrillation. During the circulatory phase, the fibrillating heart has used up much of its energy stores, and defibrillation in this phase usually results in asystole or pulseless electrical activity, unless the heart is first perfused by chest compressions. During the metabolic phase, newer approaches are needed because resuscitation during this phase is usually impossible.

In summary, during the electrical phase (the first 4 to 5 minutes) of untreated ventricular fibrillation arrest, the most important therapy is early defibrillation. During the circulatory phase (from approximately minute 5 to about minute 15) of previously untreated VF, the provision of myocardial perfusion by chest compressions before and immediately after the electrical shock is essential to allow the ventricular myocardium to produce a postdefibrillation perfusing rhythm. Importantly, the duration of both the electrical and circulatory phase of VF can be prolonged by adequate perfusion of the fibrillating heart, such as with prompt effective chest compressions.

Defibrillation

Within minutes, untreated ventricular fibrillation (VF) is fatal. Accordingly, few therapies in medicine are more dramatic or more crucial to the patient's outcome than urgent electrical defibrillation. Defibrillation has been variously defined but practically speaking, *defibrillation* means the termination of ventricular fibrillation irrespective of the resulting rhythm.

Mechanical Defibrillation (Precordial Thump)

A blow to the chest with a clenched fist, referred to as a “precordial thump,” was first reported in the 1960s.¹⁵ Precordial thump delivered soon after the onset of VF was found to be capable of defibrillating ventricular fibrillation and converting ventricular tachycardia to normal sinus rhythm. A precordial thump is the easiest, though least effective form of defibrillation. A precordial thump defibrillates less than 2% of patients with VF and does so only in those with a very recent onset of ventricular fibrillation.¹⁵ The response of ventricular tachycardia to a precordial thump is more effective but is less predictable. A blow to the chest has been estimated to convert about one third of patients with ventricular tachycardia (VT) into sinus rhythm. In another third, a precordial thump has no effect, and in the final third VT is converted to VF. Because of this observation, monitored VT in a patient without cardiac arrest should not be treated with precordial thump unless a defibrillator is present.¹⁶ Nevertheless one might consider a precordial thump as the initial therapeutic approach in an unresponsive patient with witnessed collapse and abnormal breathing because of its rapidity and ease of delivery.

Electrical Defibrillation

During the first 4 to 5 minutes or the electrical phase of ventricular fibrillation, the most important intervention is prompt electrical defibrillation. There are rare instances of spontaneous reversion of ventricular fibrillation, but many of these are in fact instances of polymorphic ventricular tachycardia incorrectly assumed to be VF. The shorter the duration of VF before electrical defibrillation, the more likely it will result in successful resuscitation. Experience with modern implantable cardioverter-defibrillators (ICDs) is that if the electrical shock is applied within seconds, nearly 100% can be defibrillated.¹⁷ Kouwenhoven's experimental studies of over a half century ago found that if the defibrillation shock was delivered within 30 seconds of the onset of ventricular fibrillation, 98% of the animals survived; if the shock was delayed just 2 minutes, only 27% lived. More recent reviews estimate that the chances of successful defibrillation decrease about 10% for each minute of untreated VF.

The technique, physics, and hemodynamics of defibrillation in cardiac arrest are addressed later in this chapter.

Ventricular Tachycardia or Fibrillation Storm

Frequently recurring episodes of ventricular tachycardia (VT) degenerating into VF requiring multiple defibrillations has been termed “VT storm.”² In such patients, in addition to appropriate defibrillations, intravenous β -blockade and/or urgent cardiac catheterization should be considered, for if ischemia is the initiating factor and it is still present, every effort needs to be directed at decreasing the ischemic burden.² Amiodarone, often in combination with β -blockers, can be useful for patients with left ventricular (LV) dysfunction because of prior myocardial infarction (MI) and recurrent VT.² If the VT storm is from polymorphic VT, intravenous β -blockade is the single most effective therapy.² All too often VT storm is secondary to the administration of multiple antiarrhythmic drugs.

Cardiocerebral Resuscitation for Cardiac Arrest

Why CCR for cardiac arrest? Although CPR has been in existence for almost a half century, in the absence of early defibrillation in patients with primary cardiac arrest, the survival rates are poor and have remained essentially unchanged for decades.^{4,5} It is now apparent that a major reason for the heretofore abysmal survival rates of patients with out-of-hospital cardiac arrest (OHCA) is that the previous guidelines were far from optimal and the current (2005) guidelines, while improved, leave much to be desired.

One reason for the poor survival is the lack of bystander-initiated CPR. This is in part due to the recommendation for mouth-to-mouth ventilation or so called “rescue breathing.”⁴ It is well known that this recommendation is a major reason individuals are not willing to perform bystander CPR on a stranger. And with the current universal precautions in hospitals, mouth-to-mouth ventilations are rarely performed in hospitals anymore. And for OHCA, if one calls 911 and does nothing until the paramedics arrive, the patient is not likely to survive. Or in large hospitals, if the cardiac arrest team is activated but bystander resuscitation efforts are not initiated until the team arrives, the chance of survival is greatly diminished. Any chain is only as strong as its weakest link, the weakest link in the chain of survival for cardiac arrest is the first link—bystander CPR. The solution to this problem is bystander continuous chest compressions or chest-compression-only CPR.

This approach is called “cardiocerebral resuscitation” or CCR.^{4,5} The major tenets of CCR are based on the fact that during resuscitation for cardiac arrest, the cardiac output or forward blood flow is so marginal that any interruption in continuous chest compressions is deleterious, and that during out-of-hospital cardiac arrest, the paramedics arrive not during the first or electrical phase of VF arrest but during the circulatory phase. And during this phase chest compression before and after defibrillation is necessary for optimal survival.⁴

Circulatory Phase of Untreated Ventricular Fibrillation

Although prompt defibrillation is often effective in the electrical phase of VF, direct current shocks, especially sequential or so-called stacked shocks are not only not effective, but are harmful during the circulatory phase of untreated VF because they interrupt or delay chest compressions during the critical circulatory phase of ventricular fibrillation.^{4,18} This concept led

to an important change in the 2005 guidelines for ACLS.⁹ These guidelines no longer recommend stacked shocks but a single shock followed by the immediate application of 200 continuous chest compressions before rhythm and pulse analysis. These recommendations have been a part of CCR since 2003.^{4,19,20}

Cardiocerebral Resuscitation—A New Approach for Cardiac Arrest

If a monitored patient develops ventricular fibrillation, the optimal approach is rapid defibrillation—a major advantage of the coronary and intensive care units. However, the majority of OHCA and some in-hospital cardiac arrests occur in a location that takes the emergency response services (EMS) several minutes to arrive. In this situation, CCR, a new approach to patients with OHCA that dramatically improves survival, is recommended.^{4,5} Why a new approach to cardiac arrest? Despite standards published in 1974, standards and guidelines published in 1980, guidelines in 1992, and updates of guidelines in 2000,²¹⁻²⁴ the survival rate of patients with OHCA has not improved, and in the absence of early defibrillation is so poor it is near that described as medical futility.²⁵ Accordingly in 2003, our University of Arizona Sarver Heart Center Resuscitation Research Group, based on more than 3 decades of defibrillation and resuscitation research and our interpretation of the literature, could no longer in good conscience follow the guidelines, and developed the CCR approach.^{4,5,19,26} This approach has now been shown to dramatically improve survival over the previous approach for patients with OHCA.^{5,26}

CCR has three components (Fig. 52-2). For bystanders, continuous chest compression (CCC-CPR) or chest-compression-only is recommended because it has been shown that patients with cardiac arrest are more likely to be in VF when the EMS arrives if a bystander initiates resuscitation efforts (or bystander CPR) and bystanders are more likely to initiate bystander resuscitation efforts if mouth-to-mouth or so called “rescue breathing” is not required.²⁷ Chest compression only, as will be described later, also results in better survival because it does not result in excessive interruptions of the marginal forward blood flow existent during traditional resuscitation efforts for cardiac arrest.^{28,29}

The second and major component of CCR is a new approach to advanced cardiac life support (e.g., the approach of medical personnel who arrive with a defibrillator, but who did not

- | CARDIOCEREBRAL RESUSCITATION |

| 2. New algorithm for advanced cardiac life support |
| 3. Postresuscitation in-hospital care that includes urgent cardiac catheterization and mild hypothermia |

Figure 52-2. Three components of cardiocerebral resuscitation. The first component is continuous chest compressions (CCC) without assisted ventilation for bystanders and first responders (CCC-CPR). The second component is a new approach to advanced cardiac life support (the details of which are shown in Fig. 52-3). The third component includes an aggressive approach to cardiac catheterization and intervention when appropriate and therapeutic hypothermia for patients who are comatose after resuscitation. CPR, cardiopulmonary resuscitation.

witness the arrest, and thus arrive most often after the electrical phase of the patient's cardiac arrest [Fig. 52-3]). If adequate continuous chest compressions are not being done by the bystander, CCR advocates an initial 200 continuous chest compressions with special attention to appropriate technique.⁴ The appropriate technique of chest compressions for cardiac arrest includes forceful chest compressions of adequate depth (1½ to 2 inches) at a rate of 100 compressions a minute, each followed by removal of the heel of the hand from the sternum to allow full chest wall recoil. This compression technique is essential during the circulatory phase of VF arrest, both before and after a single defibrillation shock.

CCR eliminates any intervention that delays or interrupts continuous chest compressions, or provides positive pressure ventilation. The reason for limiting interruptions of chest compressions is that during compressions for cardiac arrest, the forward blood flow is so marginal that any delay or interruption of chest compression significantly decreases cerebral blood flow and decreases the chance for neurologically intact survival.⁴ The use of automated external defibrillators (AEDs) while effective during the electrical phase of VF arrest is detrimental during the circulatory phase of cardiac arrest if they significantly delay and interrupt chest compressions.⁴ Thus after the shock is delivered by an AED, the verbal instructions of AED presently must be ignored. Two hundred postshock chest compressions are to be immediately instituted (see Fig. 52-3). The reason for this recommendation is that in our experimental laboratory model of OHCA, defibrillation during the circulatory phase of VF arrest

usually results in very low pressure pulses that increase with assistance of continuous chest compressions.^{4,30}

Another important component of CCR is the elimination of positive pressure ventilations (see Fig. 52-3). The reasons for the elimination of positive pressure ventilations are twofold: First, intubation results in a significant delay in chest compressions during the circulatory phase of VF arrest. Secondly, during chest compressions for cardiac arrest, the forward blood flow is so marginal that any increase in intrathoracic pressure decreases venous return and subsequent cerebral blood flow.^{4,6,29}

The prevention of positive pressure ventilations and hyperventilation (very common during the excitement of a cardiac arrest) is accomplished by using passive oxygen insufflation^{5,31} (see Fig. 52-3). Passive oxygen insufflation is applied by a second rescuer, and is accomplished by placing an oral pharyngeal airway and nonrebreather mask and high flow oxygen. Another advantage of this approach is that this frees the second rescuer to perform other critically important functions such as starting an intravenous line for epinephrine administration.⁵

Cardiocerebral Resuscitation Improves Survival of Patients with Out-of-Hospital Cardiac Arrest

It has been shown that the application of CCR dramatically improved survival of patients with OHCA compared to that existent in the same (EMS) systems that used the Guidelines for Cardiopulmonary Resuscitation and Advanced Cardiac Life Support (ACLS) hereafter referred to as "Guidelines 2000." The first report was from two rural counties in Wisconsin, where

Figure 52-3. Cardiocerebral resuscitation (CCR) approach to advanced cardiac life support (ACLS). Passive oxygen insufflation consists of placing an oropharyngeal airway, a nonrebreather mask, and high-flow (10 to 15 L/min) oxygen. AHA, American Heart Association; CCC, continuous chest compressions; IO, intraosseous; IV, intravenous.

CCR was initiated in early 2004.⁵ In the 3 years (2002 to 2005) when the Guidelines 2000 approach was used, in this report, there were 93 witnessed out-of-hospital adult cardiac arrests with an initially shockable rhythm. Nineteen patients survived and 14 of 92 (15%) were neurologically normal at hospital discharge. During the first year that CCR was instituted, the neurologically normal survival was 16 of 33 (48%).⁵ This study clearly supported the new approach of cardiocerebral resuscitation but was not definitive because of the small number of patients treated by CCR and because of a potential Hawthorne effect—that is improved performance of individuals who knew they were being studied. Longer duration of study was needed to address these concerns. Longer follow-up has been completed. During the 3 years of CCR follow-up, from 2005–2007, there were 91 patients with witnessed cardiac arrest who had a shockable rhythm on arrival of the EMS personnel. Forty-four survived (48%) and 37 (40%) were neurologically normal at hospital discharge ($P = 0.001$). The institution of CCR tripled neurologically intact survival of patients with witnessed OHCA and a shockable rhythm on arrival of the emergency medical system. One could conclude that there was some Hawthorne effect in the initial report because the second report with longer follow-up found a 250% increase in survival rather than the initial report of a 300% increase in survival (Fig. 52-4).

