Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Sabre Foundation

Dedicated to my parents, Dr. Andreas and Susanne Jeremias, who always supported me in every endeavor and made me who I am today; and to my grandfather, Dr. Nicolaus Jeremias, whose unwavering dedication to patient care has set the standard that I aspire to.

Allen Jeremias

This edition is dedicated to my mentor, Kanu Chatterjee, MBBS, on the occasion of his retirement from the Division of Cardiovascular Medicine at University of California, San Francisco, where he inspired and taught generations of trainees the art, science, and humanity of medicine.

David L. Brown

Foreword

The care of acutely ill cardiac patients has evolved over the past 40 years through a series of landmark developments and milestones. Coronary intensive care began in the 1960s with the introduction of electrocardiogram (ECG) monitoring for patients with acute myocardial infarction (MI). ECG monitoring coupled with the introduction of antiarrhythmic interventions (cardioversion, defibrillation, and lidocaine) led to a dramatic decrease in the mortality of patients with acute MI, largely through a reduction of in-hospital ventricular dysrhythmias. This was the first major milestone in the care of patients with acute MI. At this time, hemodynamic dysfunction and pump failure emerged as the leading causes of death in acute MI.

In the early 1970s, the introduction of bedside pulmonary artery catheterization, by Willie Ganz and Jeremy Swan at the Cedars-Sinai Medical Center, made possible accurate assessment of hemodynamic dysfunction in critically ill cardiac patients. This landmark development spawned a new era of coronary care that led to better assessment and management of pump dysfunction, stimulating the introduction of afterload-reducing therapy for heart failure. Around the same time, the concept of infarct size as a major determinant of ventricular dysfunction and prognosis began in the experimental laboratory, triggering a search for interventions to limit infarct size in experimental animals. The results of various therapies in this regard were inconsistent in the laboratory and in the clinical arena.

The next major milestone came in the late 1970s and early 1980s, when the role of coronary thrombosis as the proximate cause of acute MI became firmly established through the landmark study of Marcus DeWood, then a trainee in cardiology. With this observation and the elegant early experimental work of many investigators, the importance of timely reperfusion as a powerful method for infarct size limitation was recognized. The focus on reperfusion, initially with intracoronary and subsequently with intravenous thrombolysis and more recently with primary angioplasty, as a means of reducing infarct size and decreasing mortality revolutionized contemporary care of patients with developing MI.

This advance represented another major milestone in coronary care. All this stepwise progress over the years has led to a substantive and steadily declining mortality for patients with acute MI. The past several years have witnessed an explosion in our knowledge of vascular biology, atherogenesis, plaque disruption and thrombosis, and the concept of acute coronary syndromes. These concepts have led to dramatic improvements in our ability to diagnose and manage patients with unstable angina with potent antithrombotic strategies ranging from aspirin and heparin to platelet receptor antagonists and direct thrombin inhibitors to angioplasty and stent implantation.

Throughout this progress, coronary care units evolved from specialized areas catering to patients with acute ischemic syndromes to a place where we now take care of the ever-increasing population of patients with other critical cardiovascular illnesses, such as acute and severe chronic heart failure, chronic pulmonary hypertension, life-threatening cardiac dysrhythmias, aortic dissection, and other diagnoses. A modern coronary care unit is, in reality, a cardiac intensive care unit.

This second edition of *Cardiac Intensive Care*, presented in a new full-color design, edited by Allen Jeremias, MD, MSc, and David L. Brown, MD, provides a state-of-the-art compendium summarizing all of the progress that has been made in the diagnosis, assessment, and treatment of patients with critical cardiac illnesses over the past several years. The 52 chapters and 3 appendices are written by experienced authors who have made important contributions in their respective fields. Nine new chapters have been added in this new edition dealing with topics including quality assurance and improvement, physical examination, mechanical treatments for acute ST segment elevation MI, non-ST segment elevation MI, and management of post-cardiac surgery patients. The convenience of full-text online access at expertconsult.com is an added bonus.

The editors have captured the essence of what is the state-of-the-art in a rapidly evolving and dynamic field. The contents of this text provide a nice blend of pathophysiology and the more pragmatic issues of actual intensive cardiac care. In addition to dealing in detail with the issues of acute cardiac problems, this text provides a broader perspective by including many useful chapters that deal with critical care issues of a more general nature, such as airway and ventilator management, resuscitation, dialysis, and ultrafiltration. The editors and the authors are to be commended for having produced an up-to-date and useful treatise on cardiovascular critical care.

Preface

Since the publication of the first edition of *Cardiac Intensive Care*, there have been considerable changes in the level of care and the complexity of therapies provided in the cardiac intensive care unit (CICU). To reflect these changes appropriately, the second edition of *Cardiac Intensive Care* has not only been updated, but also completely restructured with many new chapters. Given that most CICU admissions are still related to coronary artery disease and its acute manifestations, one major focus of this text remains the diagnosis and therapeutic options for patients with acute coronary syndromes. Section III, Coronary Artery Disease, is divided into Acute Myocardial Infarction, Complications of Acute Myocardial Infarction, and Complications of Percutaneous Interventional Procedures. We recognize, however, the ever-increasing multifaceted disease states that are cared for in the CICU and have included sections on Noncoronary Diseases, Pharmacologic Agents in Cardiac Intensive Care Unit, and Advanced Diagnostic and Therapeutic Techniques.

The evidence base for practice in the CICU is expanding rapidly, placing high demands on the daily “rounders.” The field of cardiovascular medicine has expanded to subsume multiple subspecialties and a multitude of procedures, including percutaneous coronary intervention, percutaneous valve procedures,

peripheral arterial procedures, atrial and ventricular ablations, pacemaker and defibrillator implantations, and cardiac imaging. The cardiac intensivist is required to make informed decisions about the potential benefit versus the risks of referring patients for these procedures and to interpret the data derived from these procedures adequately. In addition, adding to the dynamic environment, optimal patient care in the CICU is delivered via a multidisciplinary approach involving physicians, nurses, ethicists, respiratory therapists, nutritionists, physical therapists, and social workers. The goal of this second edition of *Cardiac Intensive Care* is to provide a comprehensive, conceptual, yet practical and evidence-based text for all specialties involved in patient care in a CICU.

The editors thank Natasha Andjelkovic from Elsevier for her tireless efforts and her ongoing encouragement throughout this endeavor. Additionally, we express our deep appreciation to all the contributing authors. Without their expertise, dedication, and time commitment, this book would not have been possible.

Describing the Contemporary Coronary Care Unit—
the Duke Experience
Future Trends and Continued Evolution in the
Coronary Care Unit
Conclusion

ORIGINATING DURING a time of great technical and investigative discovery, the coronary care unit (CCU) has emerged as one of the most important advances in the care of patients with acute coronary syndromes. Despite the notion that the CCU has revolutionized the management of myocardial infarction (MI), however, widespread proliferation and acceptance of the CCU as “standard of care” has not been met with universal support. Complicating matters further, the CCU has changed considerably over the past several decades, bringing to light unresolved issues of patient triage, medical ethics, physician and nurse training, cost, and resource use. This chapter reviews the evolutionary history of the CCU, from its inception in the early 1960s to its contemporary role in the care of often critically ill patients with cardiovascular disease (Fig. 1-1). Future trends in cardiac care also are addressed, with particular attention given to ways in which the CCU may remain a viable entity within a continuously changing health care system.

Origins of the Coronary Care Unit

Several seminal reviews of acute MI—a highly fatal disease at the time—served to highlight the critical need for improved methods of health care delivery.^{1,2} Outside of morphine and comfort care measures, there was little available in the clinician's armamentarium to spare patients with acute MI from death or prolonged convalescence. Treatment of MI at the time has been described as “benign neglect,”³ and even minimal forms of patient exertion were discouraged.

Focus on Resuscitation

The first reasonable therapy to combat complications of myocardial ischemia finally became available after the successful implementation of open-chest^{4,5} and, later, closed-chest

defibrillation.^{6,7} After reporting on the effective open-chest defibrillation of a patient who developed life-threatening ventricular arrhythmia in the setting of MI, Beck and colleagues⁵ prophetically reported that “this one experience indicates that resuscitation from a fatal heart attack is not impossible and might be applied to those who die in hospital ... and perhaps to those who die outside the hospital.” Following closely on the heels of these discoveries and the demonstrated efficacy of closed-chest massage,⁸ the concept of the CCU as a vehicle for successful resuscitation began to take shape.

Julian, the senior medical registrar of the Royal Infirmary of Edinburgh, first articulated the idea of the CCU. In his original presentation to the British Thoracic Society in 1961,⁹ Julian described five cases of cardiac massage used in resuscitation attempts for patients with acute MI. He concluded that “many cases of cardiac arrest associated with acute myocardial ischaemia could be treated successfully if all medical, nursing, and auxiliary staff were trained in closed-chest massage, and if the cardiac rhythm of patients ... were monitored by an electrocardiographic linked to an alarm system.” His vision for the CCU was founded on four basic principles, as follows:

1. Continuous electrocardiogram monitoring with arrhythmia alarms
2. Cardiopulmonary resuscitation with external defibrillator capabilities
3. Admission of patients with acute MI to a single unit of the hospital where trained personnel, cardiac medications, and specialized equipment were immediately available
4. The ability of trained nurses to initiate resuscitation attempts in the absence of immediate physician presence

At roughly the same time, several clinician investigators in North America developed specialized units devoted exclusively to the treatment of patients with suspected MI. In Philadelphia,

Figure 1-1. Timeline of landmark events in the evolution of the coronary care unit (CCU). AMI, acute myocardial infarction; CPR, cardiopulmonary resuscitation; IABP, intra-aortic balloon pump.

Meltzer¹⁰ created a two-room research unit with an aperture in the wall through which defibrillator paddles could be passed from one patient to the other. In Toronto, Ontario, Brown and associates¹¹ erected a four-bed unit with an adjacent nursing station for the care of MI patients. Arrhythmia surveillance was provided using a converted electroencephalogram unit with electrocardiogram amplifiers. Although Brown's initial observations suggested no immediate decline in mortality associated with more attentive coronary care,¹¹ these preliminary findings did little to temper the growing enthusiasm for these specialized units.

Day,¹² a contemporary of Meltzer, Brown, and Julian, began building mobile crash carts in the attempt to resuscitate acute MI patients being monitored on the general medical floors. Similar to his colleagues, Day astutely recognized that delays in arrhythmia detection on these general wards significantly limited the success of resuscitation attempts. As a result of his observations, an 11-bed unit was established at Bethany Hospital in New York staffed by "specially-trained nurses who could give the patient with coronary disease expert bedside attention, interpret signs of impending disaster, and quickly institute CPR."¹² Day is largely credited with introducing the term *code blue* to describe resuscitation efforts for cyanotic patients with cardiac arrest and, perhaps more importantly, the term *coronary care unit*.

Shift in Paradigms—Prevention of Cardiac Arrest

Until this point, the benefit of specialized care in the CCU was predominantly related to recognition of peri-infarction arrhythmias that were incompatible with life, and the successful termination of such events. It seemed clear to physicians of the time

that the development of malignant arrhythmias posed the greatest threat to patients sustaining acute cardiac injury, and perhaps the early recognition and prompt therapy for early prodromata of cardiac arrest might have a significant impact on patient survival. The focus of the CCU moved from one of resuscitation to a more preventive role. Julian¹³ described this transformation as the "second phase" in the evolution of the CCU.

In the late 1960s, Killip and Kimball¹⁴ published their experience with 250 acute MI patients treated in a four-bed CCU at New York Hospital–Cornell Medical Center. Credited largely with the MI classification scheme that now bears their name, in which the presence or absence of heart failure or shock had significant prognostic implications, these two investigators also showed that aggressive medical therapy in the CCU seemed to reduce in-hospital mortality from 26% to 7%. This led Killip and Kimball to proclaim in their landmark report that "the development of the coronary care unit represents one of the most significant advances in the hospital practice of medicine."¹⁴ Not only did it seem that patients with acute MI had improved survival if treated in a CCU, but also all in-hospital cardiac arrest patients seemed more likely to survive if geographically located in the CCU.

"Although frequently sudden, and hence often 'unexpected,' the cessation of adequate circulatory function is usually preceded by warning signals."¹⁴ With these words, Killip and Kimball, collectively, with the influential findings of Day, Meltzer, Brown, and others, ushered in the rapid proliferation of CCUs throughout the world, with a categorical focus on the prevention of cardiac arrest.

Truly at the forefront of this new paradigm in coronary care were Lown and colleagues,¹⁵ who elaborately detailed the key

components of the CCU at the Peter Bent Brigham Hospital. “From the opening of the unit,” they reported, “the focus has been the prevention of cardiac arrest.” The foundation of their CCU revolved around employment of a “vigilant group of nurses properly indoctrinated in electrocardiographic pattern recognition and qualified to intervene skillfully with a rehearsed and well-disciplined repertoire of activities in the event of a cardiac arrest.”¹⁵ With a CCU mortality of 11.5% and an in-hospital mortality of 16.9%, these investigators concluded that an aggressive protocol emphasizing arrhythmia suppression after MI could virtually eradicate sudden and unexpected fatalities. Although more contemporary data refuting the notion of preventive antiarrhythmic therapy in MI fail to support the early premise of Lown and others,¹⁶ their debatable yet compelling results allowed the concept of the CCU to continue to flourish.

Several other developments in the late 1960s through the mid-1980s, including the use of intra-aortic balloon counterpulsation,¹⁷ the implementation of flow-directed catheters capable of invasive hemodynamic monitoring,¹⁸ and the use of systemic thrombolysis for the treatment of coronary thrombosis,¹⁹ helped to advance the frontiers of the CCU. Along with these dramatic changes in the care of patients with acute MI came a remarkable transformation in the face and philosophy of the CCU. At the same time, questions and controversies began to emerge regarding the benefits and proper use of these specialized and costly units.

Validating the Benefits of the Coronary Care Unit

Although use of a CCU for the management of patients with acute MI became more commonplace, many still questioned their true impact. These critics pointed to the dubious nature of the early comparisons between CCUs and the general medical wards, most of which were purely observational and experiential reports, and all of which unquestionably lacked the scrupulous scientific and analytic techniques of contemporary clinical research. Adding further fuel to the controversy was a study by Hill and associates²⁰ in the late 1970s comparing outcomes of patients with suspected MI managed at home with outcomes of patients managed in the hospital setting. These investigators found no significant differences in mortality for the two groups, although skeptics cite design flaws, power limitations, and dynamic advances in hospital-based care as major confounders to this study. Nonetheless, results such as these led many, including Cochrane,²¹ to exclaim, “... the battle for coronary care is just beginning.”

Much of the data in support of the CCU was largely observational. As previously described, Killip and Kimball¹⁴ attributed a nearly 20% decline in mortality to the successful implementation of their CCU. Other nonrandomized data from a Veterans Administration population²² and several Scandinavian studies^{23,24} corroborated the early uncontrolled observations of Killip, Kimball, Day, and others. These trials all showed lower mortality rates and greater resuscitation success in acute MI patients when treated in a CCU setting.

Goldman and Cook²⁵ attempted to ascribe the epidemiologic decline in mortality rates from ischemic heart disease in the United States to the presence of CCUs. From 1968-1976,

estimates suggested a decline in mortality of approximately 21%. Using complex statistical analyses and mathematical modeling, the authors surmised that nearly 40% of the decline could be directly attributable to specific medical interventions, with the CCU being one of the premier contributors. They suggested that approximately 85,000 more people would be alive at the end of 8 years because of the presence of CCUs than would have otherwise been alive; in other terms, the CCU may have accounted for approximately 13.5% of the decline in coronary disease-related mortality.²⁵ Epidemiologic estimates from other investigators seemed to corroborate these findings.²⁶

On an even broader scale, Julian¹³ and Reader²⁷ contemplated that the steady decline in mortality among people 35 to 64 years old in the United States, Australia, and New Zealand since 1967 (the advent of CCUs) may have been a direct effect of the specialized care received in the CCU. More contemporary data, in patients treated during the “thrombolytic era,” have suggested that one highly significant independent predictor of 30-day mortality among acute MI patients was treatment isolated to an internal medicine ward.²⁸ Despite the retrospective nature of this analysis, the findings seemed to underscore the importance of treating acute MI in the setting of an intensive CCU.

Although there are significant limitations to the available data, a plethora of nonrandomized studies seems to support the beneficial role of the CCU in the management of patients with acute cardiac ischemia. A truly randomized, prospective study evaluating the role of the CCU is likely impossible, given the current (albeit arguable) burden of proof in support of these units. Key opinion leaders in the field of cardiovascular medicine have nearly unanimously endowed the CCU as “the single most important advance in the treatment of acute MI.”^{29,30}

Economic Impact of the Coronary Care Unit

Evaluation of the economic impact of the CCU poses a significant challenge, and no single study has directly addressed this issue. Not only is it difficult to measure true costs in a dynamic health care system, but also evolutionary changes in the CCU (with concomitant changes in resource use, therapeutic procedures, and medication administration) makes fiscal assessments quite unwieldy.

If one were to draw correlates with other contemporary critical care units, perhaps cost could be put into some perspective. Because they are places of high resource use and high expenditure, intensive care units (ICUs) contribute significantly to the economic burden of health care facilities and, on a broader scale, to the economic burden of societal health care. Although ICUs constitute less than 10% of hospital beds in the United States, estimates suggest that ICUs consume more than 20% of total hospital costs and nearly 1% of the U.S. gross domestic product.^{31,32} It has been suggested that ICU costs have increased by nearly 200% in the years 1985-2000.³³

The argument over whether or not CCUs are comparable to ICUs, or, perhaps more importantly, whether or not they should be, is addressed later in this chapter. Data exist to support similarities in resource use, morbidity and mortality, and in-hospital length of stay^{34,35}—all of which have significant economic impact and need to be addressed in more rigorous scientific analyses of CCU populations.