CCR was then instituted in two large municipal fire departments in the Phoenix metropolitan area in 2005. Survival to hospital discharge and other data were collected from these two large fire departments when Guidelines 2000 CPR and ACLS were used, and then following training of the emergency medical services (EMS) firefighters in CCR. Among the 713 cardiac arrests in these two fire departments, survival improved from 1.8% ($n = 2/219$) pretraining to 6.5% ($n = 32/494$) posttraining. In the subgroup with witnessed arrest and ventricular fibrillation on arrival of the EMS, survival to hospital discharge improved from 5% ($n = 2/43$) pretraining to 25% ($n = 22/89$) posttraining.²⁶ The results of these initial observations on the application of CCR are shown in Figure 52-5. Application of CCR for witnessed OHCA worldwide would result in the saving of innumerable lives.

Guidelines 2005 did make some changes in recommendations for ACLS that have been shown to improve survival. The change from

multiple or stacked defibrillator shocks to a single shock followed by 200 chest compressions before pulse check or rhythm analysis, part of the tenets of CCR that we instituted in 2003, has also resulted in improved survival of patients with out-of-hospital cardiac arrest.¹⁸

Proper Technique of Chest Compressions

As noted previously, during cardiac arrest and resuscitation efforts, the perfusion pressures and forward blood flow generated by chest compressions are marginal at best. Accordingly, any interruption of chest compressions has an adverse effect on cerebral and myocardial perfusion and dramatically decreases the chance of neurologically intact survival. The delivery of near continuous, appropriate chest compressions is therefore another fundamental tenet of CCR.⁴

The emphasis on limiting interruptions of chest compressions is based upon research that showed that the major determinant of neurologically intact survival from prolonged cardiac arrest because of VF is the perfusion pressures generated by chest compressions rather than the blood gas composition, acid-base balance, or the frequency or strength of defibrillation shocks.^{32–34} During resuscitation efforts, any interruptions of chest compressions immediately curtail blood flow to the heart and the brain and resumption of chest compressions may take several compressions to restore good perfusion pressures.^{32,35,36} CCR advocates near continuous chest compressions and limits assisted ventilations until after three rounds of chest compressions, shock when indicated, and chest compressions (see Fig. 52-3). There should be no interruptions of chest compressions for anything but post-chest compression defibrillation until the return of spontaneous circulation or the termination of the resuscitation effort. Pulse checks are to be done only during pauses in chest compression for rhythm analysis after the 200 postdefibrillation chest compressions.⁵

The third component of CCR is postresuscitation care. If the patient is unconscious postresuscitation, mild hypothermia (32°C to 34°C) has been shown to improve neurologically normal survival.^{37–39} Most patients should be taken to the cardiac catheterization laboratory because some will have acute coronary occlusion without ST-segment deviation on their electrocardiogram. Attention to glucose control and electrolyte balance is also an important part of postresuscitation care.

Figure 52-4. Percent of neurologically normal survival in patients with witnessed out-of-hospital cardiac arrest and a shockable rhythm during a 3-year period when 2000 American Heart Association advanced cardiac life support (ACLS) was used (2000 Guidelines ACLS) and during the next 3 years after instituting cardiopulmonary resuscitation in the same two small counties in Wisconsin.

Figure 52-5. Percent of survivors to hospital discharge of patients with witnessed out-of-hospital cardiac arrest and a shockable rhythm during a period when 2000 American Heart Association advanced cardiac life support (ACLS) was used (2000 Guidelines ACLS) and during the time after cardiopulmonary resuscitation was introduced in two large metropolitan fire departments in Arizona.

Bystander Responder Critical

Role of Continuous Chest Compressions or Chest-Compression-Only CPR

Several studies have found that survival of patients with OHCA who receive chest compression alone without mouth-to-mouth ventilations by bystanders are not statistically different from survival of such patients who receive chest compression plus so-called “rescue breathing.”⁴⁰⁻⁴² Nevertheless, the technique of chest compressions without rescue breathing has not been recommended by the guidelines unless the bystander is unable or unwilling to perform mouth-to-mouth ventilation.^{9,24} The rationale for this recommendation is that the guidelines’ authors evidently did not want lay individuals to have to decide if the patient has a cardiac arrest or a respiratory arrest. As will be noted later, this author thinks that this is not only possible but essential because many more individuals have OHCA and respiratory arrest. In Tucson, Ariz., it has been estimated that there are about 100 out-of-hospital cardiac arrests for every drowning death. In Seattle, the reported incidence of cardiac arrest to respiratory arrest is 20 to 1.⁴² In certain cultures, for example in those with a high incidence of drug abuse, the incidence is probably higher. In other cultures the incidence of respiratory to cardiac arrests is probably lower.

Studies by Kern and associates, in realistic swine models of OHCA, found that the provision of chest-compression-only CPR was more effective than the provision of standard 2:15 CPR, when each set of 15 chest compressions was interrupted for a realistic 16 seconds, to simulate the duration without chest compressions reported for a single rescuer to deliver the recommended “two quick breaths” and resume chest compressions.³⁶ In 2007, similar findings were reported in humans.²⁸ The survey of survivors (SOS) KANTO study reported that the overall survival of patients with OHCA was 2.2% for those who had not received bystander CPR when the EMS arrived, 4.2% for those who were receiving chest compressions plus mouth-to-mouth ventilation, and 6.2% for those receiving chest-compression-only by bystanders.²⁸ More importantly, these investigators reported that in the subset of patients with the greatest chance of survival—those with witnessed arrest and a shockable ventricular arrhythmia upon arrival of the EMS personnel, the survival was nearly twice as great (11% versus 19%, $P = 0.05$) in those who had received bystander chest compression alone than in those who received chest compression plus mouth-to-mouth ventilation.²⁸

Following the publication of this important study, the guidelines were not changed despite a call for urgent changes.⁴³ The reason was that this observational study was done during a time when the recommended ventilation to chest compression ratio was still 2:15. The 2005 Guidelines of the American Heart Association (AHA), the European Resuscitation Council, and the International Liaison Committee for Resuscitation (ILCOR) changed their recommendations in the 2005 guidelines for ventilations to chest compression ratio to 2:30.⁹ The change in the 2005 guidelines from 2:15 to 2:30 was based in part on the findings of Abella and colleagues.⁴⁴ In a prospective observational study of in-hospital cardiac arrest in three hospitals during 2000-2003, those patients who had a return of spontaneous circulation (ROSC) received a greater number of chest compressions per minute than those who did not. The average number of chest compressions per minute was 90 ± 17 in those who had ROSC compared with 79 ± 18 in those who did not have ROSC.⁴⁴ In their analysis, it seemed that a compression rate of at

least 89 compressions per minute was necessary for higher rates of ROSC. Of note is the fact that the survival of patients with in-hospital cardiac arrest in these three academic hospitals was so poor that it was not reported.⁴⁴

Animal studies showed that ROSC was better with a 2:30 ventilation to compression ratio than with the previous standard of 2:15.⁴⁵ Thus there was no long-term (24-hour) survival evidence that the change to the recommended 2:30 ventilation to compression ratio would improve survival. The recommendation was based on consensus.⁹ One could argue that observational studies in man were needed before guideline changes could be made. We argue that our swine models of OHCA, showing that continuous chest compressions were better than 2:15 when a realistic 16-second interruption was used to provide the two ventilations, predicted the results found in man.^{28,43}

In subsequent studies using the same swine model of OHCA, Ewy and colleagues found that when simulated bystander resuscitation was initiated 4 to 6 minutes after the onset of VF arrest, and defibrillated after 12 minutes of VF, chest-compression-only CPR (CCC-CPR) resulted in a greater number of neurologically normal 24-hour survivors than did 2:30 ventilations to compressions.⁴⁶ Neurologically normal survival was found in 16 of 24 (64%) of the swine who received continuous chest compression compared with 6 of 23 (26%) receiving two ventilations for every 30 chest compressions before defibrillation.⁴⁶

Teaching Bystander “Chest-Compression-Only CPR”

The lay component of CCR emphasizes calling the emergency medical system (911 in the United States) followed by continuous chest compressions without mouth-to-mouth ventilation. This activity is only to be interrupted if an AED is available.⁴

We think it is important that bystanders be told that it is not necessary to remove any of the patient's clothing because this act alone prevents many bystanders from initiating bystander CPR. Bystanders are to place the fallen individual on his or her back on a hard surface or on the floor, to place the heel of one hand in the center of the patient's chest (on the sternum, usually between the nipples), with the heel of the other hand on top of the first. They are to lock the elbows so the arms are straight, and with the shoulders above the center of the patient's chest, to fall so the weight of their upper body compresses the patient's chest. Few if any are strong enough to do adequate chest compressions using just the muscles of their upper extremities. The compression rate should be 100/min. Lifting the hands or the heel of the bottom hand completely off the chest after each compression is necessary to allow full chest recoil and is specifically emphasized (see later discussion).⁴⁷ This is an important issue and one reason that external chest compressions should not be referred to as external cardiac massage. Massage implies continuing pressure and continuing pressure or any lean on the chest during the release phase of chest compression decreases forward blood flow and survival. If more than one rescuer is present, they are to trade off doing chest compressions after each 100 or 200 compressions because, properly done, continuous chest compressions at 100/min is very tiring, especially for older individuals.

Full Chest Wall Recoil Following Chest Compressions is Essential

Full chest wall recoil during the release phase of each chest compression is extremely important.⁴⁷ During the release phase of chest compression, a small negative pressure is created within

the chest as the chest wall recoils back to its resting position.⁴⁷ This draws venous blood back into the right heart from the systemic veins and may draw air into the airways. Incomplete chest recoil compromises perfusion because it interferes with the generation of this negative pressure in the chest, and thus decreases venous blood return to the heart. As a consequence, cardiac output and perfusion pressures are reduced. Incomplete chest recoil has been reported in 46% of simulated resuscitations performed by paramedics.⁴⁷ Furthermore, when incomplete chest recoil was combined with excessive ventilations, perfusion was severely compromised.⁴⁷

Placement of any device between the heel of the hand and chest wall is detrimental because one cannot allow full chest wall recoil because one is making sure the device does not fall off. In our early animal studies, we were criticized by journal reviewers because we did not report the force that we were using for chest compression. We then placed a force transducer between the heel of the hand and the anterior chest wall. Continuous pressure had to be exerted to keep the device from slipping off the chest wall. Survival of our experimental animals with this technique was markedly decreased. At the time we had no idea why, but we had to discontinue the measurement because of decreased survival compared with that present when we used only our bare hands. In retrospect, the device had to be maintained on the chest wall, so that the chest wall was never allowed to fully recoil.

There are newer thin devices that stick on the chest that are being evaluated to provide instant feedback to paramedic/firefighters doing chest compressions to ensure optimal technique. Such devices may be helpful in training.

Dispatch-Directed Chest-Compression-Only CPR Generally Accepted

A part of the first component of CCR consists of new recommendations for dispatch-directed bystander resuscitation.⁴² Continuous chest compression CPR or chest-compression-only bystander resuscitation instructions are given by phone from EMS dispatch centers. This approach is now generally followed in most metropolitan cities in the United States.

What Is the Role of Gasping or Agonal Respirations?

Gasping or agonal respirations are common early on following cardiac arrest. Clark, Eisenberg, and associates reported gasping in 56% of patients with OHCA on arrival of paramedics.⁴⁸ Gasping or agonal breathing is probably more common soon after cardiac arrest and is more common in individuals who receive bystander CPR. When these forms of abnormal breathing occur in patients with cardiac arrest, it is both unfortunate and fortunate. It is unfortunate because gasping or agonal breathing may be interpreted by uninformed lay individuals as an indication that the person who collapsed is still breathing and therefore delay initiating bystander resuscitation and the activation of the emergency medical services. However, gasping is fortunate because if recognized for what it is (e.g., agonal breathing), and chest compressions are promptly initiated, the subject is likely to continue to gasp and provide physiologic self-ventilations. And if continuous chest compressions are initiated, the nongasping subject is more likely to begin gasping. The longer the duration of untreated VF before the initiation of resuscitation efforts, the longer the duration of bystander CPR efforts before gasping resumes.