Critical Care in the Coronary Care Unit

The landscape of the CCU has evolved over the last several decades. As a result of more sensitive diagnostic tools, advanced pharmacotherapeutics, and novel interventional techniques, cardiologists now have the ability to alter the natural history of MI significantly. Consequently, the mortality rates for acute MI in several contemporary acute coronary syndrome databases have steadily declined.³⁶⁻³⁸ At the same time, however, the presence of other cardiovascular diseases and noncardiac critical illness seems to be increasing in today's CCU. An aging U.S. population, acute and chronic sequelae of nonfatal MI, comorbid medical conditions, and complications of implantable devices all result in increased susceptibility to critical illness in high-risk patients. Many, if not all, of these patients are likely to be admitted to the CCU. What were previously purely resuscitative and preventive units for patients with MI have now arguably transformed into critical care units for patients with cardiovascular disease. Some authors have suggested that perhaps even the name "coronary care unit" has become a misnomer in today's health care environment; Julian¹³ has advocated more recently that the CCU could instead be more appropriately called the *cardiac care unit*. Others have suggested that the distinction between contemporary CCUs and ICUs has become blurred—largely resulting from an increased cardiac critical care burden.³⁹

In a single-day descriptive analysis of U.S. critical care units, Groeger and colleagues³⁴ highlighted mortality statistics, resource use data, and patient characteristics of modern CCUs; results which were remarkably comparable to composite data from contemporary medical ICUs.^{34,35} Another more recent investigation concluded that severity of illness, quantified by a classic physiologic measure of critical illness (the APACHE [Acute Physiology, Age, and Chronic Health Evaluation] II score), was the greatest independent predictor of in-hospital mortality in a CCU cohort of patients—suggesting that risk stratification in the CCU could be conducted in a manner similar to other ICUs, where the APACHE II score has been well established.⁴⁰

Although limited observational data suggest that current CCU patients have become more complex from a critical care perspective, there are no large contemporary analyses that corroborate these findings on a broader scale. If the CCU has indeed evolved into an ICU for cardiac patients, re-examination of the role of the CCU, and the role of the cardiologists staffing these units, is warranted. Whether the CCU is a beneficial tool in its current stage of evolution is unknown. In a retrospective study of patients admitted to a CCU in Lazio, Italy, investigators found no significant differences in in-hospital mortality between CCU and non-CCU admissions for patients with cardiac diagnoses other than acute MI or arrhythmia.⁴¹ Additionally, a growing body of evidence now exists to support the benefits of critical care specialists to improve the care of ICU patients,⁴²⁻⁴⁴ and there has been some suggestion that the CCU may benefit from similarly requisite critical care physician training.³⁹

Describing the Contemporary Coronary Care Unit—the Duke Experience

Several contemporary databases have been used to describe operational and demographic features of ICUs in the United States.^{34,45-47} These rich datasets have been used to help

establish practice guidelines, to generate hypotheses for novel clinical research efforts, and to accelerate quality improvement initiatives in critical care medicine. The datasets contain very limited information on CCUs, however, and there have been no concerted efforts to illustrate or define, through similar registries, the role of the modern CCU.

In an effort to better understand the current practice model of a CCU in today's academic health care system, the authors of this chapter have created a single-center database containing 2 decades' worth of diagnostic, procedural, demographic, and outcome-related variables from the Duke University Medical Center CCU. Unadjusted, descriptive results are illustrated in Figures 1-2 and 1-3. These graphs highlight the growing critical care burden and increased implementation of critical care resources in the CCU at Duke, and it is our hope that this database will result in numerous novel hypothesis-generating analyses, and stimulate collaborative multicenter investigations to better understand the continued evolution of the CCU.

Future Trends and Continued Evolution in the Coronary Care Unit

Multiple nonrandomized studies seem to support the beneficial role of the CCU in the management of patients with acute MI. As a result, there has been a rapid proliferation of these specialized units in the United States and worldwide since their introduction into the medical vernacular more than 4 decades ago. At the same time, data support significant evolutionary changes within contemporary CCUs. Observational studies suggest that although the mortality for acute MI has steadily declined, there is a greater burden of noncoronary cardiovascular disease and critical illness. For these particular patients, the role and impact of CCU care are uncertain. This uncertainty has numerous implications related to patient outcomes, resource use, and costs of care. As we continue to work toward better defining the changing landscape of the CCU and its place within the current health care system, there are several key topics that need to be addressed.

Multidisciplinary Clinical Integration and the Coronary Care Unit Model

Because of the multiplicity and complexity of critical care delivery, and the advancing critical care burden in the contemporary CCU, the development of practice models for efficient and effective patient care will be an important part of the continued evolution of the CCU. At the same time, landmark documents from the Institute of Medicine have attacked several "dysfunctional" processes of past and current health care systems, with particular attention focused on the elimination of "isolationist decision-making and ineffective team dynamics" that may put patient care at risk.^{48,49} A careful appraisal of the role of multidisciplinary care in the CCU will therefore be a vital component of future study.

Currently, several models of health care delivery are employed in ICUs—the open model, the closed model, and hybrid models. All of these critical care platforms have distinct advantages and disadvantages from patient-care and systems-based perspectives. In a closed ICU model, all patients admitted to an ICU are cared for by an intensivist-led team that is primarily responsible for making clinical decisions. In a contemporary CCU, this

Figure 1-2. Unadjusted trends in selected critical illness in the Duke University Medical Center coronary care unit (unpublished data, 1987-2006).

leader might be a general cardiologist, a cardiologist with critical care expertise, or an intensivist adept in the care of patients with complex cardiovascular illness. In an open ICU model, the patient's primary physician determines the need for ICU admission and discharge and makes all management decisions. As its name suggests, a hybrid or transitional ICU model is a blend of the two more traditional critical care delivery models. The burden of evidence seems to support a closed or hybrid ICU format for delivering high-quality, cost-effective care compared with the open model,^{50,51} and descriptive studies of current practice patterns show greater implementation of these health care delivery systems in the United States.⁴⁵

Governing bodies for the major critical care medicine organizations universally espouse the benefits of multidisciplinary critical care.^{52,53} It is believed that shared responsibility for ICU team leadership is a fundamental component for providing optimal medical care for critically ill patients. A multidisciplinary approach to CCU management, in light of the growing patient complexity, seems equally reasonable. Potential members of

CCU teams, all of whom would be intimately connected in the day-to-day care of patients, might include a cardiologist, intensivist, pharmacist, respiratory therapist, critical care nurse, and social worker or case manager (Fig. 1-4). The goal of this integrated approach would be to provide the highest quality care, while limiting adverse events, curbing ineffective resource use practices, and providing an efficient patient transition out of the intensive care setting.

Nursing and Clinician Training Requirements

In today's CCU, in contrast to the CCU of the 1960s, having nurses trained in the vigilant detection of life-threatening arrhythmias and educated in the implementation of cardiopulmonary resuscitation and defibrillation is no longer sufficient. Most CCUs employ nurses with the most rigorous critical care backgrounds. With growing numbers of patients who have cardiovascular disease, many of whom will require admission to the CCU during their lifetimes, there is a significant need for training more nurses skilled in cardiovascular and critical care. At the

Figure 1-3. Unadjusted trends in selected critical care procedures in the Duke University Medical Center coronary care unit (unpublished data, 1987-2006).

same time, the burden of nursing shortages⁵⁴ raises a difficult proposition for the continued viability and growth of CCUs in the United States. It is imperative that these issues be fundamentally addressed because the CCU nurse is arguably the most influential component of the multidisciplinary team from an operational perspective.

As alluded to previously, the diversity of critical illness in today's CCU poses many challenges to the general cardiologists that most commonly staff these units. Whether we provide these clinicians with requisite skills in critical care delivery (in the form of continuing medical education), or we train cardiologists with advanced specialization in critical care medicine, or we demand obligatory intensivist input in the care of all critically ill CCU patients, there are many unresolved issues that have direct implications to the future role of CCU clinicians. There is a significant amount of pressure for all critical care units to be staffed by appropriately trained intensivists,⁵⁵ largely the result of numerous nonrandomized studies pointing to the benefits that these clinicians have on the care

of patients with critical illness.^{43,44} CCUs may be targeted for such reform in the future.

Technology Needs in Today's Coronary Care Unit

Beyond the continuous telemetry monitoring and defibrillator capabilities advocated by Julian, Brown, and others, contemporary CCUs have considerably more technologic requirements, including the ability to provide noninvasive and invasive hemodynamic monitoring, mechanical ventilation, fluoroscopic guidance for bedside procedures, continuous renal replacement therapy, methods for circulatory support (e.g., intra-aortic balloon counterpulsation, percutaneous and implantable ventricular-assist devices, extracorporeal life support), and portable echocardiography. Additionally, the development of clinical information systems for standardization of care, for monitoring outcomes metrics, and for quality assurance purposes has become widely supported. These clinical information systems often include electronic clinician order entry and real-time nursing data entry as well.

Figure 1-4. Proposed components of a multidisciplinary coronary care unit (CCU) team. Future training models may develop clinicians who have expertise in critical care and cardiovascular medicine—characteristics of an ideal CCU team leader.

Finally, there has been a growing enthusiasm for telemedicine, especially for more rural health care facilities with limited resources for critical care. This technology has also been advocated as a way to navigate the impending crisis of insufficient critical care specialists to meet the growing demands for their skills,⁵⁶ and has a potentially viable role in the operation of many U.S. CCUs.

Platforms for Coronary Care Unit–Based Critical Care Research

The evolution of the CCU also provides a fertile environment from which to conduct novel research. Existing platforms for CCU-based critical care investigation have included the ongoing development and implementation of mechanical circulatory support devices, the creation of models for the study of sepsis-associated myocardial dysfunction, and the execution of clinical analyses to study the impact of bleeding and transfusion on patient outcomes. The potential for future platforms in basic, translational, genomic, and clinical study is seemingly limitless, and the generation of knowledge culminating from such research will inevitably lead to improvements in patient care—the result of more efficient CCU operational models, standardization of cardiac critical care delivery, creation of physician decision-support tools, and advanced personnel training. Key components for developing a successful, translatable, and reproducible platform of CCU-based critical care research include the creation of uniform computerized databases for efficient data abstraction, the organization of dedicated cardiac critical care research teams, and the establishment of focused multicenter and international research networks with the necessary tools for implementing novel research constructs.

Table 1-1. Potential Platforms for Coronary Care Unit (CCU)–based Critical Care Research

Systems-of-care studies and analyses of organizational models in the CCU
Novel biologic markers for noncoronary cardiovascular critical illness
Device development (e.g., minimally invasive hemodynamic monitoring)
Risk stratification, creation of expanded physiologic scores, and appropriate triage practices
Economic analyses of CCU-based critical care delivery
Practice patterns for pharmacotherapy in the CCU and drug development for cardiovascular critical illness
Genomic studies of critical illness susceptibility in CCU patients
Optimal mechanical ventilation strategies for cardiac patients, and effective weaning protocols
Role of telemedicine, medical informatics, and other electronic innovations in the CCU
Development and implementation of novel training models to improve cardiac critical care delivery
Effectiveness of multidisciplinary clinical integration in the CCU
End-of-life issues in CCU populations
Application of current critical care quality metrics for CCU quality-of-care initiatives

Additionally, contributions from academic organizations, government agencies, philanthropic groups, and industry to provide funding and other resources for project support and investigator career development in the field of cardiovascular critical care will be crucial. Table 1-1 lists potential research areas for future study.

Conclusion

Although the future role of the CCU is uncertain, the potential viability of these units is quite remarkable. Much as the CCU seems to have revolutionized the care of patients with acute MI, the CCU now has the potential to improve the care of a wide range of cardiovascular patients for decades to come. As the premier setting for the recruitment of patients who populated some of the landmark clinical trials in acute coronary syndromes, the CCU also represents a fertile environment for untapped research opportunities in cardiac critical care. The evolution of the CCU has been a remarkable journey of discovery, and it will be no less intriguing to see what the future holds for these truly specialized units.

Ethical Issues of Care in the Cardiac Intensive Care Unit

Timothy Gilligan, Martin L. Smith, Thomas A. Raffin

CHAPTER

2

Western Biomedical Ethics
Practical Guidelines for Ethical Decision Making
Withholding and Withdrawing of Life Support

Cross-Cultural Conflict
Conclusion

Every human being of adult years and sound mind has a right to determine what shall be done with his own body.

U.S. Supreme Court Justice Benjamin Cardozo¹

CARE IN THE intensive care unit (ICU) represents one of the costliest and most aggressive forms of Western medicine. ICU patients are the sickest and the most unstable, and they often are in no position to participate in medical decision making. In addition, the patient's family and loved ones are often left reeling by the sudden onset and seriousness of the illness. These factors bring to the ICU a host of difficult and troubling ethical issues. Responding wisely in an informed and compassionate manner is an essential part of good critical care medicine.

The primary defining characteristics of cardiac intensive care unit (CICU) patients are cardiovascular instability and life-threatening disease that require intensive monitoring, advanced life-support techniques, or both. These patients often have poor prognoses; a substantial number either do not survive to leave the CICU or do leave the unit but die on the wards without leaving the hospital. Physicians and other health care providers working in critical care must be comfortable working in the presence of death and dying, and must be prepared for the attendant ethical problems that often develop. These issues include, but are not limited to, writing do-not-resuscitate (DNR) orders, negotiating with family members who do not want a patient to be told about a diagnosis of a terminal illness, trying to determine what level of care an irreversibly ill patient without decision-making capacity would choose if able, and withholding or withdrawing life support. As the ability to preserve the physiologic functioning of critically ill patients has improved, physicians, patients, and their loved ones are increasingly faced with the questions of when and how to terminate life-sustaining treatment.

When addressing these issues, physicians are best served by remembering that their primary responsibility is to act in the patient's best interest by maintaining open and honest communication with the patient, the patient's loved ones, and the members of the medical team. Acting in the patient's best interest means providing the best possible medical care for patients who can be saved and facilitating a peaceful and dignified death for patients who cannot.

Economic and resource issues threaten to complicate further the work of ICU physicians. In the United States, CICU beds cost \$2000 to \$10,000 per day. In the current climate of increasing pressures to limit health care costs, the pattern of

high charges accrued by patients with poor prognoses in ICUs has drawn increased scrutiny, and strategies to avoid prolonged futile ICU treatment have been studied.² The practice of providing tens of thousands of dollars' worth of advanced care to ICU patients who have essentially no chance of recovery is ethically problematic because health care resources are limited in terms of dollars, ICU beds, and personnel. With many CICUs routinely filled to capacity, allowing patients with no real chance of improvement to occupy unit beds may prevent other patients with a high probability of benefiting from intensive care from being able to gain access to the CICU. Although we remain generally opposed to physicians withholding potentially beneficial therapies solely for economic reasons, in the current political and economic climate, critical care physicians should become conversant with ICU economics and develop sound stewardship practices with regard to CICU resources.

This chapter provides an overview of the ethical challenges that arise in critical care medicine. After a review of basic principles, guidelines, and methods of biomedical ethics, and a discussion of the ethical problems related to health care economics in the ICU, this chapter focuses on ethical issues related to the withholding and withdrawal of life support. Brief discussions of euthanasia and cross-cultural conflict are also included.

ICU medicine regularly brings us face to face with tragedy. ICU patients and their loved ones are often confronting the worst disasters of their lives. When conflict over medical care develops in this setting, it can be wrenching for all parties involved, including physicians. It is our hope that a firm grasp of the issues addressed in this chapter allows the critical care physician to approach ethical dilemmas in the ICU with confidence and understanding.

Western Biomedical Ethics

As defined by the *Oxford English Dictionary*, ethics represents "the science of morals; the department of study concerned with the principles of human duty," and "the rules of conduct recognized in certain associations or departments of human life."³ Medical ethics addresses two distinct but overlapping areas: the generic issue of what it means to practice medicine in a manner consistent with basic moral values, and the more specific challenge of identifying principles and guidelines for proper physician conduct that can be widely agreed on by the medical profession. Although confidentiality in medicine, as in law, is a strict ethical rule, it derives less from abstract moral values and more from

its necessity for the effective practice of medicine; a psychiatrist who reports a bank robber's after-the-fact confession is violating the profession's ethics, but may not be acting immorally. For the purposes of this chapter, the term *medical ethics* represents guidelines for proper and principled conduct by physicians.

Although Western biomedical ethics dates back to the ancient Greeks,⁴ it developed into a discipline of its own in the 1970s, largely as a result of new dilemmas posed by powerful new medical therapies. As medicine developed and strengthened its ability to maintain physiologic functioning in the face of ever greater insult and injury to the body, patients, and more often their loved ones and physicians, found themselves struggling with the often painful question of when to allow the patient to die. The 1976 New Jersey Supreme Court decision in the case of Karen Ann Quinlan established that advanced life support could be withdrawn from patients who have essentially no chance to regain any reasonable quality of life.⁵ Since that time, a flurry of other legal decisions, state and federal laws, and reports and consensus statements from various medical societies and regulatory commissions have helped define in what manner, under what circumstances, and by whose authority advanced or basic life support can be withdrawn.⁶⁻¹⁶

Various methods for "thinking ethically" have been identified and used during the decades-long evolution of the field of bioethics.¹⁷ We have selected three methods that have been the most influential in bioethical analysis to date, and that are the most helpful for addressing clinical situations in the ICU: (1) principlism, (2) consequentialism, and (3) casuistry. Physicians should not feel compelled to choose one of these methods over the others as their primary way for ethical analysis and reflection, but rather using some combination of the three methods in most cases can be the most helpful.

Principlism

Principlism has a concordance with the Western philosophical theory of deontology. Deontologic arguments hold that actions must be evaluated on the basis of the inherent qualities of the action itself and the motivations or intentions underlying the action. When applied to the clinical setting, deontology asserts that physicians and other health care professionals have specific obligations, moral duties (*deon* in Greek means "duty"), and rules that in most circumstances should be followed and fulfilled.¹⁸ Beauchamp and Childress¹⁹ identified four fundamental principles and duties from which, in their opinion, all other bioethical principles and duties can be derived: autonomy, beneficence, nonmaleficence, and justice. An understanding of these principles allows the physician to approach ethical dilemmas in an organized and thoughtful manner. With medicine in its current inexact state, however, no physician is able to practice without sometimes violating one or more of these fundamental principles. Many ethical dilemmas present a clash between these principles, and in such situations, physicians must choose which principle to uphold and which to relinquish.

Autonomy

Autonomy refers to the patient's fundamental common law right to control his or her own body. As the U.S. Supreme Court ruled in 1891, in a case unrelated to medicine: "No right is held more sacred or is more carefully guarded by the common law than the right of every individual to the possession and control of his own person, free from all restraints

or interference by others, unless by clear and unquestionable authority of law."²⁰ In medical terms, autonomy means the right of self-determination—the right to choose for oneself among the various therapies that are offered. Autonomy also implies a respect for the patient as an adult individual capable of making his or her own decisions. The principle of autonomy is in contrast to paternalism, in which it is presumed that the physician knows best and decides for the patient or leads the patient to the right decision.

Respect for autonomy means that adult patients with decision-making capacity have the right to refuse medical treatment, even if the treatment is life-sustaining. It follows that, except in emergency situations, patients must consent to any treatments they receive, and they must understand the risks and benefits of any proposed therapies or procedures for this consent to be meaningful. Autonomy also demands that physicians inform patients of reasonable alternatives to the proposed therapies without framing the discussion to bias patient's decisions; physicians can and should make recommendations, but these should be distinct from the presentation of objective information about treatment options.²¹

The acuity of the typical ICU patient's illness must not be used as an excuse for failing to obtain formal consent for care in general or for procedures in particular. Physicians have the responsibility to ensure that the medical care provided is in accord with the patient's wishes. Many ICU patients have the decision-making capacity to decide for themselves what level and types of care they wish to accept. For patients lacking decision-making capacity, a close family member or other surrogate decision maker should be identified to help plan an appropriate level of care consistent with the best available knowledge of what the patient would have wanted. Patients do not have the right to demand specific treatments; only the physician has the authority to determine what therapies are medically indicated for a patient.

Minors do not have the same rights as adults and are not granted autonomy by the law to make their own health care decisions. Instead, these decisions generally fall to the minor's parents. U.S. courts have consistently been willing, however, to overrule parents in cases in which there is evidence that the parents' decisions are not consistent with the best interest of the child. Although adult Jehovah's Witnesses can refuse medically indicated blood transfusions for themselves, they cannot make the same refusal on behalf of their children.

Beneficence

The principle of beneficence represents the physician's responsibility and ethical duty to benefit the patient. The physician's duty is to reduce pain and suffering and, where possible, promote health and well-being. At its most basic level, beneficence is necessary to justify the practice of medicine, for if physicians do not benefit their patients, they lose their *raison d'être*. One caution related to the principle of beneficence is that physicians may have a tendency to judge "patient benefit" primarily in physiologic categories related to medical goals and outcomes. From the patient's perspective, benefit may include not only medical outcomes, but also psycho-social-spiritual outcomes, interests, and activities that help to define the patient's quality of life. A recommended intervention with the likelihood of a good medical outcome but that would not allow a patient to continue a significant interest or activity could be judged differently by the patient than by the physician because of differing perceptions of "benefit."

More philosophically, beneficence as a principle in medicine supports the sanctity of human life and asserts the significance of human experience. In this regard, physicians practice beneficence not only by curing diseases, saving lives, or alleviating pain, nausea, and other discomforts, but also by expressing empathy and kindness—by contributing to patients' feeling that they are cared for and that their suffering is recognized. In the ICU, with critically ill patients near the end of life, presence, compassion, and humanity are sometimes the greatest forms of care that a physician has to offer.

Nonmaleficence

Nonmaleficence requires the physician to avoid harming the patient. More colloquially cited as “first, do no harm,” the principle of nonmaleficence warns the physician against overzealousness in the fight against disease. Opportunities to do harm in medicine are innumerable. Almost every medication and procedure that physicians employ can cause adverse effects, and simply being in the hospital and in the ICU puts patients at risk for infection by a more dangerous group of microorganisms than they would likely encounter at home. Unnecessary tests may unearth harmless abnormalities, and the work-up of these may result in significant complications. An unnecessary central venous line may result in a pneumothorax. Unnecessary antibiotics may result in anaphylactic shock, Stevens-Johnson syndrome, acute tubular necrosis, pseudomembranous colitis and toxic megacolon, or subsequent infection by resistant organisms. Physicians tend to feel much more comfortable with taking action than with withholding action; in the face of clinical uncertainty, many physicians are inclined to order another test or try another medication. It is essential that physicians constantly and consistently assess the potential benefits and the potential harms (including financial costs) that may result from each test and treatment they prescribe for each patient.

There are also other harms specific to the ICU. When a patient languishes on life support without a reasonable chance of recovery, the physician violates the principle of nonmaleficence. For a patient, the ICU can be an uncomfortable and undignified setting, filled with unfamiliar and jarring sights and sounds. Being sustained on mechanical ventilation ranges from unpleasant to miserable unless the patient is unconscious or heavily sedated. The only justification for putting patients through such experiences is an expectation that they may return to some reasonable quality of life as determined by the patient's values. When physicians' care serves only to extend the process of dying and prolong suffering, they violate nonmaleficence. In ancient Greece, the *Hippocratic Corpus* described as one of the primary roles of medicine refraining from treating hopelessly ill individuals, lest physicians be thought of as charlatans.²²

Just as physicians may harm their patients by providing excessively aggressive treatments, so physicians may harm patients by withholding care from them. Working with critically ill patients demands tremendous physical and emotional stamina. When a patient remains in the ICU for a prolonged time or their disease is particularly troubling, the physician may be inclined to spend less time with the sick person or to focus on the flow sheet rather than on the patient. Illness is often a lonely and frightening experience, however, and abandonment by the physician adds to the patient's suffering.

Justice

Justice in medical ethics means a fair allocation of health care resources, especially when the resources are limited. In the United States, on the macro-allocation level, we have failed to achieve a just medical system by any standard. The quality and accessibility of medical care available to U.S. citizens remains largely a function of an individual's socioeconomic status. In 2007, approximately 47 million Americans did not have health insurance. Americans in disadvantaged economic, ethnic, or racial groups experience greater morbidity and mortality from illness and die at a younger age in most disease-specific categories than do other Americans. Unequal access to care is sometimes specifically legislated by Congress; impoverished women covered by Medicaid are denied the same access to abortion as middle-class women with private health insurance. Low Medicaid reimbursement rates limit access to physicians. The principle of justice demands that health care resources be allocated not according to the ability to pay, but rather according to need and to the individual's potential for benefiting from care.

On a micro-allocation level, the principle of justice plays a role in the ICU in terms of triage. With a limited number of beds, the physician in charge of the unit must decide which patients have the greatest need for and the greatest potential to benefit from intensive care. Because intensive care represents a very expensive form of medical intervention, consuming greater than 13% of U.S. hospital costs and 4% of total U.S. health care expenditures,²³ there is a strong national interest in curtailing wasteful ICU use. The concepts of futility and rationing help in analyzing the challenge of triage, but as Jecker and Schneiderman^{24,25} have observed, the two terms have different points of reference. Determinations of futility are related to whether identified goals of treatment are achievable.²⁶ Futility can have two distinct meanings, referring to treatment that has essentially no chance of achieving its immediate physiologic purpose or effect, or, alternatively, that has essentially no chance of meaningfully benefiting the patient. Treating a bacterial pneumonia in a brain-dead patient would be considered not futile with the former definition and certainly futile with the latter. The threshold for futility is a contentious subject, and some authors have argued that the impossibility of arriving at widely accepted objective, quantitative standards renders use of the term inappropriate.^{27,28}

Futility differs conceptually from rationing in that futility applies to an individual patient's chances of benefiting from treatment, whereas rationing refers to the distribution of limited resources within a population. Rationing is fair only when it is applied in an even-handed way for patients with similar needs, without regard to race, ethnicity, educational level, or socioeconomic status. Futility affects triage decisions because futile treatment violates the principles of beneficence and nonmaleficence. Such wasteful use of medical care also violates the principle of justice when resources are limited. Rationing comes into play when there are more patients who need ICU care than there are beds, mechanical ventilators, or other critical care resources available. As health care costs continue to increase, physicians may find increasing pressures in the ICU to limit care for patients with poor prognoses. The ethical test in such circumstances is whether rationing is necessary, and whether it is applied in a fair manner (i.e., similar cases are treated similarly). To maintain a clear understanding of what physicians are doing, it is essential that assertions of futility do not become either a

mask behind which rationing or hospital cost-saving decisions can hide or a means of bullying a patient or family into accepting decisions limiting treatment.^{29,30}

The four principles of biomedical ethics can help untangle and clarify many complex and troubling dilemmas. In different cases, each of the individual principles may seem more or less important, but they are all usually in some way pertinent. These principles can come into conflict with each other, which can signify the presence of an ethical dilemma. Practically, the principles can help to pose a series of significant, patient-centered questions for physicians: “Am I respecting my patient’s autonomy?” “Has the patient consented to the various treatments?” “Do I know my patient’s resuscitation status?” “Is my therapeutic plan likely to benefit my patient, and am I doing all I can to improve my patient’s well-being?” “Am I minimizing patient harm?” “Have I identified goals of treatment or care with my patient (or the surrogate), and are those goals achievable?” “Is there an appropriate balance between potential benefit and risk of harm?” “Is my plan of care consistent with principles of social justice?”

Consequentialism

The second method for “thinking ethically” about clinical and ICU situations is consequentialism, which has its root meaning in the Western philosophical theory of teleology (*telos* in Greek means “ends”). Consequentialist reasoning judges actions as right or wrong based on their consequences or ends. This method of reasoning and analysis requires an anticipatory, projected calculation of the likely positive and negative results of different identified options before decisions and actions are carried out.

A physician may be requested by a family members not to disclose a poor prognosis to their hospitalized loved one because, in their view, the disclosure would upset the patient. Because the patient should be at the center of a “calculation of consequences” for this scenario, the first question should be: How will the disclosure or nondisclosure impact the patient positively by way of benefit or negatively by way of harms? The patient is not the only one who would experience consequences as a result of this particular decision, however. Other stakeholders who can be affected positively and negatively include the following:

- The patient’s family: Will they be angry and feel betrayed if the poor prognosis is disclosed, or will they ultimately feel relieved?
- The bedside nurses and other involved health care professionals: Will they feel distress if they are expected to participate in a “conspiracy of silence,” or if the patient asks them a direct question about his or her prognosis?
- The hospital: Will disclosure or nondisclosure be in accord with organizational values such as respect for patients and compassion?
- The wider community and society: How will other and future patients be affected if they come to know that physicians at this particular hospital disclose or do not disclose poor prognoses to patients?

When applying consequentialism, the projected and accumulated benefits and harms for all the involved and interested parties and related to the reasonable options should be weighed against each other with the goal of maximizing benefit and minimizing harm.

One challenge of calculating consequences for the options in a given medical situation is how to be sufficiently thorough in anticipating what the projected outcomes and results might be. For many situations, experienced physicians and other clinicians, using their knowledge of previous cases and building on their collective wisdom, can reasonably project medical, legal, and psycho-social-spiritual consequences for the different options. A more problematic challenge when using consequentialism is determining how much weight to assign each of the various beneficial and burdensome consequences. Should a potential legal risk to the physician and hospital that could result from a specific bedside decision be given more weight than doing what is clearly in a patient’s best medical interests? In the end, after identifying and weighing projected burdens and benefits of reasonable options, physicians using consequentialism would be ethically required to choose and act on the option that is likely to produce the most benefit, and to avoid the option likely to bring the most harm.

Casuistry

The third method of analysis that can lead to ethically supportable actions is termed *casuistry*,³¹ a word that shares its roots with the word *cases*. Although the term may be unfamiliar to many physicians, the method itself is likely to be familiar to them. Casuistry is based on practical judgments about the similarities and differences between and among cases. Medicine and law use this method when they look to previous and precedent cases to provide insight about a new case at hand. When a patient presents to a physician with a specific set of symptoms and complaints, and after the physician analyzes the results of various diagnostic tests, a skilled and knowledgeable physician is usually able to arrive at a specific diagnosis. The diagnosis is based on attention to the details of the patient’s symptoms and the test results, but also on the physician’s training and experience of having personally seen or having read in the published literature about similar or identical cases.

Casuistry in ethical analysis uses a parallel kind of reasoning. According to casuistry, attention must be given first to the particular details, features, and characteristics of the ethical dilemma at hand. Next, the goal is to identify known previous cases that are analogous and similar to the new case, and that had reasonably good and ethically supportable outcomes. If such a previous or paradigm case can be identified for which a consensus exists about right action, this previous case may provide ethical guidance for the new case at hand. A 25-year-old ICU patient with Down syndrome and an estimated cognitive ability of a 2- to 4-year-old is in need of blood transfusions. Her family members are Jehovah’s Witnesses and adamantly object to the transfusions, based on their religious beliefs. Using casuistry and appealing to similar cases, the intensivist notes that there is an ethical and legal consensus related to pediatric patients of Jehovah’s Witness parents to override parental objections to blood transfusions and to act in the patient’s best interests. Because the 25-year-old patient’s cognitive ability is similar to pediatric patients who do not have the cognitive ability to commit themselves knowingly and voluntarily to a set of religious tenets, the ethically supportable option in the pediatric cases (i.e., overriding parental objections to blood transfusions) could be extended to the case at hand.

An additional feature of casuistry is that as cases are compared, and similarities and differences are identified, moral

maxims or ethical rules of thumb can emerge that can also be helpful for current and future cases and dilemmas. Such moral maxims include the following: (1) adult, informed patients with decision-making capacity can refuse recommended treatment; (2) a lesser harm to a patient can be tolerated to prevent a greater harm; and (3) physicians are not obligated to offer or provide treatments that they judge to be medically inappropriate. One challenge of casuistry is to pay sufficient attention to the relevant facts of the new case to be able to identify previous cases that are similar enough to provide guidance for the case at hand.

An effective use of casuistry by physicians and health care teams can lead to the building-up of a collective wisdom and practical experience from which to draw when new ethical dilemmas arise. Parallel again to a physician building up medical experience and wisdom over time, a physician can establish an ethical storehouse of knowledge and insight based on previous cases and dilemmas that he or she has experienced, heard about, or read about.

Practical Guidelines for Ethical Decision Making

In addition to the three methods discussed previously, the following four practical guidelines can facilitate the process of ethical decision making:

1. Recognize patients as partners in their own health care decisions.
2. Establish who has authority for decision making.
3. Establish effective communication with patients and their loved ones through routinely scheduled family meetings.
4. Determine patient values and preferences in an ongoing manner.

Patient Partnership

All decision making—and all health care—must occur with the recognition that patients are partners in their own health care decisions. The American Hospital Association has supported this partnership model for decision making by addressing patient expectations, rights, and responsibilities.³² Among these expectations and rights, the most salient are the right of patients to participate in medical decision making with their physicians, and the right to make informed decisions, including to consent to and to refuse treatment. To exercise these rights, patients need accurate and comprehensible information about diagnoses, treatments, and prognosis. More specifically, patients need a description of the treatment, the reasons for recommending it, the known adverse effects of the treatment and their likelihood of occurring, the possible outcomes of the treatment, alternative treatments and their attendant risks and likely outcomes, the risks and benefits involved in refusing the proposed treatment, and the name and position of the person or persons who would carry out or implement the treatment. In cases in which someone other than the patient has legal responsibility for making health care decisions on behalf of the patient, all patients' expectations and rights apply to this designee and the patient. According to the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, "Ethically valid consent is a process of shared decision-making based upon mutual respect and participation, not a ritual to be

equated with reciting the contents of a form that details the risks of particular treatments."³³

Authority for Medical Decision Making

Establishing the source of authority for making health care decisions for a patient is a common problem in critical care medicine. Although nonsuicidal adult patients with decision-making capacity retain this authority for themselves, many ICU patients are unable to participate in decision making. Whatever the patient's condition, however, he or she remains the only true source of ultimate authority, and the physician must assemble and review the best available evidence of what the patient would want done. If the patient lacking decision-making capacity has prepared a living will or a durable power of attorney for health care, these documents should be obtained and reviewed. Close family members and loved ones also should be consulted; they may have spoken with the patient about what level of care the patient would want in the event of critical illness. In most, but not all, cases, these individuals know the patient best and have the patient's best interest at heart.

Having reviewed the available evidence, the treating physicians should provide care that is consistent with their best understanding of what the patient would have wanted. The physician plays the role of guide and consultant, evaluating a patient's medical problems, presenting and explaining options for diagnosis and management, and facilitating thoughtful decision making. Except in emergencies or when further treatment is clearly futile, physicians should not proceed with management plans until individuals with true authority to consent to or refuse treatment have approved the plans.

Communication

Explaining medical problems and treatment options to patients and their loved ones, determining patient quality-of-life values and desires, and achieving consensus for a management plan all require effective communication skills. Although well-developed communication skills are always an asset in medicine, communication can be particularly difficult and important in the ICU setting. Patients and their loved ones are often anxious or intimidated by the severity of the patient's condition and by the many unfamiliar sights and sounds in the ICU. With many basic life functions taken over by the nursing and medical staff and their various machines and devices, and with visiting hours often limited, patients and their loved ones may feel powerless and experience anxiety or anger from the loss of control. Honest, effective, and recurrent communication can help alleviate these feelings and decrease the alienation that attends ICU admissions.

Effective communication requires the ability to listen attentively,³⁴ and to express empathy, understanding, and compassion. The physician must be able to employ tact without compromising honesty and to acknowledge and respond to strong emotional expressions without withdrawing or becoming defensive or antagonistic. The physician often must read between the lines and recognize subtle cues about what matters most to patients and their loved ones. Effective communication prevents and defuses conflict; helps patients and families work through their anxieties, fears, and anger; and is the most important skill in negotiating the difficult ethical dilemmas that arise in the ICU.