Clark and associates also reported that gasping or agonal breathing was highly correlated with survival.⁴⁸ We have found similar results in our swine model of OHCA laboratory. Animal research laboratories that use paralysis as part of the protocol when studying CPR eliminate this physiologically important reflex. It is our opinion that results in paralyzed animals cannot be applied to humans who are not paralyzed when they have cardiac arrest.

Recently we evaluated the role of gasping and type of bystander CPR on 24-hour neurologically normal survival. Using our swine model of OHCA, we found that subjects treated with CCC-CPR were more likely to gasp and to survive than those treated with a 30:2 chest compression ventilation ratio when each 30 chest compressions were interrupted by a realistic 16 seconds to simulate a lay bystander delivering two mouth-to-mouth breaths. In addition, we found that the longer the duration of arrest before the initiation of bystander initiated resuscitation efforts, the longer it took for the animals to resume gasping once bystander CPR was initiated.

Assisted Ventilations Should Not Be Done, Even If More Than One Qualified Person is Present

The question is frequently asked if someone should do assisted ventilations if two qualified persons respond to the arrest. The answer is no. First, properly performed continuous chest compressions are very tiring and therefore the two rescuers should spell each other after 100 or 200 continuous chest compressions. Second, as will be noted later, during cardiac arrest and chest compressions the forward blood flow is so marginal that increasing intrathoracic pressure by positive pressure decreases venous return to the chest and therefore forward blood flow. This point will be expanded upon later because it is also one of the reasons positive pressure ventilations should be limited by medical and EMS personnel as well.

Emergency Medical Services Components of Cardiocerebral Resuscitation

The first component of CCR is continuous chest compression CPR for bystanders.⁴ The second component of CCR consists of a new algorithm for ACLS (see Fig. 52-2).⁵ Law officers and other EMS rescuers who are equipped with AEDs are to defibrillate immediately only if they personally witness the collapse or if good continuous chest compression CPR is being provided by a bystander when they arrive.⁵ Otherwise, they are to bare the chest and attach the defibrillator pads if using an AED or hand-held defibrillation electrodes and promptly perform forceful uninterrupted chest compressions at 100 compressions per minute for 2 minutes (200 compressions) before quick rhythm analysis and prompt defibrillation if indicated (see Fig. 52-3).

If two rescuers are available, one begins chest compressions while the other attaches the defibrillator pads. If after 200 chest compressions, a shockable rhythm is present, a single defibrillation shock is delivered followed immediately by an additional 200 chest compressions before any rhythm and pulse analysis. The reason for the 200 immediate postshock chest compressions is that during the circulatory phase of VF arrest, the shock often defibrillates the patient into a nonperfusing rhythm, and if one delays the resumption of chest compression to try to find a pulse, the nonperfused ventricles often fibrillate again. In our experimental laboratory, where the swine are continuously monitored, we see the nonperfusing rhythm and note that

with the resumption of chest compression the arterial pressure gradually increases until there is a perfusion rhythm. Therefore, if AEDs are being used by EMS personnel, many of the voice instructions on the currently available AEDs are inappropriate for the new CCR and must be ignored.

Is the Patient in the Electrical or Circulatory Phase of VF?

Because of the difficulty in ascertaining an accurate downtime in emergency circumstances, unless the collapse is witnessed, it is difficult to determine if the victim is in the electrical or the circulatory phase of VF arrest. Although AEDs are being developed to determine the phase of VF via analysis of the VF waveforms, we think this is unnecessary and this analysis will only delay or interrupt essential chest compressions. Previous reports by Cobb and Wik and associates in humans not only demonstrated the beneficial effects of chest compression before defibrillation in the circulatory phase (after the first 4 to 5 minutes) of VF arrest (Fig. 52-6), but equally important, they did not find a detrimental effect of performing chest compressions before defibrillation during the electrical phase (first 4 to 5 minutes) of VF arrest (e.g., 90 seconds of chest compressions before defibrillation in the report of Cobb and associates⁴⁹ or 3 minutes of chest compression before defibrillation in the report of Wik and associates).

CCR simplifies the decision-making process of the EMS person arriving on the scene by advocating an initial 2 minutes of chest compressions—not deleterious in the electrical phase and improves survival in the circulatory phase of VF arrest. The recommendation of 200 chest compressions (2 minutes at 100 compressions per minute) is a compromise between the 1 and 1½ minutes used by Cobb and the 3 minutes used by Wik. Using 200 compressions has the added benefit that the EMS personnel do not have to check their watch to time the duration of

continuous chest compressions before defibrillation. They just count the number of continuous chest compressions.

Minimal Interruptions of Chest Compressions for Defibrillation Is Essential

CCR also emphasizes minimizing the time between cessation of chest compressions, the delivery of the defibrillating shock, and the resumption of chest compressions.

Three sequential shocks of increasing energy are not advocated and are no longer recommended in Guidelines 2005.^{4,9} For years, so-called stacked or three sequential shocks were recommended. The reasons were twofold: first was the conviction that defibrillation was the highest priority for everyone in VF and therefore one should do several shocks as soon as possible. We now know that in the circulatory phase of VF arrest, this approach can be deadly.

Weaver and associates reported that high energy (360 J) shocks from monophasic wave defibrillators resulted in a higher incidence of postdefibrillation heart block.⁵⁰ Accordingly, previous guidelines recommended repeated or stacked shocks of escalating energy. Heart block is rare with monophasic defibrillators and we are not aware of its being reported when biphasic defibrillators are used. And as noted previously, repeated defibrillation shocks without chest compressions in the circulatory phase of VF arrest are harmful because of the long delays and/or interruptions of cerebral perfusion during the critical circulatory phase of VF arrest.

Continuous Chest Compression Immediately After Defibrillation

Why 200 chest compressions immediately after the defibrillator shock (see Fig. 52-3)? In animal models of prolonged VF arrest (e.g., the circulatory phase of VF arrest), a direct current shock often defibrillates the subject into a nonperfusing rhythm—PEA.⁵¹ In the experimental laboratory, the low perfusion pressure following defibrillation for prolonged VF is obvious on the monitor screen and immediately resuming chest compressions increases the arterial pressures, thereby restoring coronary perfusion pressures. The initially weak contraction generated by the recently defibrillated heart gradually becomes stronger, and the low blood pressure gradually becomes higher because the PEA is converted into a perfusing rhythm.⁵¹

Observational studies in humans by paramedic units found that a pulse was rarely if ever present immediately after the initial defibrillation shock and therefore immediate postshock chest compressions without pulse or rhythm analysis are now also recommended by the 2005 guidelines.⁹ This change, instituted by our group in 2003, became part of the 2005 guidelines. This change was also instituted in 2004 by resuscitation researchers in Seattle and was reported by Rea and associates to improve survival of their patients with OHCA.¹⁸

Positive Pressure Ventilations Eliminated or Delayed

Another major difference between CCR and CPR is in the recommendations for ventilation. The three CCR recommendations concerning airway management and ventilations in cardiac arrest can be summarized as follows: (1) Bystander or first responders are to perform continuous chest compressions without ventilations or without so-called rescue breathing; (2) initial EMS airway management is limited to ensuring an open airway with a nasopharyngeal airway and administration of high flow

Figure 52-6. Percent of survivors to hospital discharge in Seattle (left) and Norway (right) with standard advanced cardiac life support (ACLS) “shock first” before and “CC (chest compressions) first” before delivering the first defibrillation shock. In the study by Cobb and associates,⁴⁹ 90 seconds of chest compressions was delivered first. In the study by Wik and associates, 3 minutes of chest compressions was delivered before delivering the first defibrillation shock. In the study by Cobb and associates, the circulatory phase of ventricular fibrillation (VF) arrest was taken as greater than 4 minutes of untreated VF. In the report by Wik and associates, the circulatory phase of VF was taken as greater than 5 minutes of untreated VF.

supplemental oxygen via a nonrebreather mask; (3) advanced airway management (intubation or bag-valve mouth ventilation) is initiated only after return of spontaneous circulation (ROSC) in those who are in a coma and need it or in those without ROSC after three sequences of defibrillation and 200 chest compressions (see Fig. 52-3).

Each of these three recommendations represents a marked deviation from the CPR and ACLS guidelines and each is counterintuitive to the “ABCs” that have been taught for decades. CCR does not advocate the elimination of ventilations; instead, it emphasizes the beneficial effects of negative intrathoracic pressure respiration (e.g., gasping or agonal breathing) and the possible “high frequency ventilation” effects afforded by rapid chest compressions. CCR does decry the interruptions of chest compressions for ventilations and the adverse effects of positive pressure ventilations during cardiac arrest and resuscitation.^{5,52}

Intubation and Positive Pressure Ventilations Eliminated or Delayed

There are three major problems with endotracheal intubation during the resuscitation efforts of cardiac arrest. The first is that intubation is often difficult, necessitating prolonged interruption of chest compressions to establish an airway. The resulting interruptions of chest compressions, during the critical circulatory phase of VF arrest, contribute to decreased survival. But even if intubation is done within seconds, positive pressure ventilations are detrimental during cardiac arrest and resuscitation efforts because positive pressure ventilations increase intrathoracic pressure, impede venous return to the chest, and thereby reduce cerebral and myocardial perfusion despite continued chest compressions. And thirdly, to make matters worse, rapid ventilation and hyperventilation are common during resuscitation efforts for cardiac arrest. Aufderheide and colleagues found that “there is an inversely proportional relationship between mean intrathoracic pressure, coronary perfusion pressure, and survival from cardiac arrest.”^{53,54} Observations of hospital-based responders to cardiac arrest and those of paramedics found that both professionals almost always performed assisted ventilation at excessively high rates. Two separate studies observed that both delivered an average of 37 ventilations per minute rather than the 10 to 12 per minute recommended; even after retraining, paramedics were observed to ventilate at 22 times per minute.^{52,55}

CCR protocols minimize these adverse effects of positive pressure and excessive ventilations by advocating passive oxygen insufflation during the initial phases of resuscitation (see Fig. 52-3). Passive oxygen insufflation consists of the placement of an oropharyngeal airway, a nonrebreather mask, and oxygenation with high flow (10 to 15 L of oxygen per minute).^{5,6} As noted above, this approach has another major benefit; it frees a professional for other critically important duties during cardiac arrest, such as obtaining vascular access for intravenous therapies and/or spelling the person doing chest compressions. Intubation or positive pressure ventilation with bag-valve-mask ventilation is delayed until after ROSC or if the patient is not awake after three single shocks, each followed by 200 chest compressions (see Fig. 52-3).⁵

Why isn't more ventilation or oxygenation necessary? Gasping, for sure, and perhaps high frequency ventilations from rapid chest compressions and/or chest wall recoil provide some oxygenation. During cardiac arrest and resuscitation, the forward blood flow is so marginal that there is not a large

ventilation-perfusion mismatch. And continuous forward blood flow is more important than interrupted flow, even if the interruptions result in better oxygenation of the blood.

Chandra and associates have shown, in an animal model of cardiac arrest, that even after 8 minutes of cardiac arrest with chest compressions but without assisted ventilations, the arterial oxygen saturation was still 75%.⁵⁶ Some of the values may be due to gasping, but it is also possible that with cardiac arrest, there are immediate cellular changes that decrease their oxygen uptake. However, the point of continuous perfusion is that blood contains many essential nutrients in addition to oxygen. With cardiac arrest, many microvascular beds close, perhaps decreasing the total amount of oxygen consumed by organs other than the heart and the brain. Although many of these explanations are speculation, the fact remains that fully oxygenated blood is not necessary for resuscitation, and interventions directed at assuring fully oxygenated blood have decreased survival of patients with OHCA.

Hemodynamics of Cardiac Arrest

Ventricular fibrillation results in totally uncoordinated contractile activity of the ventricular myocytes, resulting in almost immediate cessation of effective ventricular pump function. However, antegrade blood flow continues after cardiac arrest until the pressure gradient between the arterial and venous pressures is completely dissipated, and the pressures in the arterial and venous systems equalize at the “mean circulatory filling pressure” of Guyton.⁵⁷ Because of a variety of compensatory mechanisms, including increased sympathetic activity and the fact that some microvascular beds close, the equilibrium between the arterial and venous systems does not occur until after about 5 minutes of VF in animal models.⁵⁸

One result of the shift of blood from the arterial to the venous circuits is prompt distention of the right ventricle. Magnetic resonance imaging of the closed chest animal models of VF show a rapid increase in right ventricular volume, but not a dramatic decrease in left ventricular volume until the development of “stone heart” (extreme myocardial contraction) significantly later.⁵⁹

The changes in coronary blood flow and carotid blood flow in response to ventricular fibrillation are different. Carotid blood flow declines exponentially to zero over approximately 4 minutes but coronary blood flow rapidly declines to zero by 1 minute.⁵⁸

The Mechanisms of Blood Flow During Cardiac Arrest and Closed-Chest Compression

Closed-chest compressions during cardiac arrest result in phasic forward blood flow. The mechanisms responsible for forward blood flow during closed-chest compressions are variable and depend upon several factors. Of the factors identified, perhaps the most important is the duration between the onset of ventricular fibrillation arrest and initiation of chest compressions. Cardiac compressions as the mechanism of forward blood flow are more likely early during resuscitation and the so-called thoracic pump mechanism is more likely late in resuscitation when the heart begins to develop stone heart. Another important determinant is the patient's chest wall configuration. If the patient has a large anterior-posterior chest diameter, it is probable that cardiac compression is not likely.

According to the cardiac compression theory, direct compression of the ventricles between the sternum and the vertebral column closes the mitral and tricuspid valves and ejects blood forward out of the ventricles. The ventricles then refill during the decompression phase.

When closed-chest cardiac massage was introduced in the 1960s, it was assumed that the mechanism of blood flow was much the same as with open-chest cardiac massage, wherein the heart was grasped in the hand and the flow was produced by squeezing the fibrillating left ventricle. This was the presumed operative mechanism of forward blood flow during CPR until a study was done in humans by researchers at Johns Hopkins published in 1980.⁶⁰ Their data suggested that the mechanism of blood flow during chest compression was the “thoracic pump” mechanism: external chest compression increases intrathoracic pressure, forcing blood to flow from the thorax. A pressure gradient for cerebral flow is maintained by the jugular venous valves at the thoracic outlet. According to this paradigm, the heart acts merely as a passive conduit without having a pump function.

However, the Johns Hopkins study, while performed in humans, was performed very late in cardiac arrest, after the house staff had decided that resuscitation was not likely.⁶⁰ Thus these hemodynamic measurements were made after prolonged cardiac arrest when one would expect the onset of myocardial stiffness and swelling that progress to stone heart.⁵⁹ Thus when the thoracic pump is the mechanism of blood flow during chest compressions, resuscitation and survival are less likely.

Transesophageal echocardiography evaluations in humans during cardiac arrest and resuscitation attempts have shown both mechanisms—cardiac compression in some and the thoracic pump in others. However, the cardiac compression mechanism was more likely to be seen in patients studied early after arrest and the thoracic pump mechanism when cardiac arrest patients were studied later.⁶¹ And in one such study, survival only occurred among those studied early; there were no survivors among those who demonstrated the thoracic pump mechanism.⁶¹

It is probable that in younger individuals with compliant chest walls and/or narrow anterior posterior chest dimensions, the cardiac pump is the predominant mechanism and that they are more likely to be resuscitated. In patients with severe emphysema and a “barrel chest” the mechanism of blood flow is likely due to the thoracic pump mechanism, but these patients are also not likely to be revived by closed chest compressions.

The actual mechanism of forward blood flow during resuscitation is of great import because previous guidelines for CPR have been altered dramatically, depending upon the alleged or accepted operative mechanism. Based on the thoracic pump theory, the 1980 AHA guidelines recommended a chest compression rate of 60/min and noted that “compression should be sustained for 0.5 second, with relaxation given for an equal period.”²² In hindsight this recommendation was incorrect because it resulted in too few compressions per minute.⁴⁴

This recommendation of 60 compressions per minute was not accepted by many clinicians who had years of experience with successful resuscitations using much faster chest compression rates. Accordingly, investigators from our group at The University of Arizona and in cooperation with investigators at Duke Medical School initiated animal studies that found that the optimal chest compression rates for survival from VF arrest were 80 to 120/min.⁶² Because a chest compression rate of 120/min

was thought to be too fatiguing for the general public, the 1992 AHA guidelines compromised and recommended rates of 80 to 100/min.²³ The Guidelines 2005 recommend a compression rate of 80 to 100/min. However, as noted above, a compression rate of 80/min is probably not adequate and the target rate should be 100/min.

Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation has been defined as chest compression and assisted ventilations. CPR is indicated for respiratory arrest and appears to be critical in subjects after the complete loss of arterial pressure secondary to asphyxial cardiac arrest.⁶³ Ventilations or “rescue breathing” is considered important in cardiac arrest secondary to respiratory arrest where a respiratory problem initiated hypotension that caused the cardiac arrest and where VF or asystole is a relatively late event.⁶³

Unlike primary cardiac arrest due to sudden onset of VF or pulseless VT, cardiac arrest secondary to hypoxia is associated with severely abnormal arterial blood gases. The typical sequence for untreated respiratory arrest is hypoxia followed in several minutes of hypotension leading to hypoxic ischemia and finally cardiac arrest.⁶³

Treated early in this sequence, before hypotension ensues, the only intervention that is usually necessary is relieving the cause of the hypoxia. An example of asphyxial arrest is the so-called “café coronary,” where aspiration of a large piece of food obstructs the trachea. The Heimlich maneuver, or similar maneuver, to abruptly increase the intrathoracic pressure and cause a forceful expulsion of air from the lungs may be all that is needed to relieve an obstruction. Assisted ventilation may be all that is necessary in a patient with respiratory depression or respiratory arrest secondary to drug overdose or other causes of severe hypoxia before cardiac arrest has ensued.

Considerations in Resuscitation Research

Return of spontaneous circulation (ROSC), being alive at hospital admission, or being alive at some later designated time were all used previously as criteria for survival for out-of-hospital cardiac arrest. Most such “survivors” ultimately died before being discharged from the hospital, making these definitions objectionable. In addition, different definitions of survival made comparisons of different approaches to CPR difficult.

A more clinically relevant definition of “survival” has been introduced: neurologically normal survival at hospital discharge or at a specified time after discharge for humans, or neurologically intact survival at 24 or 48 hours for experimental animals. When definitions of survival such as neurologically normal or near normal are used, it is clear that survival rates for OHCA with cardiopulmonary resuscitation have been very low and, with the exceptions of early application of an AED, have remained stagnant over the last few decades.^{4,5}

Most survivors of OHCA are found in the subset of patients with a bystander-witnessed arrest and a shockable rhythm on arrival of EMS with a defibrillator. In this subset of patients, survival in 2002 in Los Angeles was 6%, survival from 1992 to 2002 in Tucson, Ariz., averaged 10%, survival in Tokyo was 11%, while in Rock and Walworth counties in Wisconsin during 2001-2004

it was 20%.^{5,20,28,64} These survival differences probably reflect differences in EMS response times.

Chest Compression Rates Correlate with Survival

Abella and associates reported that suboptimal compression rates during in-hospital cardiac arrest correlated with the poor ROSC.⁴⁴ Although survival rates were not reported, there would be no survival in those without ROSC. In this study, ROSC was significantly higher for patients receiving more than 87 compressions per minute than those receiving fewer than 72 compressions per minute.⁴⁴ In this in-hospital study, ventilations were given quickly by a second rescuer. In the out-of-hospital situation, where a single bystander is performing CPR, if every set of 15 compressions is interrupted for 14 to 16 seconds to deliver the recommended two ventilations, the individual will not receive enough chest compressions for ROSC. In fact, if every set of 30 compressions is interrupted 14 to 16 seconds for single bystander CPR, the delivered chest compressions would still fall short of the near 90 compressions needed for ROSC in this in-hospital population.

Mechanical Devices for Resuscitation

Mechanical Devices for Chest Compression

The major theoretical advantage of mechanical devices is that they should improve the quality of prolonged chest compression over manual techniques because manual resuscitation is susceptible to fatigue of the would-be rescuer. However, there are both real and theoretical disadvantages of these devices. The major disadvantage is the interruption of chest compressions necessary to place the device. Any significant interruption of chest compression during the circulatory phase of cardiac arrest is deleterious. Theoretical disadvantages include cost, additional interruptions of chest compression, and the possible tendency of EMS personnel to focus on the machine rather than the patient, and the potential adverse effects related to the type of chest compression. Finally, in the absence of active decompression, mechanical devices, like poorly controlled mechanical chest compressions, have the potential of limiting chest wall recoil. It is unclear to us whether such devices, in the absence of active decompression, optimally facilitate chest wall recoil.

Our view is that mechanical devices should not be used early in resuscitation efforts because they all delay or interrupt continuous chest compression, which is essential to optimal resuscitation. Like endotracheal intubation for assisted ventilation, with or without devices that decrease intrathoracic pressures with positive pressure ventilations, they may be indicated in patients who do not respond to the initial resuscitation attempts, but in whom there is a reasonable chance of survival with more prolonged aggressive therapy. However, more study is needed with these devices before they can be recommended.

Patients Often “Awake” With Good Resuscitation

In some cases of optimal CPR, either manual or with mechanical devices, the forward blood flow is so good that the patient awakes and sedation is necessary. This needs emphasis, as all too often when the patient begins moving, manual chest compressions are stopped until the patient becomes unresponsive—a procedure that should be deplored.

Postresuscitation Dysfunction

The major concern of aggressive management of a patient with cardiac arrest has always been that the patient will survive in a vegetative state with severe neurologic impairment from the global ischemia.

The best prognostic sign in cardiac arrest patients after ROSC is rapid regaining of consciousness. Often regaining of consciousness is a gradual process that may take days to evolve. There are, at present, no clinically relevant, reliable predictive tools that can be used in recently resuscitated, comatose patients to distinguish who will or will not wake up and be neurologically intact.

Although neurologic function after prolonged cardiac arrest is of major concern, there is almost always other organ dysfunction as well, a syndrome referred to as “postresuscitation disease.” This is a multiorgan pathophysiologic state that affects almost all body systems, but especially the cardiovascular, nervous, pulmonary, renal, and metabolic systems.⁶⁵ Postresuscitation disease has been postulated to consist of four different pathophysiologic mechanisms: (1) Perfusion failure consisting of multifocal no-reflow phenomenon; (2) reperfusion injuries from oxygen free radicals, invasion of inflammatory cells, defects in injured mitochondria, and trigger programmed cell death; (3) postanoxic viscera damage and dysfunction; and (4) blood derangement from stasis during the arrest.⁶⁵

Myocardial dysfunction after resuscitation from cardiac arrest has been described in both clinical studies and animal models. In a study of 165 patients who had ROSC after OHCA, 55% had hemodynamic instability requiring vasoactive drugs during the first 72 hours following resuscitation.⁶⁶ The left ventricular ejection fraction was found to be depressed in all patients. Of clinical import is the observation that hemodynamic instability was not predictive of neurologic outcome and myocardial dysfunction appeared to be reversed by 72 hours.⁶⁶

In animal models, the myocardial dysfunction has been shown to be related to the duration of arrest and resuscitation. Kern and associates noted progressive systolic and diastolic progressive dysfunction, but if the animals survived, these abnormalities spontaneously recovered.⁶⁷ In these animals, myocardial function could be improved with dobutamine but not with intra-aortic balloon counterpulsation.⁶⁷

Postresuscitation Care

Postresuscitation care includes therapeutic hypothermia, aggressive approach to performing percutaneous coronary intervention (PCI) even in the absence of ST segment changes on the electrocardiogram, and optimal management of hemodynamics, glucose and electrolytes, and ventilation (Fig. 52-7)

- Therapeutic hypothermia
- Aggressive PCI when indicated
- Hemodynamic control
- Ventilation control
- Glucose control

Figure 52-7. Formalized approach to postresuscitation hospital care. PCI, percutaneous coronary intervention.

Hypothermia Therapy

The most promising approach to resuscitated cardiac arrest patients in a coma is hypothermia.^{37,38} Hypothermia activates shivering, and in comatose patients post-cardiac arrest, shivering-produced thermogenesis is potentially deleterious. Uncontrolled hypothermia results in catecholamine release and vasoconstriction. Many of the early studies using moderate (28° C to 32° C) or severe (<28° C) hypothermia for cerebral protection had worse survival than normothermic controls. In contrast, therapeutic, controlled mild hypothermia (32° C to 34° C) has been shown to be beneficial for preserving cerebral function.