Establishing effective communication requires time and planning. Physicians must remind themselves that although ICU care may become routine for them, it is rarely that way for the patients or their loved ones. Discussions with a patient's family members or loved ones should occur either at the bedside, if the patient is able to participate, or in a private conference or waiting room; the hospital corridor is *not* an appropriate location. Because the patient and his or her loved ones are likely to feel overwhelmed by the patient's illness and by the ICU environment, communication should be simple and to the point, with more technical details provided as requested. Encouraging the various parties to ask questions and express their feelings helps to counteract any intimidation they may feel and communicates to them that the physician cares about their concerns.

Finally, for communication to be effective, information should be conveyed in language and at a level of detail that the listener understands clearly. Medical jargon, an overly sophisticated vocabulary, excessive detail, or an inappropriate emotional tone can defeat what is otherwise a sincere effort at communicating. Physicians should always ask patients or their loved ones to summarize what they have heard; this is an easy way to evaluate their comprehension and to correct any misunderstandings.

Several types of inadequate communication occur regularly in ICUs. The most common problems result either from focusing on trends rather than on the patient's overall condition or from drawing attention to favorable signs when the overall prognosis remains dismal. If a patient is unlikely to survive to ICU discharge but is not deteriorating, describing the patient to family members as stable is likely to mislead them. A more truthful report might be: "Your wife is as sick as any person could be, and the odds are overwhelming that she will not survive." A similar problem arises in telling a couple that their son with multiple organ failure has improved when in fact there has been only a slight reduction in his oxygen requirement and his overall prognosis remains poor. Such inappropriate "good news" may make the physician feel better, but it can be cruelly misleading by engendering false hopes and needlessly interfering with the grieving process. It is essential to tell the truth and to provide accurate prognostic information.

A second common problem is for patients and their families to receive conflicting information or advice from different physicians involved in the patient's care. Alternatively, different consulting services may each address a specific aspect of the patient's care without helping the patient and family to integrate the disparate pieces of data into a coherent overall understanding of the patient's condition, prognosis, and treatment plan. Multidisciplinary care conferences, which include the ICU physician, relevant consulting physicians, nurses, and, when appropriate, social workers and case managers, should be held periodically to ensure that there is a coherent, shared vision of the patient's overall management plan.³⁵ Formal, structured multidisciplinary conferences that include the patient and family and that are held within 72 hours of ICU admission have been shown to reduce the burdens of intensive care for dying patients and allow patients with lower mortality rates access to the ICU.²

The physician has a responsibility to ensure that effective communication has occurred. Not all physicians excel at communicating. When physicians find that effective communication is not taking place and conflict is developing, they should recruit assistance from an ethics consultant or another facilitator, such as a chaplain, social worker, or psychotherapist. Physicians

should think of facilitators as valuable resources and not view their use as an admission of failure. ICU physicians are generally busy with a demanding set of patients. An ICU physician typically has limited time to talk to patients and patients' families, yet these patients often have very high communication needs. Bringing in an ethics consultant or other facilitator to supplement the ICU team's efforts can help meet these needs without overtaxing the ICU physicians.

Working with critically ill and dying patients can be extremely stressful and emotionally draining on a case-by-case basis and as an accumulating problem over time. Physicians may feel burned-out or may seek to protect themselves by creating emotional distance from their patients. Although physicians cannot delegate all communication responsibilities, the assistance of a facilitator can reduce the stress on all parties involved. Not only can facilitators contribute additional communication skills, but they also have more time for establishing rapport and, as third parties with fresh perspectives, can bring new insight to ethical dilemmas. We believe that such facilitators are underused, perhaps because physicians fear a loss of control over their patients. We recommend requesting a facilitator early whenever it seems that ethical decision making may be difficult.

Determining Patients' Values and Preferences

The fourth practical guideline in ethical decision making is determining the patient's values and preferences regarding quality of life and medical care. As noted previously, ICU medicine can be a painful and undignified experience for the patient. Whether and for how long such an ordeal is appropriate are questions that in the end can be answered only by the patient, and depend on the prognosis, on how the patient judges quality-of-life issues, and on how sensitive the patient is to the discomforts and indignities of the illness and hospitalization. These questions become most significant for chronically or terminally ill patients who are dependent on advanced life support. Physicians must strive to learn each patient's views regarding what constitutes a meaningful and acceptable life compared with a mere prolongation of physiologic functioning. Physicians must never assume that they know what the patient would want, especially with individuals of different cultural, ethnic, or religious backgrounds. Patients have different preferences about how aggressively they wish to be treated and when they want their physicians to forego life-sustaining treatment. Patients' views often change over time, even during the course of the same hospitalization, so patients' perspectives should be reviewed on a regular basis. Whenever possible, discussions with patients about these matters should occur with family members and loved ones present so that all parties have the same understanding of the patient's desires; otherwise, if the patient later loses decision-making capacity, the family may balk at following the patient's wishes.

When patients do not have decision-making capacity, physicians must turn to surrogate decision makers, advance directives, or both. Decisions about life support and end-of-life care are among the most personal decisions to be made. For surrogate decision makers, being asked to make such decisions on a loved one's behalf frequently elicits feelings of grief, guilt, confusion, and being overwhelmed. Physicians can perform a tremendous service for their patients' families and loved ones by discussing resuscitation status, life support, and terminal care issues with patients before they lose decision-making capacity. Patients are not generally eager to hold such discussions;

however, this is no excuse for not broaching the subject, especially with patients who have life-threatening diseases.³⁶

Withholding and Withdrawing of Life Support

Withholding or withdrawing life support is one of the most difficult actions that a physician may have to perform. Having been trained to prolong life and overcome disease, a physician may feel like a failure when allowing a patient to die whose life could have been prolonged with life support. Physicians do not possess omnipotence, however. Death is the natural conclusion to life; although death is often viewed as an enemy in the hospital, it is also sometimes a colleague. For severely ill patients with irreversible conditions, the only choices available may be a prolonged and miserable dying versus a more rapid, comfortable, and dignified death. In these cases, death can represent an end to suffering, can prevent a life that has been happy from ending with prolonged misery, and can allow survivors to mourn and proceed with their lives. A painless and dignified death is sometimes the best a physician has to offer; there is no shame in such an admission.

Legal Precedents

Legal guidelines for withholding and withdrawing life support come predominantly from state court rulings; federal guidance has been minimal in this regard. State court rulings apply only within that state's boundaries, however; they have no legal standing in other states. Although the right to refuse medical treatment is protected by common law and by the U.S. Constitution, the exact limitations of this right and the conditions under which life support can be withdrawn from patients lacking decision-making capacity vary from state to state. In particular, significant variability exists among states regarding what courts accept as clear and convincing evidence that a patient without decision-making capacity would want life support withdrawn. As in all human affairs, various court rulings can be arbitrary, reflecting the background, politics, and moral beliefs of the judges who made the rulings. Physicians and hospitals must be familiar with their state's stance on the question of withholding or withdrawing life support. Although malpractice and criminal actions resulting from withholding or withdrawing life support have been extremely rare, this likely stems from the extreme reluctance, bordering on refusal, of physicians and hospitals to terminate life support contrary to the wishes of the patient's family. Instead, legal action tends to result from a medical team's refusal to withdraw treatment.

Patients with Decision-Making Capacity

The right of adult patients with decision-making capacity to refuse advanced life support and medically supplied nutrition and hydration is well established in the United States through case law and hospital policies.³⁷ The case of *Bouvia v. Superior Court*³⁸ concerned a young, quadriplegic woman with cerebral palsy who was experiencing unrelenting pain and requested that the hospital withhold her medically supplied tube feedings so that she could die. The hospital refused. In its 1986 ruling, the California State Court of Appeals found that "to insist on continuing Bouvia's life ... at the patient's sole expense and against her competent will, thus inflicting never ending physical torture

on her body until the inevitable, but artificially suspended, moment of death ... invades the patient's constitutional right of privacy, removes her freedom of choice and invades her right to self-determination."

Patients Lacking Decision-Making Capacity

The 1976 Karen Ann Quinlan case⁵ helped spur the development and dissemination of biomedical ethics. This groundbreaking case involved a 22-year-old woman who was in a persistent vegetative state. Her father, who had been appointed her legal guardian, requested that mechanical ventilation be withdrawn, asserting that she would not have wanted to be kept alive under such circumstances. Her physicians refused to comply. The case was ultimately decided by the New Jersey Supreme Court, which evaluated "the reasonable possibility of return to cognitive and sapient life as distinguished from ... biological vegetative existence."⁵ The decision indicated that advanced life support provided a clear benefit to the patient only if it would result in "at very least, a remission of symptoms enabling a return toward a normal functioning, integrated existence." The court ruled that life support could be withdrawn from patients if they had essentially no chance of regaining any reasonable quality of life.

The New Jersey Supreme Court's ruling based Quinlan's right to be removed from the ventilator on her constitutional right to privacy. In the absence of any indication from the patient herself of her preferences or values, the court found that the family and physicians were entitled to exercise substituted judgment on the patient's behalf, with the family's decision taking precedence over that of the physicians. When Quinlan's ventilator was withdrawn, she was able to breathe on her own and lived for an additional 10 years, never regaining any cognitive function.

The major challenge in cases such as *Quinlan* involving patients lacking decision-making capacity is deciding who is the appropriate decision maker. Although state courts have consistently recognized the right of patients to refuse treatment, including medically supplied nutrition and hydration, they have been much less consistent with regard to the question of how decisions should be made for patients who cannot decide for themselves.³⁹⁻⁴⁴ Some states have permitted families to make decisions to withdraw life-sustaining treatment from patients lacking decision-making capacity, whereas other states have required that there be clear and convincing evidence that the patient himself or herself would not have wanted such treatment. States allowing surrogate decisions in the absence of clear and convincing evidence about what the patient would have wanted have tended to follow a standard of either substituted judgment or best interest. The substituted judgment standard allows a surrogate to make his or her best judgment of what the patient would have decided if the patient were competent. The best interest standard applies when it remains unclear what the patient would have decided. In this eventuality, the surrogate and the medical team base the decision on the patient's best interest.

The concept of proportionate treatment can help guide best interest decision making: "Proportionate treatment is that which, in the view of the patient, has at least a reasonable chance of providing benefits to the patient, which benefits outweigh the burdens attendant to the treatment. Thus, even if a proposed course of treatment might be extremely painful or intrusive, it would still be proportionate treatment if the prognosis was for complete cure or significant improvement in the patient's

condition. On the other hand, a treatment course which is only minimally painful or intrusive may nonetheless be considered disproportionate to the potential benefits if the prognosis is virtually hopeless for any significant condition.”⁴⁴

Many states have codified the substituted judgment standard, enacting laws that give families the right to make decisions on behalf of patients lacking decision-making capacity. For patients who did not identify a surrogate decision maker before they lost decision-making capacity, most states identify a hierarchy among relatives so that it is clear who the decision maker should be. Most of these statutes apply only to patients who are terminally ill, however.⁴⁵

From a legal and ethical perspective, no distinction is made between nutrition and hydration provided through a medical device (e.g., a gastrostomy or nasogastric tube or intravenous line) and other forms of life-sustaining treatment such as mechanical ventilation. As one California court ruled, “... medical procedures to provide nutrition and hydration are more similar to other medical procedures than to typical human ways of providing nutrition and hydration. Their benefits and burdens ought to be evaluated in the same manner as any other medical procedure.”⁴⁴

A different problem arises for patients who have never had decision-making capacity because they have never been in a condition in which they could meaningfully indicate what level of health care they would want if they were critically ill. Such patients include young children and individuals with severe mental retardation. Different states have dealt with this problem differently. Some have ruled that the right to refuse medical treatment must extend to incompetent patients because human dignity has value for them just as for patients who are competent, and that legal guardians or conservators have the right to make such decisions on behalf of their ward.⁴⁶ In such cases, some courts have opined, decisions about withholding treatment from patients who have never been competent should be based on an attempt to “ascertain the incompetent person's actual interests and preferences.”³⁹ In other words, the decision should be that which the patient would make if the patient were competent but able to take into account his or her actual incompetency. Other courts have ruled that it is unrealistic to try to determine what a patient who had never been competent would have wanted, and that, for legal purposes, such patients should be treated as children.⁴⁷ Some courts have specifically rejected the substituted judgment standard, finding that a third party should not have the power to make quality-of-life judgments on another's behalf.

Many legal issues regarding the termination of life-sustaining treatment remain unresolved. The courts have given essentially no guidance in the area of whether physicians have the authority to terminate life support for patients lacking decision-making capacity against the wishes of the patient's family. Generally, the courts have respected the physician's right to refuse to provide treatments that the physician considers to be medically inappropriate, but the applicability of this right to life support has yet to be established. In most cases involving attempts by hospitals or physicians to use a futility argument to justify foregoing life-sustaining treatment requested or demanded by patients or their family, the courts have ruled in favor of continuing treatment.⁴⁸

Advance Directives

Since the *Quinlan* decision,⁵ state legislatures and the federal government have passed laws designed to increase the authority of individuals to control the level of treatment they will receive

when they are incapable of participating in decision making. These laws set standards for several types of documents, but primarily living wills and medical powers of attorney. Collectively, these documents are known as written advance directives. These documents usually have legal standing only within the state where they are completed, and only if they conform to the state's statutory language, although some states grant some degree of validity to other states' advance directives. These documents can assist loved ones and health care professionals in determining what an individual would have wanted, especially if the patient has an irreversible condition such as a terminal illness or a persistent vegetative state. Health care providers can play a key role in encouraging patients to engage in advance care planning that culminates in completion of written advance directives.

Living Wills and Medical Powers of Attorney

Living wills indicate what level of life support and other medical care a patient would want under specified circumstances. The specific forms of treatment covered by living wills vary among states and are sometimes restricted to life-sustaining treatments. Some state laws specifically exclude medically supplied nutrition and hydration from the treatments that can be withheld or withdrawn. With the exception of Missouri, however, state courts have ruled that these exclusions refer only to nonmedical feedings.⁴⁹ The requirement that living wills provide for a wide range of unforeseeable eventualities forces the documents to be general in nature and limits their usefulness.⁶ In a study of 102 elderly individuals in Florida, Walker and colleagues⁵⁰ found that there was a wide range of resuscitation status preferences among patients who had completed living wills, and that the language of the living wills was too vague in most cases to determine their preferences.

Medical powers of attorney provide more flexibility than living wills because they name a surrogate decision maker who is authorized to make health care decisions on the patient's behalf if the patient loses decision-making capacity. The advantage of a medical power of attorney lies in the authority it grants the designated agent to make decisions on the basis of the specific details of the patient's circumstances and condition. Studies have found that spouses and other close family members are often inaccurate at predicting what their loved one would want.⁵¹ In addition, living wills and medical powers of attorney are limited by the well-documented fact that an individual's desire to receive aggressive medical care can change over time.⁵²⁻⁵⁴ What level of care a healthy individual imagines wanting during a hypothetical illness may be very different from what that individual wants when ill.⁵² On the one hand, as patients become increasingly ill, they may be willing to settle for a decreasing quality of life. On the other hand, when facing a long illness, patients may grow weary of hospitalization and invasive or otherwise unpleasant medical procedures or treatments and decline treatment that they previously thought they would have wanted.

Patient Self-Determination Act

The U.S. federal government encouraged the use of advance directives when it enacted the 1990 Patient Self-Determination Act (PSDA).⁵⁵ The law requires hospitals, nursing homes, and other health care institutions to (1) provide to patients written information regarding advance directives and the patient's right to accept or refuse treatment; (2) document in the patient's medical record whether an advance directive has been completed;

and (3) provide education about advance directives for patients, their families, and the facility's staff. Health care institutions failing to follow the PSDA may have their federal Medicare and Medicaid reimbursements withheld. Despite this legislation, studies in the 1990s reported that only a few hospitalized patients had their advance directives acknowledged, and that physicians were usually unaware when their patients with life-threatening illness preferred not to be resuscitated.^{56,57} A study of hospitalized patients with life-threatening diagnoses found that less than 50% of physicians knew when their patients did not want to receive cardiopulmonary resuscitation (CPR).⁵⁷ The proportion of elderly Americans who have completed advance directives is reported to have increased, however.⁵⁸

Deciding to Withhold or Withdraw Life Support

Physicians withhold or withdraw life support in two general circumstances: (1) when the patient or the patient's surrogate refuses further treatment, or (2) when the physician of record determines that further treatment is medically futile or inappropriate. In most cases in which life support is foregone, both criteria are met.⁵⁹ Ideally, such a momentous decision by physicians would be based on individual patient preferences and objective medical information. However, studies of ICU health care professionals found that personal characteristics of physicians are significantly associated with their decision making about withholding or withdrawing life support.⁶⁰⁻⁶³ These characteristics include age, religion, number of years since graduation, amount of time spent in clinical practice, level and type of specialization, type of hospital, and number of ICU beds where the physician works. In the study by Cook and colleagues,⁶¹ in which ICU health care professionals chose an appropriate level of care for 12 patient scenarios, there was extreme variability among individuals' decisions: only 1 of the 12 scenarios did more than half of the respondents make the same choice, and opposite extremes of care were chosen by more than 10% of the respondents in 8 of the 12 cases. Physicians have also been found to be much more willing to offer life support to patients with life-threatening cardiovascular or pulmonary disease than to patients with cancer, even when the prognosis is the same.⁶² That physicians' personal characteristics influence their decision making should not be surprising; rather, it should caution against intransigence and remind physicians of their own potential biases and of the likelihood that other equally competent professionals may disagree with their decisions. These findings re-emphasize the importance of ascertaining the patient's values and preferences; if life-support decisions can be significantly influenced by physicians' personal characteristics, leading to physicians disagreeing on appropriate levels of treatment, decision making should be based on the values and desires of the individual patient.