The modern era of postarrest hypothermia was ushered in by Peter Safer's group, which focused on mild hypothermia, (32° C to 34° C).⁶⁸ These studies set the stage for major clinical trials.

The International Liaison Committee on Resuscitation (ILCOR) issued an advisory statement in 2003 recommending "Unconscious adult patients with spontaneous circulation after OHCA should be cooled to 32° C to 34° C for 12 to 24 hours when the initial rhythm was ventricular fibrillation (VF). Such cooling may be beneficial for other rhythms or in-hospital cardiac arrest." Similar recommendations were echoed in the 2005 guidelines and by ILCOR.^{9,69}

The mechanism of action of hypothermia is unknown, but is thought to be related to its inhibitory effect on adverse enzymatic and chemical reactions that are initiated by the global ischemia. It is well known that cooling slows chemical reactions. It is therefore logical to assume that the sooner therapeutic cooling is begun the better.

There is evidence that cooling should be started by the paramedics in the field. Bernard and colleagues began cooling measures in 22 comatose patients following resuscitation from OHCA by a rapid infusion of 30 mL/kg of 4° C Ringer's lactate solution over 30 minutes.^{70,71} The Seattle CPR research group used a similar approach but used 4° C normal saline. Rapid infusion of 2 L of 4° C cold normal saline (20 to 30 minutes into a peripheral vein with a high-pressure bag) resulted in a mean temperature drop of 1.4° C 30 minutes after the initiation of the infusion.⁷² The rapid infusion of cold saline was not associated with clinically important changes in vital signs, electrolytes, arterial blood gases, or coagulation parameters. The initial mean left ventricular ejection fraction was 34%, and the infusion did not affect ejection fraction or increase central venous, pulmonary, or left atrial filling pressures as assessed by echocardiography.⁷² Following the infusion, passive cooling (fans, directed on the uncovered patient) was compared with active cooling (cooling blankets, neuromuscular blockade) to maintain mild hypothermia. This study showed that active cooling was necessary.⁷²

Because the management of such patients with hypothermia is complex, a team approach is essential. Hospitals with this interest and proven ability might rightfully be designated as "Cardiac Arrest Centers" much the same way that "Trauma Centers" are presently designated in the United States. There are efforts in Arizona to designate certain hospitals as "cardiac arrest hospitals."

Therapeutic hypothermia may be associated with hyperglycemia. Although control of blood glucose in the range of 80 to 110 mg/dL has not been specifically studied in postcardiac arrest patients, studies of patients with stroke or other serious cardiovascular conditions suggest that control of blood glucose is another important therapeutic goal. Attention to other details,

such as raising the head of the bed of the intubated comatose patient to decrease aspiration is important.

Ending Resuscitative Efforts

It is essential to determine and document the patient's resuscitation status soon after admission to the hospital. The cost of providing emergency medical service to victims in an OHCA is considerable. Given this fact, the cost benefit ratio might be examined. At one end of the spectrum of patients with OHCA are those in whom the arrest was not witnessed, or in whom the arrest was witnessed but no bystander resuscitation efforts were made, or for whom the arrival of those delivering emergency medical services was delayed. This subset of patients has little chance of survival. Studies have found that, if in addition, a defibrillator shock is not delivered or advised and there is no ROSC, almost no one lives. It has therefore been acknowledged by expert groups that there are some patients with little or no chance of survival for whom continued efforts at resuscitation in the field are perhaps not merited.

The AHA 2005 guidelines state that resuscitation efforts should be continued until "reliable criteria indicating irreversible death are present."⁹ This position leaves considerable latitude for the judgment of the medical personnel involved but is more difficult to apply uniformly in practice.

Techniques of Defibrillation

Contraindications

Defibrillation is contraindicated when the patient's desire not to be resuscitated has been clearly documented in the patient's medical record or other legal document, when continued resuscitation is determined to be futile by the treating physician, or in the extremely rare situation where there is danger to the rescuers because of the patient's location or environment.

Ventricular Fibrillation

Ventricular fibrillation results from the chaotic electrical excitation of the ventricles. Ventricular fibrillation is best explained by re-entrant depolarization initially in larger waves that then take circuitous routes and then often degenerate into smaller re-entry circuits. The hemodynamic consequence is the loss of coordinated contractions of the myocytes, resulting in the loss of the rhythmic contractile function of the ventricles so essential to life.

The larger the heart and the more diseased, the easier it is to fibrillate. Small hearts are difficult to fibrillate. It is difficult to kill a rodent by ventricular fibrillation because once the 60 Hz current is removed, the heart often returns to sinus rhythm. If a fibrillating heart of a larger animal is cut in two, both halves continue to fibrillate, but when cut again and again fibrillation stops when the remaining ventricular muscle size is too small to sustain the re-entrant circuits of ventricular fibrillation. These observations have immense clinical importance because cardiac arrest in neonates and children is most commonly due to asystole from respiratory arrest or prolonged periods of inadequate myocardial perfusion and not because of ventricular fibrillation. In contrast, the diseased, dilated, or hypertrophied adult heart is prone to ventricular fibrillation.

The electrocardiographic reflection of ventricular fibrillation is characteristically a chaotic irregular pattern that frequently

Figure 52-8. ECG tracing of ventricular fibrillation.

passes through but spends no time at the isoelectric point (Fig. 52-8). Although ventricular fibrillation is easy to recognize, in some subjects, in some leads, ventricular fibrillation can appear as a very fine ventricular fibrillation or even as a straight line.⁷³

Ventricular fibrillation is usually short-lived because the resulting fall in blood pressure and lack of myocardial perfusion causes the myocardium to use up its energy stores. The electrocardiographic VF wave form decreases in amplitude and becomes finer. However, if myocardial perfusion is maintained by the precordial compressions, VF duration is prolonged. The longest duration of ventricular fibrillation that we observed is 10 days. The patient was in our intensive care unit with an implanted left ventricular assist device when he developed VF. Several attempts at defibrillation were not successful, so the patient was left in ventricular fibrillation, his blood pressure being maintained by the left ventricular assist device. The patient could be seen in a chair reading the paper, with the electrocardiographic monitor showing ventricular fibrillation. His blood pressure was being maintained by the left ventricular assist device.

This observation is important because continuous chest compression in patients with ventricular fibrillation results in prolongation of VF, increasing the patient's chance of survival.

Electrical Defibrillation

Electrical defibrillation is accomplished by passing an adequate current density of appropriate waveform through the fibrillating myocardium. Since it takes a critical mass of muscle to sustain fibrillation, it is not necessary to defibrillate every myofibril. However it appears that most of the myocardial mass must be defibrillated.⁷⁴ This requires among other things appropriate electrode size and placement. The electrodes cannot be placed just anywhere on the chest. If the electrodes are too close together, the current tends to shunt between the electrodes and will not depolarize enough of the left ventricular mass (Fig. 52-9). For most emergency defibrillation, the recommended electrode position is anterior-apical. One paddle electrode is placed under the right clavicle just to the right of the sternum and the other just below the level of the left of the nipple in the anterior axillary line (Fig. 52-10).

Defibrillation Energy, Current, and Voltage

When one selects the strength of the shock for defibrillation, one selects an energy level in watt-seconds or joules. However, it is not the energy that defibrillates the patient. When the capacitor of the defibrillator discharges, the output can be measured in current and voltage. An analogy can be made with the cardiovascular system. When the heart ejects blood, the result can be measured in terms of blood flow and blood pressure. The current is analogous to the flow and the voltage to the pressure. When the defibrillator capacitor is charged, this

Figure 52-9. Improper electrode placement for defibrillation of ventricular fibrillation. If the electrodes are too close together, the current does not traverse enough of the left ventricle to defibrillate.

Figure 52-10. Proper electrode placement for defibrillation of ventricular fibrillation.

charge is measured in volts because there is no current flow. If, upon discharge, the voltage in volts is multiplied by the current in amperes, the result is expressed in watts. The watt is a unit of power. If this is done at each point along the discharged current and voltage wave, a power wave can be constructed (Fig. 52-11). When the area under the power wave is time-integrated in seconds, one derives energy measured in watt-seconds or joules. One watt-second is equal to one joule. Energy is the unit of strength that is indicated on defibrillators. As shown (Fig. 52-12), when the simultaneous current (I) and voltage (V) waves from a defibrillator, with the same stored energy, are delivered into 25, 50, and 75 ohms of resistance or impedance, the delivered peak current decreased with increasing resistance or impedance. Since it is the current that defibrillates, impedance or resistance is important. With constant energy selected, defibrillation effectiveness is related to the resistance between the defibrillator and the patient's heart. The lower the resistance or impedance, the higher the defibrillation success (Fig. 52-13). Impedance or resistance to defibrillation or cardioversion becomes critical to success.

Figure 52-11. Current, voltage, and power waves of a defibrillator discharge delivering a damped half-sinusoidal waveform. Power equals the watts in amperes $\times$ the volts. Energy is the time integral of the power wave. The charge is the time integral of power. (From Ewy GA: *Cardiac arrest and resuscitation: defibrillators and defibrillation*. In: *Current Problems in Cardiology*, Vol 2, No. 2. Chicago, Year Book Medical Publishers, 1978.)

Figure 52-12. Improving effectiveness of defibrillator shock by reducing transthoracic impedance. Simultaneous voltage (V) and current (I) waveforms delivered from a direct current defibrillator with the same energy settings. The defibrillator was discharged into resistive (impedance) loads of 25 Ω , 50 Ω , and 75 Ω . The current decreases with increasing resistance.

Factors Determining Transthoracic Impedance

Transthoracic impedance varies widely among victims of cardiac arrest. Kerber and associates found that transthoracic impedance could range from 15 to 143 Ω , thereby varying by a factor of nearly 10.⁷⁵ The author measured transthoracic impedance during elective cardioversion. In these studies, the variation in transthoracic impedance to defibrillator discharge was not as large, and the mean transthoracic impedance was about 55 Ω .⁷⁶

The lower the impedance, the greater is the defibrillation success. There are several factors that influence transthoracic impedance or resistance of defibrillation discharge. One factor is the diameter of the electrode. As one increases the diameter of the electrodes, the impedance decreases and defibrillation success increases. In our laboratory cardiac arrest model this proved to be true. Standard 8 cm diameter paddles applied within the first minutes of ventricular fibrillation successfully defibrillated 71%. A larger paddle with a 12.8 cm diameter successfully defibrillated 88%.⁷⁷ Kerber showed lower impedance

Figure 52-13. Relationship between defibrillation shock success and transthoracic impedance when shock strength is held constant. This observation shows that it is the delivered current and not the energy that defibrillates. (After Thomas ED, Ewy GA, Dahl CF, Ewy MD: *Effectiveness of direct current defibrillation: role of paddle electrode size*. *Am Heart J* 1977;93:463.)

with larger (13 cm) paddles in human defibrillation and, when coupled with firm pressure to the chest, better current delivery.⁷⁵ In very large electrodes (larger than those commercially available)—that is, much larger than the diameter of the heart—defibrillation success decreases, showing that in fact it is not current but current density through the heart that is the major factor in defibrillation.⁷⁷

A second factor known to effect transthoracic impedance, and thus defibrillation success, is the interface used between the skin of the chest wall and the electrode.⁷⁸ Impedance is relatively high if the electrodes are applied directly to the skin without some form of conductive medium. The impedance will drop by adding appropriate gels, pastes, or saline-soaked gauze pads.⁷⁸

We found a wide discrepancy in the impedance of commercially available creams, pastes, and gels. Of the 26 products tested, we found Hewlett Packard's Redux paste to have the lowest impedance.^{76,79-82} One should avoid gels that have not been shown to have a low resistance. For example, the gels used for echocardiography are very poor conductors of electricity and have very high impedance.

An alternative to paste and gels are self-adhesive electrodes. Self-adhesive disposable electrodes are effective for routine defibrillation and cardioversion, and provide an advantage in certain circumstances, such as in the electrophysiologic laboratory and in the transportation of the high-risk patient with cardiac disease, but because of their somewhat higher impedance they are, in our opinion, not optimal for cardioversion or defibrillation in patients with other factors that predispose to a higher transthoracic impedance to defibrillator discharge. This includes individuals with large and barrel-shaped chests. Other disadvantages include cost, and when purchased in quantity, the fact that they often become out-dated before their use.

Another determinant of transthoracic impedance to DC shock is the phase of respiration. Our laboratory found higher impedance and decreased defibrillation effectiveness when shocks are delivered at full inspiration compared with full expiration induced by firm pressure on the paddle electrodes.⁸¹ Likewise, defibrillation is rarely possible if there is a left-sided pneumothorax, one of the few indications for open-chest defibrillation.

Adequate pressure must be applied to the paddles to ensure a low impedance electrode thoracic interface. Typical recommendations are for application of at least a 25-pound pressure.⁷⁵ Self-adhesive electrode pads are said to have an advantage when applied before the need of defibrillation in high-risk patients, thereby ensuring correct positioning should defibrillation be required at a later time. Their disadvantage, however, is the lack of firm pressure and less than optimal impedance characteristics. If the initial shocks with self-adhesive pads are not successful in defibrillating a large individual, one should apply pressure over the chest electrode with a towel during the shock. This forces air from the lungs, decreasing resistance, and increases the chances of defibrillation success. There is no danger to the individual applying the pressure on the towel if that is all that is touched.

Other factors that have been shown to affect transthoracic impedance to defibrillation shocks include the number, strength, and time interval of previous shocks.^{75,83} Transthoracic impedance decreases with subsequent shocks. Kerber and associates found that for at least 1 month following open heart surgery, the transthoracic impedance remains lower.⁸⁴ The impedance is also higher with greater distance between the electrodes.

Defibrillation Waveforms

The first waveform used for ventricular defibrillation was the 60 Hz alternative current (AC) similar to that used as standard household current. AC current can be used to induce ventricular fibrillation and to defibrillate the heart. Because of myocardial damage from AC defibrillation, direct current (DC) units were developed. Initially, most defibrillators delivered monophasic waveforms. Biphasic waveforms are more effective than monophasic waveforms, and therefore all new defibrillators deliver biphasic waveforms. However, the monophasic defibrillators are effective, so there is no need to replace monophasic with biphasic defibrillators until monophasic replacement is necessary.¹² Experimental triphasic and even multiphasic defibrillators have been developed and are being evaluated.

Defibrillation Threshold

Irrespective of the theories of defibrillation, there is a defibrillation threshold. Shock strength below this threshold will not defibrillate. The shock strength must be above the defibrillation threshold to defibrillate. The defibrillation threshold is increased by some antiarrhythmic drugs. Those that have been shown to increase the defibrillation threshold include lidocaine and flecainide and perhaps high doses of the Class I antiarrhythmic drugs. If the patient has an implanted cardioverter-defibrillator (ICD), these drugs must be added to the medical regimen with caution and the ICD's defibrillation threshold rechecked once therapeutic drug levels have been obtained.

Larger patients have a higher defibrillation threshold, and as our population increases in size and weight, this may become a concern.

Shock Strength

Shock strength must be adequate for defibrillation.⁸⁵ Shocks of subthreshold strength are of insufficient strength to defibrillate. Shock strength in considerable excess of this threshold causes myocardial damage.^{86,87} Gettes and associates showed that over a wide range of body size, the smaller the animal the less energy is needed for defibrillation.⁸⁵ The larger the animal, the

higher the shock strength that is needed. Less energy is needed to defibrillate small children than is needed to defibrillate large adults.

Recurrent ventricular fibrillation may occur after successful defibrillation. In such circumstances, it is reasonable to use energy levels similar to those that were previously effective. Particularly in the cases where ventricular fibrillation reoccurs frequently, shock strength should be kept as low as effective to minimize myocardial damage. Myocardial injury associated with defibrillation corresponds not only with total joules used (energy), but also with the time interval between the defibrillation shocks.^{86,87}

Electrical Cardioversion of Atrial Arrhythmias

Atrial Fibrillation

Atrial fibrillation is the most common arrhythmia and its prevalence increases with age. Accordingly it has not only been called the *grandfather of arrhythmias*, but also the *arrhythmia of grandfathers*.

The major predisposing factors for atrial fibrillation are increasing age and left atrial enlargement. In the absence of valvular heart disease, left ventricular diastolic dysfunction is a major predisposing cause of left atrial enlargement. In fact it has been said that left atrial size is to diastolic function as left ventricular ejection fraction is to systolic function. The aging of our population and the increased incidence of hypertension are two major causes of left ventricular diastolic dysfunction.

Atrial fibrillation is undesirable for a number of reasons. It is a major cause of thromboembolism and it results in a decreased contribution of atrial filling to ventricular function. A rapid ventricular response rate may cause symptoms and if prolonged may produce the myopathy of tachycardia. The major therapeutic intervention should be anticoagulation, even if the atrial rhythm is paroxysmal or if the rhythm is atrial flutter.

Who Should Be Cardioverted?

The theory of cardioversion, as Lown stated decades ago, is that the sustaining mechanism is different from the initiating mechanism.⁸⁸ Therefore, it is not logical to perform cardioversion in someone in whom the initiating mechanism for the atrial fibrillation or flutter is still present. Accordingly, successful cardioversion is not the only goal. Almost everyone can be cardioverted, but some for only one beat, some for several beats, and others for short periods of time. The goal is to select the patient in whom the initiating mechanism has been eliminated or mitigated. If the initiating mechanism is still present and cannot be corrected, the clinical decision is simple: the patient must be managed with rate control.

Accordingly, an important question the physician has when confronted with a patient with atrial fibrillation is: rhythm control (cardioversion) or rate control? Since it is often difficult to determine if the initiating mechanism for atrial fibrillation is still present, both approaches may appear to be logical. In the past the approach has usually been rhythm control with chemical or electrical cardioversion. This approach was used in the belief that rhythm control was associated with better survival, fewer symptoms, better exercise tolerance, lower risk of stroke, better quality of life, and the absence of the need for long-term

anticoagulation. However, several clinical trials comparing rate control with rhythm control have failed to demonstrate these advantages.⁸⁹⁻⁹⁴

If rhythm control, should this be done with direct current cardioversion, medications, ablation techniques, or both? A discussion of medications and the ablation techniques is beyond the scope of this chapter. However, the reported marked improvement in the left ventricular ejection fraction with ablation of atrial fibrillation in patients with congestive heart failure suggests that in many patients with atrial fibrillation and a decreased left ventricular ejection fraction, the myopathy of tachycardia is a contributor to this dysfunction.⁹⁵

Rate Control or Rhythm Control

Should atrial fibrillation be treated with rate control or rhythm control? If rate control, the most effective therapy appears to be the combination of digoxin and a β -adrenergic blocker.⁸⁹ If, however, the patient has asthma or other contraindications to β -blockers, the combination of diltiazem and digoxin or verapamil and digoxin could be considered.⁸⁹ Digoxin should be given during the evening or at bedtime so that when one measures the digoxin level in the morning, there has been appropriate time for blood tissue equilibration. The most common cause of an elevated serum digoxin level is that the blood was obtained within 6 or so hours of digoxin dosing. Although possible, rhythm control should not be accomplished with toxic doses of digoxin.

For rhythm control the major question is whether the patient has heart disease. If no or minimal heart disease, propafenone, sotalol, or flecainide should be considered first. If these drugs are not effective, consideration should be given to amiodarone. If these drugs are not effective, consideration might be given to nonpharmacologic options.⁹⁶ If heart disease is present, the type often determines the initial choice of medical therapy. For patients with heart failure, once the patient is compensated, the drugs of choice are amiodarone and β -adrenergic blockers. If ischemic heart disease is present, the initial drug might be sotalol, followed by amiodarone, and perhaps quinidine.⁹⁶ If hypertension is present with marked (greater than 1.4 cm) left ventricular hypertrophy, a reasonable choice is amiodarone, and if less than 1.4 cm, flecainide or propafenone, and if these fail, amiodarone.⁹⁶

Electrical Cardioversion of Atrial Fibrillation or Flutter

Essential to successful cardioversion of atrial fibrillation or flutter is the fact that it requires the delivery of adequate current density through the fibrillating or fluttering chambers. In the case of atrial fibrillation or flutter the affected chambers are the atria. The same considerations of electrode size and transthoracic impedance apply for cardioversion as for defibrillation. However, electrode positioning should be significantly different for atrial cardioversion than for ventricular defibrillation since the goal is to pass the current through the atria rather than the ventricles. The shock must be synchronized with the intrinsic electrical activity of the ventricles by sensing the R wave of the ECG to ensure that the electrical shock does not occur during the vulnerable phase of the cardiac cycle.⁸⁸

Electrode Positions

Electrode position is often decisive since the current must traverse a critical mass of the atrial muscle for cardioversion to occur. Lown reported that the anterior-posterior electrode

position was more effective for cardioversion of atrial fibrillation than the anterior-anterior electrode position.^{88,97} Lown wrote, "The anterior paddle is held with pressure over the upper sternum at the level of the third intercostal space. . . . This anterior-posterior position, compared with the previously employed anterior-lateral placement, shortens the pathway between the electrodes and augments the density of the electrical field which traverses the heart, thereby diminishing by about 50% the energy required for reversion."⁹⁸ In contrast, Kerber and associates reported that the electrode position or size made little difference to cardioversion success.⁹⁹ However, in Kerber's study the 111 patients with atrial fibrillation were divided into four groups, each with high success rates, making a statistical β -error so likely that the study is not definitive.⁹⁹

Analysis of CT scans of the thorax at the level of the heart provides insight into appropriate electrode positions for defibrillation of the atria. For successful cardioversion the current vector must traverse a critical mass of the atrial muscle. The anterior-posterior positions fulfill these criteria the best. The right anterior-left posterior position or Lown's sternal-posterior are the position of choice if the pathology involves both atria (i.e., atrial fibrillation due to atrial septal defect or diffuse cardiomyopathy). This position has more of the right atria between the electrodes. The anterior-anterior electrode or the apical-left posterior positions are at times effective but are not recommended for elective electrical cardioversion of atrial fibrillation because these positions probably do not provide optimal current flow through the atria.

Predictors of Long-Term Cardioversion Success

Lown's initial enthusiasm for elective cardioversion of all patients in atrial fibrillation was dampened by the high recurrence rate in some subsets of patients. As Lown emphasized, often the initiating mechanism and the sustaining mechanism of atrial fibrillation were different.⁸⁸ If the initiating mechanism was no longer present, then cardioversion would have lasting success. If, however, the initiating mechanism was still present, atrial fibrillation would recur. Such patients are not suitable candidates for cardioversion. Untreated thyrotoxicosis, significant untreated mitral valve disease, and congestive heart failure are obvious examples of situations where the initiating mechanism is still present. Atrial fibrillation of more than 1 year's duration, first degree heart block greater than 0.24 second before the onset of atrial fibrillation, and significant left atrial enlargement are markers that the initiating pathology is still present, since these factors predict early recurrence.

Anticoagulation before Elective Cardioversion

Hemodynamically unstable patients or patients with marked ischemia secondary to recent-onset atrial fibrillation may need urgent cardioversion. In this setting there may be no time for anticoagulation.

Patients should be anticoagulated before elective cardioversion if at all possible. The landmark study of Bjerkelund and Orning was not randomized since all patients admitted on oral anticoagulation, including all patients with previous emboli, were placed in the anticoagulated group.¹⁰⁰ The incidence of postcardioversion emboli was 5.3% in the group not anticoagulated and 0.8% in the anticoagulated group.¹⁰⁰ Based on this study, most physicians have routinely anticoagulated patients before pharmacologic or electrical cardioversion. Anticoagulation is just as

important in patients with atrial flutter as in those with atrial fibrillation.

For elective cardioversion without transesophageal evaluation before elective cardioversion, the patient's INR/PT should be in therapeutic range for 3 months.

Heparin anticoagulation is recommended for patients undergoing earlier cardioversion, even when transesophageal echocardiograms do not reveal evidence of left atrial or left atrial appendage clot because the shock itself may result in atrial stunning and possible clot formation. The shock itself results in atrial stunning and blood stasis for some period of time that evidently predisposes to clot formation.

Another issue concerning the timing of elective cardioversion is the effect of the duration of atrial fibrillation on the time of the return of atrial contractile function following cardioversion. The longer the duration of atrial fibrillation, the longer it takes for normal atrial contractile function to return.⁸⁹ Manning and associates found in patients with relative brief duration of atrial fibrillation (less than 6 weeks) a near complete return of atrial function within 1 week of restoration of sinus rhythm. This fact would argue in favor of a transesophageal echocardiographic evaluation of patients with documented recent onset atrial fibrillation, with the possibility of 2 days of intravenous heparin therapy, followed by cardioversion. If pharmacologic therapy did not result in cardioversion, one could proceed with electrical cardioversion. At the same time the heparin is initiated, the patient is started on oral anticoagulation.