One challenge in end-of-life decisions is the uncertainty associated with predicting patient outcomes. The common use of the word *futility* implies that there exist accurate tools for identifying which patients are likely to improve or recover. Despite the existence of multiple prognostic and severity scoring systems useful in predicting aggregated group outcomes, foreseeing the outcome of individual patients remains an inexact science.⁶⁴ In most ICU cases, the concept of futility remains ephemeral and ill-defined, and physicians must depend on their clinical judgment to determine when further treatment has virtually no chance to return the patient to a reasonable quality of life

according to the patient's values. That such determinations are not completely accurate does not obviate their necessity, but does make caution and humility appropriate.

There is a broad consensus among medical societies, critical care physicians, and ethicists that withdrawing and withholding life support do not differ ethically from one another.^{6,9,11,65-67} Nonetheless, physician surveys have repeatedly found that many physicians feel differently about the two actions.⁶⁸⁻⁷⁰ Withdrawing a life-sustaining intervention, especially if the patient dies soon afterward, may feel more like causing death than withholding that same intervention. Because the two actions of withholding and withdrawing share the same justification, motivation, and end result, however, there is no moral basis for differentiating them. Physicians are in a stronger position to assert that they have "tried everything" to save the patient when withdrawing interventions than when declining to initiate a lifesaving intervention in the first place.

Finally, any decision to withhold or withdraw life support should be part of a coherent, comprehensive management plan. Decisions to continue or terminate specific treatments or tests should be related to clearly identified, patient-oriented goals. The decision to withdraw advanced life support represents a decision to allow a patient to die; continuing antibiotic therapy or ordering diagnostic tests makes no sense in such a context, unless they can be shown to contribute to patient comfort or an identified patient goal. In the same manner, failing to treat the infection of a patient who is being maintained on mechanical ventilation bespeaks confusion concerning the goals of treatment. In most cases, ICU physicians, patients, and family members should choose between providing palliative care and, alternatively, using all available means acceptable to the patient to prolong the patient's survival.

Withholding and Withdrawing Basic Life Support

Denying basic life support (e.g., medically supplied nutrition and hydration, oxygen) is a difficult step in medicine. Although more advanced life support may be viewed as "heroic" or "extraordinary," and other medical therapies such as antibiotics are aimed at treating infection, basic life support is simply that which everyone depends on to live; it may not seem to be part of medicine so much as part of normal human existence. Allowing a patient to die of malnutrition or dehydration may even seem like murder to some physicians. As noted previously, however, state courts have generally concluded that medically supplied nutrition and hydration are akin to other medical treatments. Ethicists⁷¹⁻⁷³ and medical societies have likewise generally denied an ethical distinction between terminating advanced and basic life support, although there has been some disagreement with this position.⁷⁴ Nonetheless, denying a patient without decision-making capacity medically supplied nutrition and hydration remains ethically and legally controversial.⁷⁵ Physicians should be familiar with their own state's laws and legal precedents; hospital attorneys can be of assistance in this regard. As always, the problem lies in identifying the patient's preferences when the patient cannot decide for himself.

Whatever a physician's personal views, thoughtful decision making about basic life support is essential in the ICU. Clinicians should consider four major points. First, any medical intervention should serve what the patient considers to be in his or her best interest as determined by open and forthright communication with the patient and the patient's family and loved

ones. Second, close family members and loved ones should be included in the decision-making process. This involvement not only serves to protect the best interests of the patient, but also helps prevent conflict regarding the course of treatment chosen. Third, physicians should anticipate the range of different medical courses that the patient is likely to follow and determine what the patient would want done for each predicted development. This anticipation makes possible a coherent medical plan that facilitates goal-centered decision making and that does not have to be reconceptualized with every change in the patient's condition. Fourth, physicians often find that withdrawing a life-sustaining intervention is psychologically more troubling than withholding it. Although this feeling can never serve as justification for withholding treatment, it emphasizes the desirability of not starting interventions without a thoughtful evaluation of whether they are consonant with the patient's best interests.

Terminally ill patients who are suffering are often best served by the withholding of antibiotics or steroids when infections or cerebral edema develop; these treatments frequently pull patients back from a peaceful death to live out a few more days or weeks in pain and indignity. Similarly, the placement of intravenous lines and the monitoring of blood chemistries and even vital signs should proceed only if they are part of a clearly defined, patient-oriented goal. If the patient or the patient's family want everything done to prolong the patient's life and these wishes seem inappropriate, a direct, logical challenge often fails, whereas a nonjudgmental and compassionate exploration of underlying feelings often results in more reasonable decisions. In the rare event that a family's decisions seem clearly at odds with the patient's best interests, physicians must remember that their first responsibility is to serve the patient.

Withholding Advanced Life Support

The major difference between withholding and withdrawing advanced life support (e.g., CPR, mechanical ventilation, inotropic and vasopressor agents) concerns the context in which the decision is made. The decision to withhold these treatments generally takes the form of a DNR order. In contrast to other medical treatments, patients are presumed to have consented to CPR unless they have specifically refused it. Because CPR must be initiated immediately to be effective, physicians and patients must make resuscitation status decisions before the need for CPR. The patient or surrogate is asked to make decisions about treatments that may or may not become necessary during the patient's hospital stay. Conversely, the decision to withdraw advanced life support involves treatments that the patient is experiencing; no hypothetical reasoning is necessary. This distinction bears on the nature of the communication that must occur between the physician and the patient and family.

In discussing resuscitation status with patients, physicians have a responsibility to convey an understanding of what is involved in CPR and mechanical ventilation, the probability of survival to hospital discharge if CPR is instituted, the near certainty of death if CPR is withheld, and why the physician does or does not recommend a DNR order. Physicians should stress that, regardless of resuscitation status, all other treatments and care will continue as previously planned; limits are being set, but a DNR order does not mean that the medical team is giving up on or abandoning the patient. Although determining a patient's resuscitation status represents an essential part of providing

responsible care to critically ill patients, studies continue to show that communication about this issue remains very poor, and most physicians do not know their patients' preferences.⁵⁷ Research has shown that physicians and family members cannot accurately predict patient preferences, so there is no substitute for talking with the patient.^{76,77} Historically, physicians often postponed making resuscitation status decisions until the patient no longer had decision-making capacity, but at least in some regions, there has been a shift toward establishing resuscitation status earlier in a patient's hospitalization.^{78,79}

Several major impetuses have focused increased attention on determining patients' preferences regarding resuscitation status, including studies showing poor post-CPR survival, an increased emphasis on patient autonomy and the right to refuse treatment, and growing concern about wasteful health care expenditures. Many studies have examined post-CPR survival, showing a range of 5% to 25% of patients surviving to discharge.⁸⁰⁻⁸⁴ For the CICU, patients resuscitated from ventricular arrhythmias, including ventricular fibrillation after myocardial infarction, have fared significantly better, with 50% surviving to discharge. In a 1995 study of CPR survival in ICU and non-ICU patients, Karetzky and colleagues⁸⁵ found that resuscitation was successful for only 3% of ICU patients receiving CPR compared with 14% of non-ICU patients.

These findings emphasize the dilemma posed by CPR, especially in the ICU. CPR represents an invasive and frequently brutal intervention, and can be justified only if it has a reasonable chance of benefiting the patient, and if it is in accord with patient wishes. Judgments of reasonableness must be informed by the patient's values because this is a subjective determination: A 5% chance of survival to discharge may be acceptable to some patients, but not to others. For patients to make informed decisions, they require clear and accurate information about the probability of survival.⁸⁶ Two surveys of more than 200 elderly patients each found that respondents consistently overestimated the likelihood of survival to discharge after CPR; in one of the studies, the overestimation was by 300% or more.^{87,88} Both studies found that patients' choices to accept or refuse CPR was strongly influenced by the probability of surviving to discharge. In the second study, Murphy and colleagues⁸⁸ found that the percentage of elderly patients who said they would opt for CPR after cardiac arrest during an acute illness decreased from 41% to 22% after they were informed of the probability of survival.

Because CPR is often a brutal and invasive procedure with a low likelihood of survival, and given the evidence that most elderly patients assert that they would not want CPR under many circumstances, there can be little ethical justification for not discussing CPR with this patient population. Patients should also be asked what they would want done following a successful resuscitation if, after 72 hours of aggressively sustaining their lives, the physician determines that they have little or no chance to regain a reasonable quality of life. To avoid conflict, physicians should include the patient's loved ones in these discussions and should ensure that there is consensus among the various members of the medical team.

For patient resuscitation status decisions to be respected, they must be documented in a readily accessible and legible manner in the medical record. Health care institutions using electronic medical records have immediate access to resuscitation status documentation if DNR orders are placed in a prominent place in the electronic medical record. Physicians who believe that they

cannot participate in resuscitation status decision making probably should not provide care for critically ill patients.

Many physicians find discussions about resuscitation status with patients difficult. Time limitations, stress, and the emotional difficulty of such discussions all contribute to this problem. These conversations become particularly challenging when terminally ill patients wish to have CPR attempted despite their physician's counsel that death is imminent or that CPR would be ineffective. When such conflicts arise, thoughtful and empathic communication can lead to a mutually acceptable resolution. Humans are endowed with a strong will to live, and even chronically and terminally ill patients find it difficult to accept death. When patients refuse to consent to a DNR order, they often agree to having life support withdrawn if, after a successful resuscitation, the physician determines that the patient has virtually no chance of regaining a reasonable quality of life as defined by the patient's values.

The most contentious DNR problem centers on the question of medical futility. Can physicians write a DNR order contrary to the wishes of the patient or the patient's surrogate when the physician judges that CPR would be medically futile? This is a complex dilemma in which ethical principles and duties are in conflict (e.g., patient autonomy, nonmaleficence, professional integrity). As noted previously, the term *futility* in medicine remains vague without a widely accepted definition.²⁶ In the literature regarding DNR orders written against patient wishes, two basic points of view emerge that are separated mainly by differing views of futility. Some authors have argued that determining what range of treatments to offer a patient must remain the physician's prerogative. When a physician determines that a certain therapy should be withheld because it is futile (i.e., because it has no reasonable likelihood of benefiting the patient), the patient's preferences become irrelevant. This position asserts that physicians have the professional responsibility to judge whether a specific medical intervention has what the physician considers to be a reasonable chance of benefiting the patient.⁸⁹

Opponents of this perspective argue that determinations of what is reasonable and what constitutes a benefit are subjective judgments that reflect the decision maker's underlying values.^{28,90} In this view, the value judgment of what constitutes an acceptable likelihood of offering a meaningful benefit is best made by the patient. This second perspective argues for a physiologic definition of futility, by which a treatment is futile only if it cannot achieve its immediate physiologic objective. Waisel and Truog⁹⁰ stated: "CPR is futile only if it is impossible to do cardiac massage and ventilations. As long as circulation and gas exchange are occurring, CPR is not futile, even if no one expects improvement in the patient's condition."

Hospitals have adopted different policies with regard to futility-based DNR orders, with some requiring physiologic futility and others allowing physicians greater leeway. The states of New York and Missouri have enacted statutes that specifically require a patient's consent or the consent of the patient's surrogate (when the patient lacks decision-making capacity) before a DNR order may be written. The issue of how to respond to patients who demand futile medical treatment is drawing increased attention in the context of rapidly increasing health care costs and the difficulty many Americans have with accessing care.

In resolving individual cases of conflict over appropriate levels of treatment, health care professionals should use clinical judgment and a clear consideration of the patient's values

and expressed goals. Assertions of medical futility must not be employed as a means of avoiding difficult discussions with patients and their loved ones. Before writing a DNR order contrary to a patient's wishes, a physician must communicate this intention to the patient and family and allow them the opportunity to transfer to a physician who would honor their wishes. It also is essential for physicians to be aware of their hospital's specific policy for handling such cases.

Withdrawing Advanced Life Support

The withdrawal of advanced life support is usually followed quickly by death and represents one of the most anguishing medical decisions for patients, loved ones, nurses, and physicians. When physicians have discussed life support and critical care preferences with their patients in advance and developed an appreciation of the patient's goals and quality-of-life values, the decision about whether to withdraw life support is often much clearer and less troubling. There are no strict guidelines for deciding how or when to withdraw advanced life support, although many position papers have been published.^{7,9,59,67} Generally, life support is withdrawn when the patient has virtually no chance of regaining a reasonable quality of life, or when the burdens of continued treatment outweigh the benefits.

Withdrawal is usually considered only for patients who have terminal and irreversible conditions, but there are exceptions. Each patient must be evaluated in terms of the specific clinical context and the patient's expressed values and wishes. Patients and their families have a right to know the best and most current data regarding the patient's condition and prognosis and the efficacy of the available treatments. Studies such as APACHE (Acute Physiology, Age, and Chronic Health Evaluation) III⁹¹ can be extremely valuable, but physicians should not exaggerate medicine's ability to make predictions about individual patients.

Patients on mechanical ventilators should not be presumed to lack decision-making capacity. To be judged as having decision-making capacity, patients must be able to appreciate their circumstances and their condition, understand the respective consequences of accepting or rejecting any proposed treatments, exhibit rational decision making, and articulate a choice.⁹² Psychiatric consultation may be useful when competency is questionable. For a patient to give informed consent for the withdrawal of life support, all narcotics must have been discontinued long enough for the patient to be clear-headed, and any treatable depression must have been clinically addressed.

Although most patients on advanced life support are determined to lack decision-making capacity, many are not. Physicians must make a rigorous effort to solicit the patient's wishes concerning the continuation or withdrawal of treatment. Patients with decision-making capacity who wish to have life support withdrawn must be carefully evaluated. They have an ethical and legal right, as noted previously, to control what is done to their bodies and to refuse medical treatments, even if these treatments are necessary to maintain life. Conversely, some patients on advanced life support often experience severe reactive depressions and, if they survive their critical illness, are grateful that their requests to discontinue life support were not honored. Evaluating patient requests and refusals can be extremely difficult. When patients with curable illnesses request that life support be withdrawn, physicians should vigorously re-evaluate the patient's decision-making capacity. When such

patients have dependent minors, legal guidance may be appropriate.

When considering the withdrawal of advanced life support, physicians should always seek unanimity among the members of the health care team and actively solicit different members' opinions. Nurses spend more time with ICU patients than anyone else, and their long hours at the bedside can give them valuable information and insights, especially regarding areas such as family dynamics and the range of the patient's alertness or discomfort over the course of the day. Problems can develop when any professional feels excluded from the decision-making process.

Withdrawing life support is a stressful proposition, and decision making by patients and family members cannot be rushed. The negotiations represent delicate processes that have their own timing, processes integrally involved with coming to accept the inevitability of death and loss.⁹³ As discussed previously, facilitators can assist in these situations. When the patient lacks decision-making capacity, the physician should engage the family and the patient's surrogate to work toward consensus on all life-support decisions.

When there is conflict between the family and medical team, establishing time-limited goals based on clinical judgment and outcome studies can facilitate resolution. Families often feel overwhelmed when advised that life support should be withdrawn. They frequently experience grief, guilt, anger, and confusion, and they may resist the physician's advice. Identification of concrete temporal milestones by which progress can be evaluated often helps facilitate the development of acceptance and coping. Family members might be told, "If we see no signs of improvement over the next 72 hours, then we believe you should consider withdrawing life support. We believe your loved one is suffering and has essentially no chance to regain any reasonable quality of life. To withdraw life support would allow your loved one a more peaceful and dignified death."

Time-limited goals serve the function of providing perspective. They remind the family to step back from day-to-day management concerns and consider the overall circumstances. The interlude also allows families and loved ones an opportunity to adjust what may have been unrealistic expectations of recovery and to express pent-up emotions. Physicians must be able to tolerate expressions of anger or hostility without becoming defensive or withdrawing. The anger usually subsides when the family understands that the physician is compassionate, supportive, and understanding.

When proposing that life support be discontinued, good communication skills assume central importance. One effective approach is to say, "It is my best judgment, and that of the other physicians and nurses, that your loved one has virtually no chance to regain a reasonable quality of life. We believe that life support should be withdrawn, which means your relative will probably die." This statement contains two important components: it is qualified in a way that acknowledges uncertainty and encourages shared decision making; it also clearly states that death is the anticipated result of withdrawing treatment. Without such information, true informed consent cannot be achieved.

At times of critical illness, grief-stricken or guilty family members may press for disproportionate treatment as a way to relieve their own distress. An open and understanding exploration of the underlying feelings usually resolves such difficulties.

Sometimes an honest disagreement persists: what seems disproportionate to the physician seems reasonable to the family. Several guidelines can help in such circumstances: (1) the physician's primary responsibility is to the patient; (2) in most cases, the family has the patient's best interests at heart and knows the patient better than the medical team; (3) ethicists, chaplains, social workers, and ethics committee members can assist in facilitating an agreement on the treatment plan; and (4) care can sometimes be transferred to a physician who agrees to comply with the family's wishes.

Health care professionals should avoid direct involvement in cases that conflict with their ethical values. Clinical judgment may be compromised by the tension and resentment that can arise in such circumstances. If possible, care should be transferred to another physician in these situations. When such involvement is unavoidable, the physician's disclosure of his or her own feelings to understanding colleagues or a psychotherapist make optimal care more likely.

Patients lacking decision-making capacity who have left no indication of quality-of-life values or life-support preferences can present a special challenge. In such circumstances, physicians must be familiar with their hospital's policy, state's laws, and legal precedents concerning substituted medical judgments. If a thorough discussion of the patient with family and loved ones fails to yield sufficient information about the patient's values, the hospital ethics committee should organize a multidisciplinary group composed of physicians, nurses, patient advocates (e.g., a social worker, chaplain, or ombudsman), and the patient's family or loved ones. The group can negotiate decisions based on the patient's best interests. Legal assistance rarely becomes necessary.