For a number of reasons, including the difficulty in determining the duration of atrial fibrillation, most patients with atrial fibrillation may require a different approach. If the patient is hemodynamically stable and hospitalization is not required for some other reason, the patient may receive oral anticoagulant therapy with warfarin for 3 months before elective outpatient cardioversion. If hospitalization is necessary for other reasons, and cardioversion is necessary, transesophageal echocardiography to rule out intra-atrial thrombi followed by 2 days of heparin therapy prior and 1 day of heparin therapy postcardioversion is recommended.⁸⁹

Our practice is to keep patients on chronic oral anticoagulation therapy for 6 months after cardioversion because of the high recurrence rate during this time. If they have no other reason for chronic anticoagulation, we obtain an ambulatory electrocardiography monitor because many patients go in and out of atrial fibrillation and are not aware of the rhythm change. Twenty-four hour monitoring is not enough to ensure that patients do not have intermittent atrial fibrillation, but longer durations of monitoring are presently not economically feasible.

Role of Antiarrhythmic Therapy before Electrical Cardioversion

Lown instituted quinidine therapy 1 or more days before attempted electrical reversion, stating that quinidine: (1) improved the chance of the patient remaining in normal sinus rhythm immediately after cardioversion, (2) decreases by about 40% the energy required, (3) diminishes the incidence of post-cardioversion arrhythmias, and (4) to "obtain a small dividend of repeat cardioversions which results in about 10% of patients."⁹⁸ Quinidine is seldom used now, but if one prescribes quinidine, the digoxin dose should be held or halved because quinidine doubles the serum digoxin level. Now, the drugs of choice are amiodarone, flecainide, and propafenone. Amiodarone is not a

very effective drug for cardioversion, but it is an effective drug for maintenance of sinus rhythm postcardioversion. Its selection for use, however, must be balanced against its many adverse side effects and reactions.

Flecainide in low doses (50 mg twice a day) is often prescribed for 2 to 3 days, followed by 100 mg flecainide twice a day for 3 days before elective cardioversion in patients without ischemic heart disease. Electrocardiographic monitoring is critical if flecainide is used to ensure the patient does not develop the electrocardiographic signs of Brugada syndrome on flecainide. Other commonly used antiarrhythmic drugs include propafenone and sotalol. A safer precardioversion drug is sotalol, but it is less likely to be effective.⁹⁶

Shock Strength

If biphasic units are used for the cardioversion, the initial dose should be 150 J. The strength of the initial shock for cardioversion of atrial fibrillation with monophasic defibrillators should be 200 J (stored energy) since only 50% of patients will be successfully cardioverted with 100 J.⁷⁶ About 85% of those who will electrically convert will do so at 200 J.⁹⁸ The next shock should be 360 J since almost all patients who will convert electrically via the external technique will do so at the maximum setting.⁹⁸ If the first 360 J shock is not successful, one should assess electrode position. If the electrode positions are to be unchanged, one should wait a full 3 minutes before delivering a final 360 J shock.¹⁰¹ This 3-minute wait allows a greater decrease in transthoracic impedance from the previous DC shock than will occur with shocks delivered at 15-second or 1-minute intervals. In addition, a number of patients will not revert to sinus rhythm immediately after the shock but will do so a few seconds or minutes later.¹⁰¹ This phenomenon is thought to represent depolarization of a major portion but not all of the atrium. The remaining rhythm does not have a large enough area for continued re-entry and dies out. This "delayed" cardioversion is thought to occur in about 4% of electrical cardioversions.¹⁰¹

Does Electrode Type Make a Difference?

The electrode type does make a difference. Based on our animal research and measurement of transthoracic impedance during elective cardioversion, we have long recommended the use of hand-held paddle (Fig. 52-14) electrodes for external

Figure 52-14. Anterior-posterior metal electrodes for cardioversion of atrial arrhythmias.

Figure 52-15. Proper electrode placement for electrical cardioversion of atrial fibrillation.

cardioversion of atrial fibrillation.^{76,78,80,81,101-105} Recently a study by Kirchhof and associates confirmed that the use of reusable hand-held steel paddle electrodes, including a back paddle electrode instead of adhesive gel-covered patch electrodes, improved cardioversion success.¹⁰⁶ They noted that the increase in effectiveness was similar in magnitude to the increase in cardioversion success achieved with biphasic shocks.¹⁰⁶ They concluded that the combination of biphasic shocks, paddle electrodes, and an anterior-posterior position (Fig. 52-15) renders outcome of external cardioversion almost always successful.¹⁰⁶ In their study, this technique resulted in successful cardioversion 100% of the time in the 104 patients reported.¹⁰⁶

Summary

The optimal approach to electrical cardioversion includes appropriate patient selection, anticoagulation, careful selection and monitoring of antiarrhythmic therapy, and proper electrical cardioversion technique. The optimal technique is one that uses metal electrodes with one electrode at least 8 cm in diameter placed over the sternum or in the left parasternal anterior position. The second 12.8-cm diameter metal electrode is placed on the back just below the left scapulae, with generous amounts of the appropriate low impedance gel (such as Hewlett-Packard Redux Paste) as the electrode-skin interface. Firm pressure to the paddle electrode is applied with the patient in the expiratory phase of ventilation, thus decreasing the anterior-posterior chest diameter and ensuring less air between the electrodes.

Electrode pads are commonly used and work most of the time, but in larger adults, optimal techniques are necessary. This may include applying pressure with a folded towel over the anterior electrode, decreasing the anterior-posterior diameter of the chest, and decreasing the amount of air between the electrodes. Appropriate energy is selected. The shock is synchronized with the electrocardiographic QRS complex.

Conclusion

Book chapters are useful to gain a basic knowledge of a subject. However, it is important to stress that medicine is a rapidly evolving discipline and recommendations will certainly change as the profession learns more about problems and new approaches and new forms of therapy become available.

American College of Cardiology/ American Heart Association Management Guidelines

Dileep Menon, Allen Jeremias

APPENDICES

Color Key to ACC/AHA Management Guidelines: Estimate of Certainty (Precision) of Treatment Effect

APPENDIX

1

	Size of Treatment Effect		
	Level A	Level B	Level C
	Multiple (3-5) population risk strata evaluated; general consistency of direction and magnitude of effect	Limited (2-3) population risk strata evaluated	Very limited (1-2) population risk strata evaluated
Class I Benefit >>> risk Procedure/treatment <i>should</i> be performed/administered	Recommendation that procedure or treatment is useful/effective Sufficient evidence from multiple randomized trials or meta-analyses	Recommendation that procedure or treatment is useful/effective Limited evidence from single randomized trial or nonrandomized studies	Recommendation that procedure or treatment is useful/effective Only expert opinions, case studies, or standard-of-care
Class IIA Benefit >> risk Additional studies with focused objectives needed <i>It is reasonable</i> to perform procedure/administer treatment	Recommendation in favor of treatment or procedure being useful/effective Some conflicting evidence from multiple randomized trials or meta-analyses	Recommendation in favor of treatment or procedure being useful/effective Some conflicting evidence from single randomized trial or nonrandomized studies	Recommendation in favor of treatment or procedure being useful/effective Only diverging expert opinion, case studies, or standard-of-care

(Continued)

<i>Size of Treatment Effect—cont'd</i>			
	Level A <i>Multiple (3-5) population risk strata evaluated; general consistency of direction and magnitude of effect</i>	Level B <i>Limited (2-3) population risk strata evaluated</i>	Level C <i>Very limited (1-2) population risk strata evaluated</i>
Class IIB Benefit $\geq$ risk Additional studies with broad objectives needed; additional registry data would be helpful Procedure/treatment <i>may be considered</i>	Recommendation's usefulness/efficacy less well established Greater conflicting evidence from multiple randomized trials or meta-analyses	Recommendation's usefulness/efficacy less well established Greater conflicting evidence from single randomized trial or nonrandomized studies	Recommendation's usefulness/efficacy less well established Only diverging expert opinion, case studies, or standard-of-care
Class III Risk $\geq$ benefit No additional studies needed Procedure/treatment should <i>not</i> be performed/administered <i>because it is not helpful and may be harmful</i>	Recommendation that procedure or treatment is not useful/effective and may be harmful Sufficient evidence from multiple randomized trials or meta-analyses	Recommendation that procedure or treatment is not useful/effective and may be harmful Limited evidence from single randomized trial or nonrandomized studies	Recommendation that procedure or treatment is not useful/effective and may be harmful Only expert opinion, case studies, or standard-of-care

ACC/AHA Guidelines for Primary Percutaneous Coronary Intervention of ST Segment Elevation Acute Myocardial Infarction

APPENDIX

2

	A	B	C
Class I	STEMI or MI with new-onset LBBB and <12 hr since onset or >12 hr with persistent ischemic symptoms if performed in a timely fashion (door-to-balloon time <90 min) by operators skilled in the procedure* and performed in a PCI skilled facility† Primary PCI should be performed for patients <75 yr old with STEMI or LBBB who develop shock within 36 hr of MI, and are suitable for revascularization that can be performed within 18 hr of shock	Primary PCI should be performed as quickly as possible, with the goal of a door-to-balloon time of <90 min Symptom onset <3 hr and the expected door-to-balloon time minus the expected door-to-needle is: (a) <1 hr—PCI preferred; (b) >1 hr—fibrinolytic therapy (fibrin-specific agents) Symptom onset >3 hr, primary PCI should be performed with a door-to-balloon time as brief as possible (<90 min) Primary PCI should be performed in patients with severe congestive heart failure or pulmonary edema or both and onset of symptoms <12 hr with a door-to-balloon time as brief as possible (<90 min)	
Class IIa		Primary PCI is reasonable for selected patients >75 yr old with STEMI or LBBB who develop shock within 36 hr of MI, and are suitable for revascularization that can be performed within 18 hr of shock	Primary PCI may be reasonable for patients with onset of symptoms within the prior 12-24 hr and one or more of the following: (a) severe congestive heart failure; (b) hemodynamic or electrical instability; (c) persistent ischemic symptoms
Class IIb			Primary PCI for STEMI patients eligible for fibrinolysis is not well established when performed by an operator who performs <75 PCI procedures/yr
Class III			Primary PCI should not be performed in a noninfarct artery in patients without hemodynamic compromise Primary PCI should not be performed in asymptomatic patients >12 hr after onset of STEMI if they are hemodynamically and electrically stable

LBBB, left bundle branch block; MI, myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST segment elevation myocardial infarction.

*Individuals who perform >75 PCI procedures/year.

†Performs >200 PCI procedures/year of which at least 36 are primary PCI for STEMI and has cardiac surgery capability.

ACC/AHA Guidelines for Early Hospital Care of Patients with Unstable Angina/Non–ST Segment Elevation Myocardial Infarction

APPENDIX

3

A. Anti-Ischemic and Analgesic Therapy

	A	B	C
Class I	ACE inhibitor should be administered orally within the first 24 hr to UA/NSTEMI patients with pulmonary congestion or LVEF $\leq 40\%$, in the absence of hypotension (SBP < 100 mm Hg or < 30 mm Hg below baseline) or known contraindications to that class of medications Angiotensin receptor blocker should be administered to UA/NSTEMI patients who are intolerant of ACE inhibitors and have either clinical or radiologic signs of HF or LVEF $\leq 40\%$	Intravenous NTG is indicated in the first 48 hr after UA/NSTEMI for treatment of persistent ischemia, HF, or hypertension Oral β-blocker therapy should be initiated within the first 24 hr for patients who do not have one or more of the following: (1) signs of HF; (2) evidence of a low-output state; (3) increased risk for cardiogenic shock; or (4) other relative contraindications to β-blockade (P–R interval > 240 ms, second-degree or third-degree AV block, active asthma, or reactive airway disease) In UA/NSTEMI patients with continuing or frequently recurring ischemia and in whom β-blockers are contraindicated, a nondihydropyridine calcium channel blocker (e.g., verapamil or diltiazem) should be given as initial therapy in the absence of clinically significant left ventricular dysfunction or other contraindications	Patients with UA/NSTEMI with ongoing ischemic discomfort should receive sublingual NTG (0.4 mg) every 5 min for a total of 3 doses, after which assessment should be made about the need for intravenous NTG, if not contraindicated Because of the increased risks of mortality, reinfarction, hypertension, HF, and myocardial rupture associated with their use, NSAIDs except for ASA, whether nonselective or COX-2 selective agents, should be discontinued at the time a patient presents with UA/NSTEMI
Class IIa		In the absence of contraindications to its use, it is reasonable to administer morphine sulfate intravenously to UA/NSTEMI patients if there is uncontrolled ischemic chest discomfort despite NTG, provided that additional therapy is used to manage the underlying ischemia	Intra-aortic balloon pump counterpulsation is reasonable in UA/NSTEMI patients for severe ischemia that is continuing or recurs frequently despite intensive medical therapy, for hemodynamic instability in patients before or after coronary angiography, and for mechanical complications of MI

A. Anti-Ischemic and Analgesic Therapy—cont'd

	A	B	C
Class IIb		It is reasonable to administer intravenous β-blockers at the time of presentation for hypertension to UA/NSTEMI patients who do not have one or more of the following: (1) signs of HF; (2) evidence of a low-output state; (3) increased risk for cardiogenic shock; or (4) other relative contraindications to β-blockade (P–R interval >240 ms, second-degree or third-degree AV block, active asthma, or reactive airway disease) Use of extended-release forms of nondihydropyridine calcium antagonists instead of a β-blocker may be considered in patients with UA/NSTEMI Immediate-release dihydropyridine calcium antagonists in the presence of adequate β-blockade may be considered in patients with UA/NSTEMI with ongoing ischemic symptoms or hypertension	
Class III	Immediate-release dihydropyridine calcium antagonists should not be administered to patients with UA/NSTEMI in the absence of a β-blocker It may be harmful to administer intravenous β-blockers to UA/NSTEMI patients who have contraindications to β-blockade, signs of HF or low-output state, or other risk factors for cardiogenic shock (age >70 yr, SBP <120 mm Hg, sinus tachycardia >110 beats/min or heart rate <60 beats/min, increased time since onset of symptoms of UA/NSTEMI)	Intravenous ACE inhibitor should not be given to patients within the first 24 hr of UA/NSTEMI because of the increased risk of hypotension (a possible exception may be patients with refractory hypertension)	Nitrate should not be administered to UA/NSTEMI patients with SBP <90 mm Hg, severe bradycardia (<50 beats/min), tachycardia (>100 beats/min) in the absence of symptomatic HF, or right ventricular infarction Nitrates should not be administered to patients with UA/NSTEMI who had received a phosphodiesterase inhibitor for erectile dysfunction within 24 hr of sildenafil or 48 hr of tadalafil use NSAIDs (except for ASA), whether nonselective or COX-2 selective agents, should not be administered during hospitalization for UA/NSTEMI because of the increased risks of mortality, reinfarction, hypertension, HF, and myocardial rupture associated with their use

B. Antiplatelet Therapy

	A	B	C
Class I	ASA should be administered to UA/NSTEMI patients as soon as possible after hospital presentation and continued indefinitely in patients not known to be intolerant to that medication Clopidogrel (loading dose followed by daily maintenance dose) should be administered to UA/NSTEMI patients who are unable to take ASA because of hypersensitivity or major GI intolerance In UA/NSTEMI patients in whom an initial invasive strategy is selected, antiplatelet therapy in addition to ASA should be initiated before diagnostic angiography (upstream) with either clopidogrel or an intravenous GP IIb/IIIa inhibitor For UA/NSTEMI patients in whom an initial conservative strategy is selected, clopidogrel (loading dose followed by daily maintenance dose) should be added to ASA and anticoagulant therapy as soon as possible after admission and administered for at least 1 mo	In UA/NSTEMI patients with a history of GI bleeding when ASA and clopidogrel are administered alone or in combination, drugs to minimize the risk of recurrent GI bleeding (e.g., proton pump inhibitors) should be prescribed concomitantly Abciximab as the choice for upstream GP IIb/IIIa therapy is indicated only if there is no appreciable delay to angiography, and PCI is likely to be performed; otherwise, intravenous eptifibatide or tirofiban is the preferred choice of GP IIb/IIIa inhibitor	
Class IIa		For UA/NSTEMI patients in whom an initial invasive strategy is selected, it is reasonable to initiate antiplatelet therapy with clopidogrel and an intravenous GP IIb/IIIa inhibitor Abciximab as the choice for upstream GP IIb/IIIa therapy is indicated only if there is no appreciable delay to angiography, and PCI is likely to be performed; otherwise, intravenous eptifibatide or tirofiban is the preferred choice of GP IIb/IIIa inhibitor	For UA/NSTEMI patients in whom an initial conservative strategy is selected and who have recurrent ischemic discomfort with clopidogrel, ASA, and anticoagulant therapy, it is reasonable to add a GP IIb/IIIa antagonist before diagnostic angiography
Class IIb		For UA/NSTEMI patients in whom an initial conservative strategy is selected, it may be reasonable to add eptifibatide or tirofiban to anticoagulant and oral antiplatelet therapy	
Class III	Abciximab should not be administered to patients in whom PCI is not planned		

C. Anticoagulant Therapy

	A	B	C
Class I	For patients in whom an invasive strategy is selected, regimens with established efficacy including enoxaparin or UFH should be added to antiplatelet therapy in UA/NSTEMI patients as soon as possible after presentation For patients in whom a conservative strategy is selected, regimens using either enoxaparin or UFH have established efficacy	In patients in whom a conservative strategy is selected and who have an increased risk of bleeding, fondaparinux is preferable	
Class IIa		For UA/NSTEMI patients in whom an initial conservative strategy is selected, enoxaparin or fondaparinux is preferable to UFH as anticoagulant therapy, unless CABG surgery is planned within 24 hr	

ACE, angiotensin-converting enzyme; ASA, acetylsalicylic acid; AV, atrioventricular; CABG, coronary artery bypass graft; COX, cyclooxygenase; GI, gastrointestinal; GP, glycoprotein; HF, heart failure; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SBP, systolic blood pressure; UA/NSTEMI, unstable angina/non–ST segment elevation myocardial infarction; UFH, unfractionated heparin.

ACC/AHA Guidelines for the Management of Chronic Heart Failure

APPENDIX

4

A. Patients at High Risk for Developing Heart Failure (Stage A)

	A	B	C
Class I	In patients at high risk for developing HF, systolic and diastolic hypertension and lipid disorders should be treated in accordance with contemporary guidelines	Ventricular rate should be controlled or sinus rhythm restored in patients with supraventricular tachyarrhythmias who are at risk for developing HF	For patients with diabetes mellitus, blood glucose should be controlled in accordance with contemporary guidelines Left ventricular function should be assessed in patients with a strong family history of cardiomyopathy or in patients receiving cardiotoxic interventions
Class IIa	ACE inhibitors can be useful in preventing HF in patients with a history of atherosclerotic vascular disease, diabetes mellitus, or hypertension with associated cardiovascular risk factors		ARB can be useful to prevent HF in patients with a history of atherosclerotic vascular disease, diabetes mellitus, or hypertension with associated cardiovascular risk factors
Class III			Routine use of nutritional supplements solely to prevent the development of structural heart disease should not be recommended for patients at high risk for developing HF

B. Patients with Cardiac Structural Abnormalities or Remodeling Who Have Not Developed Heart Failure Symptoms (Stage B)

	A	B	C
Class I	β -blockers and ACE inhibitors should be used in all patients with a recent or remote history of MI regardless of ejection fraction or presence of HF ACE inhibitors should be used in patients with a reduced ejection fraction and no symptoms of HF, even if they have not experienced MI	ARBs should be administered to post-MI patients without HF who are intolerant of ACE inhibitors and have a low LVEF	β -blockers are indicated in all patients without a history of MI who have reduced LVEF with no HF symptoms
Class IIa		ACE inhibitors or ARBs can be beneficial in patients with hypertension and left ventricular hypertrophy with no symptoms of HF ICD is reasonable in patients with ischemic cardiomyopathy who are at least 40 days post-MI, have an LVEF of $\leq 30\%$, are NYHA class I on long-term optimal medical therapy, and have reasonable expectation of survival with a good functional status of >1 yr	ARBs can be beneficial in patients with low ejection fraction and no symptoms of HF who are intolerant of ACE inhibitors

B. Patients with Cardiac Structural Abnormalities or Remodeling Who Have Not Developed Heart Failure Symptoms (Stage B)—cont'd

	A	B	C
Class IIb		ICD might be considered in patients without HF who have nonischemic cardiomyopathy and LVEF $\leq 30\%$ who are in NYHA class I with long-term optimal medical therapy, and who have a reasonable expectation of survival with good functional status of >1 yr	
Class III			Digoxin should not be used in patients with low ejection fraction, sinus rhythm, and no history of HF symptoms Calcium channel blockers with negative inotropic effects may be harmful in asymptomatic patients with low LVEF and no symptoms of HF after MI

C. Patients with Current or Prior Symptoms of Heart Failure (Stage C)

	A	B	C
Class I	ACE inhibitors are recommended for all patients with current or prior symptoms of HF and reduced LVEF unless contraindicated β-blockers (i.e., bisoprolol, carvedilol, and sustained-release metoprolol succinate) are recommended for all stable patients with current or prior symptoms of HF and reduced LVEF unless contraindicated ARBs (candesartan, losartan, and valsartan) are approved for the treatment of HF in patients with current or prior symptoms of HF and reduced LVEF who are intolerant of ACE inhibitors ICD is recommended as secondary prevention to prolong survival in patients with current or prior symptoms of HF and reduced LVEF who have a history of cardiac arrest, ventricular fibrillation, or hemodynamically destabilizing ventricular tachycardia ICD is recommended for primary prevention to reduce total mortality in patients with ischemic heart disease who are at least 40 days post-MI, have an LVEF $\leq 30\%$ with NYHA class II or III symptoms while receiving long-term optimal medical therapy, and have reasonable expectation of survival with a good functional status for >1 yr	Addition of an aldosterone antagonist is recommended in patients with moderately severe to severe symptoms of HF and reduced LVEF who can be carefully monitored for preserved renal function and normal potassium concentration	Diuretics and salt restriction are indicated in patients with current or prior symptoms of HF and reduced LVEF who have evidence of fluid retention

(Continued)

C. Patients with Current or Prior Symptoms of Heart Failure (Stage C)—cont'd

	A	B	C
	ICD is recommended in patients with nonischemic cardiomyopathy who have an LVEF $\leq 30\%$, with NYHA class II or III symptoms while receiving long-term optimal medical therapy, and have reasonable expectation of survival with a good functional status for >1 yr Cardiac resynchronization therapy is recommended in patients with LVEF $\leq 35\%$, sinus rhythm, and NYHA class III or IV despite optimal medical therapy and who have QRS duration >120 ms		
Class IIa	ARBs are an alternative to ACE inhibitors in patients with mild to moderate HF and reduced LVEF	Digoxin can be beneficial in patients with current or prior symptoms of HF and reduced LVEF to decrease hospitalizations for HF Hydralazine and nitrate can be added for patients already on ACE inhibitors and β-blockers for symptomatic HF and who have persistent symptoms ICD is reasonable in patients with LVEF 30-35% with NYHA class II or III who are receiving optimal medical therapy, and who have reasonable expectation of survival with good functional status of >1 yr	
Class IIb		Addition of ARBs may be considered in persistently symptomatic patients with reduced LVEF who are already being treated with conventional therapy	Hydralazine and nitrate combination might be reasonable in patients with current or prior symptoms of HF and reduced LVEF who cannot be given ACE inhibitors or ARBs because of drug intolerance, hypotension, or renal insufficiency
Class III	Calcium channel blockers are not indicated as routine treatment		Combined use of ACE inhibitors, ARBs, and aldosterone antagonists is routine Long-term use of an infusion of a positive inotropic drug is recommended

D. Patients with Refractory End-Stage Heart Failure (Stage D)

	A	B	C
Class I	Referral to HF program with expertise in management of refractory HF is recommended	Control of fluid retention is indicated Referral for cardiac transplantation is recommended	Options for end-of-life care may be discussed
Class IIa		Left ventricular assist device is recommended as permanent or destination therapy in patients with a 1-yr mortality of $\geq 50\%$	Pulmonary catheter placement may be reasonable to guide therapy Continuous intravenous infusion of a positive inotropic agent may be considered for palliation of symptoms in patients with refractory end-stage HF
Class IIb			
Class III		Routine intermittent infusions of positive inotropic agents are not recommended	Partial left ventriculectomy is not recommended in patients with nonischemic cardiomyopathy and refractory end-stage HF

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; HF, heart failure; ICD, implantable cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association.