When implementing a decision to withdraw life support, the emphasis should be on maximizing patient comfort and minimizing emotional trauma to the family and loved ones. Although curtailing inotropic support may not result in distress, withdrawing mechanical ventilation can present the potential for extreme discomfort, especially if the patient is abruptly extubated and experiences airway obstruction. We advocate rapidly dialing down the supplemental oxygen, pressure support, and intermittent mandatory ventilation rate while maintaining a protected airway. Air hunger and anxiety should be controlled with intravenous morphine as necessary.⁹⁴

Euthanasia and Assisted Suicide

Euthanasia and assisted suicide received increased attention in the first half of the 1990s. From Dr. Jack Kevorkian and his suicide machine to various state ballot initiatives, the issue of whether physicians should be authorized to assist patients to die has become a significant social policy issue.⁹⁵ The term *euthanasia* literally means "good death"; traditionally, it has referred to putting terminally ill and suffering patients to death in a painless manner. Euthanasia in this sense is not usually directly relevant to critical care because ICUs are designed for patients who can be kept alive only with life-sustaining interventions; most ICU patients would die simply as a result of discontinuing all nonpalliative therapies.

The euthanasia debates touch on several important ICU issues, however. How does withdrawing life support differ from euthanasia? How does withholding antibiotics from a patient with bacterial pneumonia and advanced metastatic carcinoma differ from euthanasia? How does prescribing large doses of

narcotics, which in addition to relieving pain can cause respiratory depression and hasten death, differ from euthanasia?

The difference in these cases lies in causality and intentionality. When a physician withdraws life support from a terminally ill patient, it is the patient's disease that causes the death, not the withdrawal. Withdrawing treatment honors the patient's legal and ethical right to refuse treatment. Similarly, withholding antibiotics respects the patient's autonomy; it is the infection that kills the patient, not the withholding of medication. In the case of prescribing narcotics, the distinction becomes more subtle, but remains important; this is referred to as the *principle of double effect*.⁹⁶ Almost all medications and treatments in a physician's armamentarium have the potential for known side effects. Some side effects are desirable, and some are harmful, but the existence of side effects does not preclude treatment. When prescribing morphine and other narcotics to patients who are having mechanical ventilation withdrawn or who have terminal diseases and are in pain, the goal must be pain control, the reduction of anxiety, or even sedation; respiratory depression is a side effect, and it is tolerated in such cases, even to the point of hastening death, as long as the patient has been fully informed and has consented. Dosages must be titrated to achieve the intended goal. What is neither ethical nor legal is for physicians to prescribe medications or treatments in such a manner that the intended result is death. To some, these distinctions may seem purely semantic,⁹⁷ but they are legally valid and represent widely shared ethical thinking. Active euthanasia is a crime in the United States and is opposed by many leading physicians, philosophers, and biomedical ethicists; we oppose active euthanasia as well.

Cross-Cultural Conflicts

Patients' cultural values and beliefs must be understood to appreciate what their illness signifies to them and what they want from physicians.⁹⁸ Cultural patterns have great influence on how individuals and families view illness, medicine, dying, and death, and on their behavioral response during periods of critical illness. Individuals facing death tend to fall back on their traditional cultural or religious beliefs.⁹⁹ Health care providers in the United States increasingly find themselves in cross-cultural situations, confronted with the cultural dimensions of ethical decision making. Cross-cultural ethical issues in medicine have received increasing attention since the mid-1980s, and there has been growing acceptance within the medical community that bioethics is at least partly culturally determined.¹⁰⁰⁻¹⁰⁶ This means that ethical decision making in medicine depends on the specific cultural context in which the decision is being made, and that the ethical principles that Anglo-Americans consider important may seem unimportant to people from other societies.

Anglo-American biomedical ethics accords paramount status to the individual, underscoring the principles of individual rights, autonomy, and self-determination in decisions regarding health care. The fundamental ethical principle of patient autonomy has its basis in Western philosophy and in U.S. cultural values, which emphasize liberty, privacy, and individual rights. The central importance of individuals maintaining control over their body translates into the right to accept or refuse medical interventions. For individuals to be able to make medical decisions, they require an accurate understanding of their medical

condition and any proposed treatments; truth telling and informed consent are also stressed in Western medical ethics. Knowledge and understanding form the basis of informed consent and autonomous decision making.¹⁰⁷

Many other cultures view human identity in profoundly different ways, with much less emphasis on the individual. Many cultures have more relational understandings of human identity (i.e., individuals are defined by their relationships to others rather than by their characteristics as individuals), and the Western emphasis on individual rights and autonomy may not make sense to them.¹⁰⁸ Traditional Chinese society emphasizes the value of family bonds, community, harmony, and responsibility.¹⁰⁹ Respecting communal or familial hierarchies is more important than asserting individual autonomy. It is not that the interests of the family outweigh the interests of the individual; rather, the individual is conceived of primarily as a member of a family. Korean, Italian, and Mexican cultures show similar family-centered structures.^{110,111} The responsibility to show filial duty and protect the elderly may be what the family views as the most important factor in the care of terminally ill patients.¹¹²

The most common source of medical conflict resulting from these relational value systems concerns the disclosure of terminal diagnoses and negative prognostic information; many cultures object to informing patients of terminal diagnoses, especially diagnoses of cancer. A 1995 study of attitudes toward patient autonomy of different ethnic groups found that Korean-Americans and Mexican-Americans generally believed that patients should not be told about terminal diagnoses, and that the family, not the patient, should make life-support decisions. European-Americans and African-Americans were more likely to favor full disclosure and patient participation in decision making.^{113,114} The objection to disclosing distressing information stems from several different beliefs. Traditional Chinese and Southeast Asian cultures view the sick person as needing protection, similar to a child. From this perspective, telling patients upsetting diagnoses adds to their suffering, whereas healthy family members are in a stronger position to bear the bad news and make appropriate decisions. In addition, some cultures often view telling someone that they are dying as bad luck, similar to a curse. Traditional Navajo culture, which believes that "thought and language have the power to shape reality and to control events," also objects to discussing negative information as potentially harmful to the patient.¹¹⁵

When a family does not want a patient to know about a diagnosis, physicians face a difficult ethical dilemma because patient autonomy and the need for informed consent are central to American medical ethics and jurisprudence. From a legal standpoint, courts have ruled that physicians should not be liable for honoring a patient's specific request not to disclose information.^{115,116} Regarding issues of autonomy, Gostin¹⁰⁸ and Pellegrino¹⁰⁴ argue that patients have the right to use their autonomy to choose not to be informed. In the end, physicians must determine for themselves how to negotiate conflicts between their own value systems and the value systems of their patients. It is unreasonable to assert that physicians should strive to follow basic ethical principles and then claim that it is acceptable to toss these principles aside when they conflict with a patient's values. When conflict arises, open communication is essential, and a willingness to compromise serves all parties well. For such culturally conflictual situations, Freedman¹¹⁷ has proposed a strategy of "offering truth" to the patient, rather than "forcing

truth.” Using this strategy, a physician would ascertain directly from the patient how much he or she wants to know about diagnosis and prognosis, and the patient’s expressed wishes would be honored. At the very least, physicians should remain sensitive to cultural differences and maintain an open-minded and respectful attitude about other cultural beliefs and practices. Physicians should remember that a family’s cultural background can be a source of tremendous strength during the crisis of critical illness; violating a patient’s cultural mores should be avoided whenever possible.

In striving to understand a patient’s cultural background, the pitfall of stereotyping must be avoided; within a given culture, there can be great variation among individuals, and there is no substitute for talking directly to patients and their families to determine their cultural values and beliefs. Among patients who are immigrants, the patient and his or her family frequently span more than one generation, with different levels of retention of traditional cultural practices. It is important to note the contribution of various elements in the cultural fabric, such as socio-economics, education, and degree of acculturation. The role of culture must be seen in context with other factors that come into play in an individual’s decision making or behavior, such as economic considerations and individual attributes. Culture is only one component in a complex matrix of influences.

Medical decision-making for patients who lack decision-making capacity and who have no surrogate decision-maker

Medical decision-making for patients with neither decision-making capacity nor a surrogate decision-maker presents an ethical challenge for healthcare providers because there is no way to obtain informed consent for treatment. The challenge is particularly acute when these decisions involve the withholding or withdrawing of life-sustaining treatments but are also pertinent to any invasive or life-threatening procedures. Decision making for these patients should be guided by the best obtainable understanding of what the patient would have wanted using substituted judgment. Aggressive efforts to locate people who knew the patient well are encouraged. Where inadequate information is available to make a substituted judgment, the decision-making should be based on the patient’s best interest.

Although different medical organizations have recommended have recommended and different hospitals have adopted different specific policies for dealing with these scenarios, there is an emerging consensus that the medical team recommending invasive or life-threatening treatment or the withholding or withdrawing of life-sustaining treatments cannot also play the dual role of surrogate by consenting to their proposed actions.¹¹⁸⁻¹²³ Instead one of two approaches has been recommended by a number of hospitals and organizations when decisions involve limiting or withdrawing life support: either having a multidisciplinary review of the treatment plan by individuals not involved in the patient’s care (such as by the hospital ethics committee) or else involving the courts in order to have a guardian appointed to serve as a surrogate decision-maker. In cases involving invasive or high-risk procedures, an ethics consultant or other individual who is not involved in the patient’s care and who has expertise in patient rights and decision-making should participate in the decision-making process unless immediate treatment is needed

for a medical urgency or emergency. In all these cases, familiarity with and adherence to relevant state law is mandatory.

Conclusion

The two major goals of critical care physicians are to save salvageable patients and to facilitate a peaceful and dignified death for patients who are dying. The difficulty of achieving certainty and consensus regarding in which of these two categories an individual patient belongs leads to challenging ethical issues. These issues are best approached in an ordered and thoughtful manner. Whether the issue is a family insisting on treatment that the physician believes is futile or a ventilator-dependent patient requesting that life support be withdrawn, “thinking ethically” about these situations by being attentive to the four basic ethical principles (autonomy, beneficence, nonmaleficence, and distributive justice), by calculating consequences, and by using casuistry can facilitate a thorough analysis and help to resolve disagreements. In addition, four guidelines provide a procedural approach to ethical problems: (1) respect the role of patients as partners, (2) determine who has authority to make health care decisions for the patient, (3) establish effective communication with the patient and family, and (4) determine in an ongoing manner the patient’s quality-of-life values and desires.

Good communication skills are the most powerful tool in ethical conflicts. When questions about life and death are treated in a patient, nonjudgmental, and sensitive manner, ethical conflicts arise less often and tend not to become intractable. Physicians should encourage patients, families, and members of the health care team to express their thoughts and feelings about difficult cases. Whenever possible, decision making should occur by means of consensus.

From an ethical and legal perspective, patients with decision-making capacity have a clearly established right to refuse medical treatments. Providing treatment against a competent patient’s will can constitute battery. At the same time, patients do not have the right to demand specific treatments; only the physician can decide what therapies are appropriate to offer to a patient. The authority for decision making becomes less clear with legally incompetent patients; different states have different judicial precedents and laws concerning when treatment must be provided, and how life-sustaining treatment may be withdrawn from incompetent patients. Some states allow family members to provide substituted judgment for incompetent patients, whereas New York and Missouri require clear and convincing evidence that the patient, before becoming incompetent, had indicated that he or she would want life support to be withdrawn. Patients can protect their ability to help determine what types of medical care they receive by engaging in advance care planning and documenting their wishes via living wills or, preferably, medical powers of attorney.

Decisions about withholding or withdrawing life support occur frequently in ICUs and they represent a painful and difficult process for many physicians. The essential principle in these decisions is that end-of-life decision making must reflect the individual patient’s goals and quality-of-life values. At the same time, physicians are not obliged to provide futile treatments. How to communicate with patients and families and what words to use are probably the most important factors. Although some physicians may object to withholding or withdrawing life-sustaining treatment, patients have a clear and incontestable

right to refuse life support and other treatments, even when such refusal results in their death.

Some Asian, Hispanic, Native American, and European cultures do not share the Anglo-American prioritization of individual rights and autonomy. Patients from family-centered cultures may expect that medical decision making will be handled by the family and the physician with limited or no patient involvement. Many cultures believe that distressing diagnoses should be withheld from patients so they are not burdened with bad news. Physicians should be sensitive and tactful when treating patients from cultural backgrounds other than their own. Although physicians must remain true to their own personal ethics, they should also be cautious about imposing their own cultural values on patients who are guided by a different set of beliefs and customs. In many situations, cultural beliefs and practices can be accommodated without harm to the patient.

Cardiac Intensive Care Unit Admission Criteria

Shepard D. Weiner, LeRoy E. Rabbani

CHAPTER

3

History
Diagnoses
Periprocedure and Postprocedure Setting

Specific Populations
Conclusion

Cardiovascular disease (CVD) accounted for 36.3% of all deaths in the United States in 2004.¹ Nearly 2400 Americans die of CVD each day, an average of 1 death every 36 seconds. The United States leads the world in spending on health care, whether measured as a percentage of gross domestic product or as dollars per capita.² Despite this cost, cardiac intensive care unit (CICU) beds remain a limited resource. There is evidence that physicians can safely adapt to substantial reductions in the availability of CICU beds.³ Determining the appropriateness for admission to the CICU can be challenging, however, and has been the subject of study since the early 1980s.^{4,5}

Many disease processes typically lead to admission to the CICU (Table 3-1). This chapter discusses these conditions and the rationale for intensive care in their treatment.

History

The first description of the coronary care unit (CCU) was presented to the British Thoracic Society in July 1961.⁶ CCUs were initially established in the early 1960s in an attempt to reduce mortality from acute myocardial infarction (MI). The ability to abort sudden death from malignant ventricular arrhythmias in the post-MI setting led to the continuous monitoring of cardiac rhythm and an organized system of cardiopulmonary resuscitation, including external defibrillation.⁷ An early experience of patients with acute MI treated in the CCU published in 1967 showed that patients treated in the CCU had better survival rates compared with other patients with acute MI in the absence of cardiogenic shock.⁸ With creation of Myocardial Infarction Research Units in the United States by the National Heart, Lung and Blood Institute and evolving technologies, the foundation was in place for the CCU to expand into the modern-day CICU where comprehensive advanced care is provided for many cardiovascular conditions. The CICU has been called one of cardiology's 10 greatest discoveries of the 20th century.⁹

Diagnoses

Admissions to the CICU for chest pain and acute coronary syndromes (ACS), including acute MI, have been the most extensively studied. Algorithms exist to assist in the appropriate triage of chest pain patients to the CICU. These are reviewed in the next section. For other cardiovascular conditions, there is less developed efficacy and cost-effectiveness research, and the

decision to admit to the CICU is largely determined on clinical grounds depending on the individual patient care scenario. These other diagnoses are discussed separately.

Chest Pain and Acute Coronary Syndromes, and Acute Myocardial Infarction

Chest pain accounts for approximately 6 million annual visits to emergency departments in the United States, making chest pain the second most common complaint in the emergency department.¹⁰ ACS are life-threatening causes of chest pain seen in the emergency department and include unstable angina, non-ST segment elevation MI (NSTEMI), and acute MI or ST segment elevation MI. Less than 15% to 30% of patients who present to the emergency department with nontraumatic chest pain have ACS, however.^{11,12} An important challenge is to identify patients with ACS appropriately and admit them to the appropriate setting for further care. For the evaluation and management of patients with acute chest pain, prediction models have markedly improved our ability to estimate risk, and cost-effectiveness analyses have helped guide the development of new paradigms and the incorporation of new technologies.¹³

In addition to treating patients with ACS, the CICU has traditionally been considered appropriate for monitoring patients with acute chest pain until ACS is diagnosed or excluded. Increasing health care costs have created pressures, however, to increase the efficiency of CICUs. Possible strategies seek to decrease resource use by identifying low-risk patients for initial triage or early transfer to lower levels of care. The application of management algorithms and the development of intermediate care units are allowing for a distinction between intensive coronary care and careful coronary observation.¹⁴ The development of chest pain units located in the emergency department is another alternative to CICU admission. These units are safe, effective, and a cost-saving means of ensuring that patients with unstable angina who are considered to be at intermediate risk of cardiovascular events receive appropriate care.¹⁵ Patients at low clinical risk can receive immediate exercise testing in the chest pain unit if the appropriate diagnostic modalities are available. This approach is accurate for discriminating low-risk patients who require admission from patients who can be discharged to further outpatient evaluation.¹⁶

Several reports have detailed strategies to identify high-risk patients early. To achieve more appropriate triage to the CICU of patients presenting with acute chest pain, Goldman and

Table 3-1. Cardiovascular Conditions Requiring Admission to the Cardiac Intensive Care Unit

Chest pain, acute coronary syndromes, and acute myocardial infarction
Acute decompensated heart failure
Pulmonary hypertension
Arrhythmias
Sudden cardiac death
Cardiogenic shock
Conditions requiring IABP or other forms of mechanical circulatory support
Adult congenital heart disease (decompensated)
Valvular heart disease (with hemodynamic instability)
Aortic dissection
Hypertensive emergency
Cardiac tamponade
Pulmonary embolism (massive or submassive)
Postprocedure monitoring (percutaneous coronary intervention and electrophysiologic study)

IABP, intra-aortic balloon pump.

coworkers¹⁷ used clinical data on 1379 patients at two hospitals to construct a computer protocol to predict the presence of MI. This protocol was tested prospectively, and it had a significantly higher specificity (74% versus 71%) in predicting the absence of infarction than physicians deciding whether to admit patients to the CICU, and it had a similar sensitivity in detecting the presence of infarction (88% versus 87.8%). Decisions based solely on the computer protocol would have reduced the admission of patients without infarction to the CICU by 11.5% without adversely affecting the admission of patients in whom emergent complications developed that required intensive care.

In another study,¹⁸ the acute cardiac ischemia time-insensitive predictive instrument (ACI-TIPI) was used to triage patients with symptoms suggestive of acute cardiac ischemia to the CICU, telemetry unit, ward, or home. Use of ACI-TIPI was associated with reduced hospitalization among emergency department patients without acute cardiac ischemia. Appropriate admission for unstable angina or acute infarction was not affected. If ACI-TIPI is used widely in the United States, its potential incremental impact is estimated to be more than 200,000 fewer unnecessary hospitalizations and more than 100,000 fewer unnecessary CICU admissions.¹⁸

In a cost-effectiveness analysis, Fineberg and colleagues¹⁹ found that for patients with a 5% probability of infarction, admission to a CICU would cost \$2.04 million per life saved and \$139,000 per year of life saved compared with intermediate care. For the expected number of such patients annually in the United States, the cost would be \$297 million to save 145 lives.

In another study by Goldman and associates,²⁰ a set of clinical features was defined; if these features were present in the emergency department, they were associated with an increased risk of complications. These clinical features included ST segment elevation or Q waves on the electrocardiogram (ECG) thought

to indicate acute MI, other ECG changes indicating myocardial ischemia, low systolic blood pressure, pulmonary rales above the bases, or an exacerbation of known ischemic heart disease. The risk of major complications in patients with acute chest pain can be estimated on the basis of the clinical presentation and new clinical observations made during the hospital course. These estimates of risk help in making rational decisions about the appropriate level of medical care for patients with acute chest pain.

Despite these findings, the implementation of these algorithms in clinical practice by physicians without specific training in their use has been minimal.^{21,22} This situation may relate to physicians' reporting that they are too busy, are unsure of the value of the algorithms, and are concerned about the consequences of inappropriately discharging patients who are later found to have had MI.²³

A more recent analysis by Tosteson and colleagues²⁴ indicates that the CICU usually should be reserved for patients with a moderate ($\geq 21\%$, depending on the patient's age) probability of acute MI, unless patients need intensive care for other reasons. Clinical data suggest that only patients with ECG changes of ischemia or infarction not known to be old have a probability of acute MI this high. A summary has been developed that outlines the location to which chest pain patients should be admitted (Table 3-2).²⁵

Another important issue to consider is the length of stay in the CICU after patients are admitted. If patients are initially triaged to the CICU, the lack of cardiac enzyme abnormalities or recurrent chest pain during the first 12 hours of hospitalization are parameters that can be used to identify patients for whom a 12-hour period of CICU observation is sufficient to exclude acute MI.²⁶ In a study by Weingarten and colleagues,²⁷ physicians caring for patients with chest pain who were at low risk for complications received personalized written and verbal reminders regarding a guideline that recommended a 2-day hospital stay. Use of the practice guideline recommendation with concurrent reminders was associated with a decrease in length of stay from 3.54 ± 4.1 days to 2.63 ± 3 days and a total cost reduction of \$1397 per patient. No significant difference was noted in complications, patient health status, or patient satisfaction when measured 1 month after hospital discharge.

The European Society of Cardiology and American College of Cardiology restructured the definition of acute MI in 2000 (Table 3-3).²⁸ The principal revision compared with the previous World Health Organization definition²⁹ is the inclusion of biomarkers, specifically troponin, as a necessary component. There have been some attempts to assess the new definition and the widespread introduction of troponin measurement on CICU admitting practices. One study by Amit and colleagues³⁰ was a retrospective cohort study in which all admissions to the CICU the year before and after the introduction of troponin measurement and the updated MI definition were examined. There was a 20% increase in the number of CICU admissions, driven by a 141% increase in the number of NSTEMIs. Length of stay in the CICU decreased by 1 day for all ACS patients, and the 30-day mortality for acute MI did not change significantly. In another study by Zahger and associates,³¹ the number of NSTEMI patients increased by 33% after the definition change, whereas the number of patients with ST segment elevation MI remained the same. There was no change in the number of CICU beds at the participating institutions. The proportion of patients given

Table 3-2. Indications to Guide Where to Admit Patients with Acute Chest Pain**Intensive Care Unit**

One of the following:

- Substantial ischemic ECG changes in two or more leads that are not known to be old
 - ST segment elevation ≥ 1 mm or Q waves of ≥ 0.04 second
 - ST segment depression ≥ 1 mm or T wave inversion consistent with the presence of ischemia

Any two of the following, with or without substantial ECG changes:

- Coronary artery disease known to be unstable (in terms of frequency, duration, intensity, or failure to respond to usual measures)
- Systolic blood pressure < 100 mm Hg
- Serious new arrhythmias (new-onset atrial fibrillation, atrial flutter, sustained supraventricular tachycardia, second degree or complete heart block, or sustained or recurrent ventricular arrhythmias)
- Rales above the bases

Intermediate Care Unit

Any of the following conditions but meeting no criteria for intensive care:

- Coronary artery disease known to be unstable
- Systolic blood pressure < 110 mm Hg
- Rales above the bases
- Major arrhythmias (new-onset atrial fibrillation, atrial flutter, sustained supraventricular tachycardia, second-degree or complete heart block, or sustained or recurrent ventricular arrhythmias)
- New onset of typical ischemic criteria that meet the clinical criteria for unstable angina and that occur at rest or with minimal exertion

Evaluation or Observation Unit

New-onset symptoms that may be consistent with ischemic heart disease, but are not associated with ECG changes or a convincing diagnosis of unstable ischemic heart disease at rest or with minimal exertion

Known coronary artery disease whose presentation does not suggest a true worsening, but for which further observation is thought to be beneficial

Home with Office Follow-up in 7-10 Days to Determine Whether Further Testing Is Needed

Other conditions

ECG, electrocardiogram.

Table 3-3. European Society of Cardiology/American College of Cardiology Definition of Acute, Evolving, or Recent Myocardial Infarction

Typical increase and gradual decrease (troponin) or more rapid increase and decrease (CK-MB) of biochemical markers of myocardial necrosis with at least one of the following:

- Ischemic symptoms
- Development of pathologic Q waves on the ECG
- ECG changes indicative of ischemia (ST segment elevation or depression)
- Coronary artery intervention (e.g., angioplasty)

Adapted from Antman E, Bassand J-P, Klein W, et al: Myocardial infarction redefined—a consensus document of The Joint European Society of Cardiology/American College of Cardiology Committee for the redefinition of myocardial infarction. *J Am Coll Cardiol* 2000;36:959-969.

the diagnosis of NSTEMI increased significantly more in centers with high use of troponin. These changes have a significant impact on resource use.

Given this increased demand for a relatively fixed resource, the question of whether all NSTEMI patients need to be admitted to the CICU arises. The CRUSADE registry³² showed that patients with NSTEMI often receive excess doses of anti-thrombotic therapy, and that dosing errors occur more often in vulnerable populations and predict an increased risk of major bleeding. Some institutions have interpreted these data to indicate that all NSTEMI patients should be admitted to the CICU because a maximally observed setting may limit excess dosing and bleeding complications.

At our institution, it is practice for only NSTEMI patients who are high risk by the TIMI risk score³³ to be admitted to the

CICU. The lower risk NSTEMI patients are admitted to a telemetry unit with cardiac nurses. There is preliminary evidence that admission of patients with initially uncomplicated chest pain with a relatively low probability of acute MI to a stepdown unit does not place at increased risk those who eventually “rule in” for MI.³⁴ Regardless of specific setting, the adherence to clinical pathways offers the potential to improve the care of patients with ACS while reducing the cost of care.³⁵

Heart Failure

It is estimated that 5.2 million people in the United States are being treated for heart failure.¹ Hospital discharges for heart failure increased from 402,000 in 1979 to 1,101,000 in 2004.³⁶ Interventions to improve adherence, the control of hypertension, and the appropriate use of angiotensin-converting enzyme

Table 3-4. Events and Procedures for Congestive Heart Failure Patients during Hospital Stay

Event or Procedure	All Patients (N = 105,388) (%)	ICU/CICU Patients (n = 19,754) (%)

CPR, cardiopulmonary resuscitation; PCI, percutaneous coronary intervention.

inhibitors may prevent many hospitalizations of heart failure patients.³⁷ Device therapy, including biventricular pacemakers and implantable cardioverter-defibrillators, has also led to significant improvements in outcomes for certain heart failure patient populations.^{38,39} Nonetheless, some patients admitted to the hospital with heart failure require advanced cardiac care in the CICU. Standard criteria for management of acute decompensated heart failure (ADHF) in the CICU are not clearly established. Management usually involves invasive hemodynamic monitoring and inotropic or vasopressor support that cannot be done outside the CICU in most institutions.

Admission for heart failure is a high-risk event for patients, particularly patients admitted to an intensive care unit (ICU) setting.⁴⁰ Table 3-4 shows the events and procedures that occurred during hospitalization of patients with congestive heart failure (CHF) in the ADHERE registry.

Weingarten and associates⁴¹ found that nearly one third of patients with CHF hospitalized in either the CICU or intermediate care unit are lower risk and potentially suitable for transfer 24 hours after admission. In this study, *low risk* is defined as patients without acute MI or ischemia, active or planned cardiac interventions, unstable comorbidity, worsening clinical status, or lack of response to diuretic therapy. A more common planned cardiac intervention for heart failure patients is the use of the pulmonary artery catheter. Although addition of the pulmonary artery catheter to careful clinical assessment increases anticipated adverse events, it does not affect overall mortality

and hospitalization in patients with severe symptomatic and recurrent heart failure.⁴²

In most hospitals, certain medical therapies used in the treatment for decompensated heart failure are delivered in the CICU setting. The need for pronounced afterload reduction is an indication for intravenous nitroprusside.⁴³ This therapy is commonly delivered in the CICU because it requires continuous blood pressure monitoring. The major limitation to the use of nitroprusside is its metabolism to cyanide, possibly leading to development of cyanide toxicity or rarely thiocyanate toxicity that may be fatal.⁴⁴

Patients with systolic dysfunction who remain volume-overloaded despite vasodilator and diuretic therapy may require intravenous inotropic support to improve systemic perfusion. The β agonist dobutamine is a useful inotropic agent for ADHF.⁴⁵ In patients with severe CHF, short-term administration of dobutamine selectively improves vascular endothelial function.⁴⁶ Another class of inotropic agents commonly used is the phosphodiesterase inhibitors. In addition to being given in the acute setting, prolonged outpatient therapy with milrinone, a phosphodiesterase inhibitor, has been employed.⁴⁷ The use of intravenous continuous infusion of inotropes, including dobutamine and milrinone, has not been shown to have a benefit in mortality.⁴⁸

Another treatment modality that has been used in the CICU or cardiac stepdown unit is the exogenous administration of nesiritide, recombinant human brain natriuretic peptide. In patients hospitalized with ADHF, nesiritide improves hemodynamic function.⁴⁹ More recent independent analyses have questioned the safety of nesiritide, however. Compared with non-inotrope-based control therapy, nesiritide may be associated with an increased risk of worsening renal function⁵⁰ and death⁵¹ after treatment for ADHF. If used, these treatments are best used in the CICU or cardiac stepdown unit to achieve hemodynamic targets.

Certain causes of heart failure require specific therapies. Patients with giant cell myocarditis have improved outcomes if they receive immunosuppressive treatment.⁵² Patients with a fulminant presentation from giant cell myocarditis, or more rarely from other etiologies such as lymphocytic or viral myocarditis, require an intensive level of hemodynamic support with inotropes and vasopressors in the CICU.⁵³

Patients receiving inotropic therapy can go on to have improved outcomes with the use of mechanical circulatory support, specifically left ventricular assist devices (LVADs), as destination therapy.⁵⁴ Although cellular recovery and improvement in ventricular function are observed, the degree of clinical recovery is insufficient for device explantation in most patients with chronic heart failure.⁵⁵ If not used as destination therapy, the LVAD may serve as a bridge to heart transplantation, and these patients are cared for in the cardiothoracic surgery ICU after surgery. Also, at cardiac transplantation centers, some advanced CHF patients require continuous infusion of a single high-dose intravenous inotrope (e.g., dobutamine, ≥ 7.5 $\mu\text{g/kg/min}$, or milrinone, ≥ 0.50 $\mu\text{g/kg/min}$), or multiple intravenous inotropes, in addition to continuous hemodynamic monitoring of left ventricle filling pressures, which satisfies criteria for listing as Status 1A by the United Network of Organ Sharing.⁵⁶ Additionally, patients undergoing new advanced cardiac care procedures, such as percutaneous mechanical devices,⁵⁷ require management in the CICU.

Multiorgan dysfunction in the setting of heart failure requires admission to the CICU. A reduced glomerular filtration rate is associated with an increased mortality in patients with heart failure.⁵⁸ Because many patients with ADHF and renal failure have compromised hemodynamics, a form of renal replacement therapy, such as continuous venovenous hemofiltration or hemodialysis, in the intensive care setting is commonly required. Other volume management techniques for heart failure treatment, such as ultrafiltration,⁵⁹ may necessitate care in the CICU or stepdown unit.

While the patient is hospitalized, careful attention to certain laboratory values such as serum sodium and blood urea nitrogen is reasonable because both values have been shown to be independent predictors of subsequent mortality.^{60,61} Treatment with tolvaptan, a vasopressin V2 receptor blocker, has been shown to increase serum sodium concentrations effectively in patients with euvolemic or hypervolemic hyponatremia,⁶² but has no effect on long-term mortality or heart failure–related morbidity.⁶³

Pulmonary Hypertension

Several treatments for pulmonary arterial hypertension are approved in the United States, including epoprostenol, treprostinil, bosentan, and sildenafil. Because limited data are available from head-to-head comparisons of approved therapies, the choice of treatment is dictated by clinical experience and by patients' preferences.⁶⁴ There are no evidence-based guidelines on when to admit patients with pulmonary hypertension to the CICU. Generally, patients with New York Heart Association or World Health Organization functional class IV may require an intensive care setting for management. Intravenous epoprostenol is an advanced pulmonary hypertension therapy that has been shown to improve functional capacity and survival in patients with idiopathic pulmonary arterial hypertension.⁶⁵ In addition to vasoreactivity testing in the cardiac catheterization laboratory, inhaled nitric oxide is sometimes used in acutely ill patients with severe pulmonary hypertension in the CICU.⁶⁶

Arrhythmias

Many arrhythmias require admission to the CICU. The decision to manage a patient with an arrhythmia in the CICU largely depends on the underlying rhythm disturbance, and whether it is associated with signs and symptoms of hemodynamic instability. Patients with arrhythmias needing management in the CICU include patients with tachyarrhythmias and bradyarrhythmias and survivors of sudden cardiac death. Length of stay in the CICU should be determined by the type of underlying rhythm, the clinical state of the patient, and whether measures have been taken to reduce the recurrence of an unstable arrhythmia. If the patient is deemed low risk, the patient can be transferred from the CICU.

Narrow-complex tachycardias can lead to unstable hemodynamics. In this situation, immediate synchronized cardioversion is indicated.⁶⁷ This is best done in the controlled setting of a CICU if possible. If a patient is out of the hospital or in a less monitored unit, admission or transfer to the CICU should be arranged for further management.

Wide-complex tachycardias may represent either supraventricular or ventricular arrhythmias. The mechanism of wide-complex tachycardias can be determined with clinical information and analysis of the 12-lead surface ECG.⁶⁸

Regardless of the cause, a wide-complex tachycardia that is unstable and associated with hemodynamic compromise must be treated promptly with electrical cardioversion. Pulseless ventricular tachycardia or ventricular fibrillation requires immediate defibrillation. Admission to the CICU may be required even in patients with implantable cardioverter-defibrillators. Electrical storm, or three or more appropriate shocks delivered because of repeated episodes of ventricular tachycardia or ventricular fibrillation occurring within a 24-hour period, often requires antiarrhythmic medical therapy to suppress arrhythmias and further shocks. In the AVID cohort, electrical storm was a significant independent risk factor for nonsudden cardiac death.⁶⁹

More recently, the American College of Cardiology/American Heart Association/European Society of Cardiology updated their guidelines for the management of ventricular arrhythmias and the prevention of sudden cardiac death.⁷⁰ For successfully resuscitated cardiac arrest victims, whether the event occurred in or out of the hospital, post–cardiac arrest care includes admission to an ICU and continuous monitoring for 48 to 72 hours.⁷¹ The outcome of patients experiencing sudden cardiac death remains poor. In the Seattle series, survival to hospital discharge for patients treated between 1998–2001 was not significantly better than for patients treated between 1977–1981.⁷² Protocols involving induction of hypothermia after return of spontaneous circulation phase in the ICU have been associated with improved functional recovery and reduced cerebral histologic deficits in various animal models of cardiac arrest. Additional promising preliminary human studies have been completed.⁷³

Bradyarrhythmias that require temporary transvenous pacing are an acceptable indication for admission to the CICU. Indications for temporary pacing are less clearly described than the indications for permanent pacing. Table 3-5 lists recommendations by class of evidence for transvenous pacing in the setting of acute MI, which includes several bradyarrhythmias.⁷⁴ Regardless of level of evidence, in practice patients who receive temporary transvenous pacemakers should be admitted to the CICU. Monitoring in the CICU should continue until the acute and reversible cause of the bradyarrhythmia is corrected, or a permanent pacemaker is placed.

Withdrawal of pacemaker or implantable cardioverter-defibrillator support at the end of life is becoming a more frequently encountered clinical scenario. Granting terminally ill patients' requests to remove unwanted medical support is legal and ethical.⁷⁵ An analysis by Lewis and coworkers⁷⁶ showed that only one third of terminally ill patients with ICDs actually had shock therapy withdrawn as part of a comfort care strategy.

Cardiogenic Shock

Cardiogenic shock is the most severe form of left ventricular failure. It can occur as a complication of acute MI or from other cardiovascular conditions (Table 3-6).⁷⁷ For the acute MI subgroup, the CICU is used for temporizing measures, such as intra-aortic balloon pump (IABP) counterpulsation and use of vasopressor support. These patients benefit from early revascularization with a mortality benefit at 6 months⁷⁸ that persists at 6 years of follow-up.⁷⁹ The use of early intravenous β blocker therapy in patients admitted to the CICU with acute MI complicated by unstable hemodynamics reduces the risk of reinfarction and ventricular fibrillation, but increases the risk of cardiogenic shock during the first day after admission.⁸⁰ Appropriately selected patients with acute cardiogenic shock in the

Table 3-5. Recommendations for Temporary Transvenous Pacing**Class I**

Asystole
 Symptomatic bradycardia (includes sinus bradycardia with hypotension and type I second-degree AV block with hypotension not responsive to atropine)
 Bilateral BBB, including alternating BBB, or right BBB with alternating LAFB/LPFB (any age)
 New or indeterminate age bifascicular block (right BBB with LAFB or LPFB, or left BBB)
 Mobitz type II second-degree AV block

Class IIa

Right BBB and LAFB or LPFB (new or indeterminate)
 Right BBB with first-degree AV block
 Left BBB, new or indeterminate
 Incessant VT, for atrial or ventricular overdrive pacing
 Recurrent sinus pauses (>3 seconds) not responsive to atropine

Class IIb

Bifascicular block of indeterminate age
 New or indeterminate age isolated right BBB

Class III

First-degree heart block
 Type I second-degree AV block with normal hemodynamics
 Accelerated idioventricular rhythm
 BBB known to exist before acute MI

A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Acute Myocardial Infarction). *J Am Coll Cardiol* 1996;28:1328-1428.

AV, atrioventricular; BBB, bundle branch block; LAFB, left anterior fascicular block; LPFB, left posterior fascicular block; MI, myocardial infarction; VT, ventricular tachycardia.

setting of acute MI managed in the CICU have had encouraging initial experiences with use of ventricular assist devices.⁸¹

Other Indications for Intra-Aortic Balloon Pump

Other indications for IABP placement are clinical situations where admission to the CICU is necessary. IABP may be useful in a high-risk or complicated percutaneous coronary intervention (PCI),⁸² rescue PCI after failed thrombolysis,⁸³ and acute MI with mechanical complications such as acute ventricular septal defect and mitral regurgitation.⁸⁴ The prophylactic placement of an IABP before coronary artery bypass graft surgery has been performed in patients with left main coronary artery stenosis, severely depressed left ventricular systolic function, diffuse coronary artery disease, and redo surgery.^{85,86}

Adult Congenital Heart Disease

The total population of adult congenital heart disease patients in the United States in 2000 was 785,000.⁸⁷ This number, which exceeds the number of pediatric cases, reflects tremendous advances in pediatric cardiac care. Adult congenital heart disease patients may require management in the CICU. The need for CICU care is commonly due to the main consequences of

Table 3-6. Causes of Cardiogenic Shock

Complications of Acute Myocardial Infarction
Extensive left ventricular infarction
Extensive right ventricular infarction
Ventricular septal rupture
Acute severe mitral regurgitation
Cardiac tamponade with or without free wall rupture
Other Conditions
Aortic dissection
Myocarditis
Massive pulmonary embolism
Critical valvular stenosis
Acute mitral or aortic regurgitation
Calcium channel blocker or β blocker overdose

congenital cardiac lesions: cyanosis, congestive heart failure, pulmonary hypertension, Eisenmenger syndrome, and cardiac arrhythmias. These patients are best cared for by a multidisciplinary team at designated adult congenital heart disease centers.⁸⁸

Valvular Heart Disease

There are many considerations in diagnosing and treating patients with valvular heart disease. Most center around the more common management decisions involving chronic valvular lesions. There are instances, however, of acute valvular pathology that require care in the CICU.

Patients with acute mitral regurgitation are often critically ill with significant hemodynamic abnormalities. In most cases, definitive treatment is surgery, but medical therapy in the CICU is needed to support the patient initially. Intravenous nitroprusside can reduce mitral regurgitation leading to increased forward cardiac output and diminished pulmonary congestion.⁸⁹ Nitroprusside should not be given as monotherapy in patients who are hypotensive at presentation. Some benefit may be achieved initially by concurrent administration of an inotropic agent such as dobutamine, but an IABP is often inserted.⁹⁰

Acute aortic insufficiency is a valvular condition that can require management in the CICU. The two most common causes of acute aortic insufficiency are endocarditis and aortic dissection.⁹¹ Treatment of acute severe aortic insufficiency is emergency aortic valve replacement. If there is any delay in surgery, stabilization may be attempted in the ICU using intravenous vasodilators, such as nitroprusside, and possibly inotropic agents, such as dopamine or dobutamine, in an attempt to enhance forward flow and lower left ventricular end-diastolic pressure.⁹⁰ An IABP is contraindicated because inflation of the balloon in diastole would worsen the severity of aortic insufficiency.

A special consideration is acute valvular disease in the setting of infective endocarditis. Surgery in native valve endocarditis is sometimes delayed to allow a longer duration of antibiotic

therapy; however, several studies support the use of early surgery in patients with acceptable indications.^{92,93} The decision as to when to operate is often difficult and requires close consultation with surgical colleagues for each case.

Patients with severe aortic stenosis and hemodynamic instability are managed in the CICU. If the patients are high risk for aortic valve replacement, percutaneous balloon valvuloplasty has been performed. This procedure has been shown to reduce aortic valve gradient, but morbidity and mortality remain high in this population.⁹⁴ The 2006 American College of Cardiology/American Heart Association guidelines for management of patients with valvular disease⁹⁰ concluded that balloon valvuloplasty is not a substitute for valve replacement in adults. The guidelines do recognize the above-mentioned situation as a setting in which balloon valvuloplasty may be reasonable. Its use for palliation in patients with serious comorbid conditions that prevent performance of aortic valve replacement is also a reasonable exception. These patients require intensive management in the CICU during the periprocedure time period. Two catheter-based techniques for replacing the aortic valve have also been investigated: percutaneous implantation via a retrograde femoral approach and direct apical puncture. These techniques are currently experimental, and more experience is required before either approach can be recommended for routine clinical practice.⁹⁵⁻⁹⁷

Aortic Disease

Patients with uncomplicated aortic dissections confined to the descending thoracic aorta (Stanford type B or DeBakey type III) are best treated with medical therapy in the ICU.⁹⁸ The acute management usually involves an intravenous β blocker, plus an intravenous vasodilator such as nitroprusside if further blood pressure lowering is needed to minimize aortic wall stress.⁹⁹ Pain control is also an important component of treatment. Patency or thrombosis of the false lumen has been found to have prognostic implications. Partial thrombosis of the false lumen, compared with complete patency, is a significant independent predictor of postdischarge mortality in patients with type B acute aortic dissection.¹⁰⁰

Patients with aortic intramural hematoma of the ascending aorta are at high risk for early progression to overt dissection and rupture and require undelayed surgical repair.¹⁰¹ Acute aortic dissection of the ascending aorta, or type A dissection, is highly lethal, with a mortality rate of 1% to 2% per hour after the onset of symptoms.¹⁰² Although the definitive treatment for type A dissections is emergent surgery, medical therapy including intravenous β blockade to reduce blood pressure and the force of left ventricular ejection is needed initially as the diagnosis is confirmed.⁹⁹

Hypertensive Emergency

Although there have been many advances in antihypertensive therapy, only 31% of patients with diagnosed hypertension have adequate blood pressure control.¹⁰³ Adherence to therapy remains a problem¹⁰⁴ and contributes to poor blood pressure control that can lead to hypertensive emergency. Nonadherence to medical therapy is the most common reason patients present to the emergency department with hypertensive crises.¹⁰⁵ Multiple classes of intravenous antihypertensive medications, including vasodilators, adrenergic inhibitors, and diuretics, are available for use in the CICU for the treatment of hypertensive emergency.¹⁰⁶ Intravenous infusion of nitroprusside is effective, reliable, and safe in this situation.¹⁰⁷ Labetalol is used

parenterally for rapid control of blood pressure in hypertensive emergencies.¹⁰⁸ Although useful as adjunctive therapy in hypertensive crises, diuretics should be used with caution if volume depletion is suspected.¹⁰⁹ The continuous infusion of parenteral antihypertensive agents is usually performed with concomitant invasive blood pressure monitoring by an arterial catheter. Patients can be transferred from the CICU after they are transitioned to oral therapy for blood pressure control and with improvement or stabilization of end-organ damage.

Cardiac Tamponade

A stable pericardial effusion without clinical signs of cardiac tamponade may not require admission to the CICU. In a patient with a known pericardial effusion, the clinical examination may help guide decisions about the appropriateness of expectant management or more urgent, invasive intervention.¹¹⁰ Cardiac tamponade with only mild hemodynamic compromise may be treated conservatively; this may require admission to the CICU for careful monitoring, serial echocardiographic studies, and therapy aimed at the underlying cause. Volume expansion is valuable in hypovolemic patients.¹¹¹ Tamponade with overt hemodynamic compromise requires urgent removal of pericardial fluid, which produces a rapid improvement in cardiac hemodynamics.¹¹² Removal of pericardial fluid can be performed by catheter pericardiocentesis or surgical pericardiectomy. Positive-pressure mechanical ventilation should be avoided if possible in patients with acute tamponade because it reduces cardiac filling further.¹¹³

Pulmonary Embolism

Thrombolysis can be lifesaving in patients with cardiogenic shock from massive pulmonary embolus.¹¹⁴ If performed in the emergency department, the patient should be admitted to the ICU for monitoring. Thrombolysis can minimize escalation of therapy—defined as the need for pressors, mechanical ventilation, cardiopulmonary resuscitation, or open-label thrombolysis—without an increase in major bleeding in patients with normal systemic blood pressure, but with right ventricular dysfunction or pulmonary hypertension.¹¹⁵

Periprocedure and Postprocedure Setting

The risk of producing a major complication (death, MI, or major embolization) during diagnostic cardiac catheterization is generally less than 1%.¹¹⁶ Rates of major complications after PCI are also low.¹¹⁷ If a coronary artery complication, myocardial ischemia, or vascular complication is suspected or detected, however, admission to the CICU after the procedure may be warranted. In particular, vascular access complications, including retroperitoneal bleeding, pseudoaneurysm formation, and arteriovenous fistula formation, may require postprocedure admission to the CICU. Patients with major bleeding after PCI have higher in-hospital and 1-year mortality compared with patients with minor or no bleeding.¹¹⁸ The need for transfusion of red blood cells for a bleeding complication after PCI is independently associated with in-hospital mortality.¹¹⁹

Complications of invasive cardiac electrophysiology studies are low. In one series, the complication rate was reported

at approximately 2%, and there was no mortality.¹²⁰ If a serious complication such as tricuspid valve damage, pulmonary embolism, cardiac chamber perforation, cardiac tamponade, or other vascular injury occurs, however, management in the CICU is appropriate in conjunction with cardiothoracic surgeons if needed.

Marenzi and coworkers¹²¹ have shown that periprocedural hemofiltration effectively prevents the deterioration of renal function resulting from contrast agent–induced nephropathy, and is associated with improved in-hospital and long-term outcomes. More frequent use of this treatment paradigm in patients with chronic kidney disease undergoing an invasive cardiac procedure requiring a contrast agent would result in a larger number of periprocedural admissions to the CICU.

Specific Populations

As CICUs are becoming more widespread, it is important to consider whether this valuable resource is being used appropriately for various patient populations. Emerging data investigating this topic are available for several patient populations.

Elderly

The elderly population, defined as individuals 65 years old or older, numbered 37.3 million in 2006, which represents 12.4% of the U.S. population, about one in every eight Americans.¹²² Patients 75 years old or older with acute MI were 2.5 times more likely not to be admitted to the CICU than younger patients with acute MI.¹²³ There is evidence that after cardiac surgery and intensive care admission, surviving elderly patients have experienced a favorable outcome in terms of quality of life, and mortality rates are acceptably low.¹²⁴ Efforts need to be directed toward narrowing this discrepancy in CICU admission rates. In a study of nonagenarians and centenarians with NSTEMI, increasing adherence to guideline-recommended therapies was associated with decreased mortality.¹²⁵ These findings reinforce the importance of optimizing care patterns for even the oldest patients with NSTEMI, while examining novel approaches to reduce the risk of bleeding in this rapidly expanding patient population.¹²⁵

Women

Attempts at making cardiovascular randomized controlled trials more inclusive of women seem to have had limited success. Women remain underrepresented in published trial literature relative to their disease prevalence¹²⁶; this has important implications because safety and efficacy can vary as a function of gender. In one cohort of patients with known coronary artery disease, less aggressive treatment of coronary artery disease and less use of aspirin among women than among men was found during 1 year of observation.¹²⁷ After controlling for baseline differences, women with coronary artery disease in this study experienced a more rapid decline in physical health status than did men. There is evidence that gender differences in the treatment of cardiac disease seem to be evident. There are no data reviewing gender differences in the CICU specifically, but some differences in the use of cardiac procedures have been observed. These gender differences may involve other factors, however. Mark and colleagues¹²⁸ reported that academic cardiologists made appropriately lower pretest predictions of categories of disease in women with possible coronary artery disease than in

men, and these assessments, along with women's lower rate of positive exercise tests, rather than bias based on sex, accounted for the lower rate of catheterization among women. Gender differences may also be augmented by varying practice patterns. Women with ACS experience more bleeding than men whether or not they are treated with glycoprotein IIb/IIIa inhibitors. Because of frequent excessive dosing in women, however, one fourth of this sex-related risk difference in bleeding is avoidable.¹²⁹ Gender differences in cardiac care is an issue that needs further exploration.

Minority Populations

After adjustment for sociodemographics, comorbidity, and illness severity, African Americans admitted to hospitals without revascularization services remain less likely to be transferred, and African Americans admitted to hospitals with revascularization are less likely to undergo revascularization compared with whites.¹³⁰ In a study by Johnson and associates,¹³¹ after adjustments were made for multiple clinical factors, a lower proportion of African Americans presenting with acute chest pain were admitted to the hospital, and, after being admitted, African Americans were less likely to be triaged to the CICU. It is imperative that all CICUs distribute resources to the patients in greatest medical need regardless of other factors.

Conclusion

The spectrum of patients managed in the CICU continues to evolve as advances in critical care and the diagnosis and treatment of cardiac disorders move forward. Remarkable progress has been made in the care of critically ill cardiac patients. Optimal use of the resources available in the CICU requires a successful integration with other hospital services, particularly the emergency department, cardiac catheterization laboratory, and cardiothoracic ICU and operating rooms. The CICU is a specialized unit with limited capacity that is commonly exceeded by its demand. Adherence to careful admission criteria would optimize potential benefits we can provide to our patients in the CICU.

Physical Examination in the Cardiac Intensive Care Unit

Hal A. Skopicki, George Gubernikoff

CHAPTER

4

General Assessment

Vital Signs

Head, Eyes, Ears, Nose, and Throat Examination

Jugular Venous Pulse and Abdominojugular Reflux

Chest and Lung Examination

Thorax and Heart Examination

Abdominal Examination

Neurologic Examination

Vascular Examination

Musculoskeletal and Integument Examination

Conclusion

The trouble with doctors is not that they don't know enough, but that they don't see enough.

Sir Dominic J. Corrigan (1802-80)

In the intensive care unit (ICU), the ubiquitous presence of advanced technology and "super-star" laboratory analyses has resulted in an over-reliance on imaging and testing and physicians less able to adequately examine critically ill patients. Yet particularly at the moments of initial patient contact, acute decompensation and after therapeutic interventions, when physicians may not have immediate access to these test results the ability to perform an outstanding physical evaluation remains critical. Since in the words of William Osler, "Medicine is the art of uncertainty and the science of probability," the physical examination should be used as a paramount tool, in concert with laboratory analysis and diagnostic imaging, to limit the uncertainty and increase the probability of accurate assessment.

The ideal physical examination requires time, patience a quiet room, and the ability to think and examine simultaneously. These elements are rarely present in an ICU setting. Yet through the tangle of electrocardiogram leads and intrusive sounds of intravenous pumps, cardiac monitors, ventilators, and conversations, it is the physician's responsibility to optimize the management of critically ill patients by focusing their senses and performing the physical examination to the best of their abilities.

General Assessment

The general assessment should include a broad evaluation of the patient's emotional status, appearance, and nonverbal cues. Although apprehension may be part of a patient's natural temperament, abrupt-onset or escalating anxiety should elicit serious diagnostic consideration until acute and life-threatening processes (e.g., escalating ventricular arrhythmias, impeding pulmonary edema, crescendo angina, extension of a myocardial infarction, aortic dissection) can be ruled out. Reassuring the patient may gain time for further investigation. A patient who needs to sit up to catch his or her breath suggests the presence

of pulmonary edema or a large pleural effusion, where a patient who finds relief of chest pain while sitting up and leaning forward may have acute pericarditis. The inability to get comfortable in any position often occurs with abdominal and genitourinary disorders, such as cholecystitis, penetrating ulcers, nephrolithiasis, ischemic bowel, and colonic obstruction. Cachexia, with decreased generalized muscle mass or temporal muscle wasting, suggests long-standing disease and is often seen with heart, renal, or hepatic failure, cancer, or nutritional disorders.

Vital Signs

When asked to examine a critically ill patient, careful consideration of the vital signs is often the difference between successful and unsuccessful outcomes. Being called on to evaluate a patient who is acutely decompensated necessitates that the physician obtain vital signs that are current and accurate. A "tachycardia" can occur when a cardiac monitor inadvertently counts the T wave. Similarly, "hypotension" may be urgently reported only to reveal an improperly situated or sized blood pressure cuff.

A critical aspect of vital sign assessment is the evaluation of trends. A patient whose heart rate has increased from a consistent baseline of 60 to 70 beats/min to 100 beats/min should be a cause for concern, similar to a patient who appears with an initial heart rate of 120 beats/min. Likewise, a patient with a respiratory rate that has gone from 12 to 22 breaths/min should be considered as seriously as one who presents with acute tachypnea.

Temperature

Because core body temperature is carefully controlled within a narrow range, the detection of hyperthermia or hypothermia offers important clinical clues. Normal oral body temperature is approximately 37° C (98.6° F) with early morning temperatures (approximately 1° C lower) compared with later in the afternoon. By convention, fever is defined as an oral temperature greater than 38° C (>100° F), although it is common practice to consider temperatures greater than 38.4° C (>101.1° F) in

hospitalized patients to be clinically significant (albeit without significant data to support this assumption).

Hyperthermia associated with infection (for patients not receiving negative chronotropic agents or with intrinsic cardiac conduction disease) should be accompanied by an increase in the pulse rate of approximately 8.5 beats/min for each 1° C increase in temperature (Liebermeister's rule).¹ The presence of a factitious fever is suggested by the lack of a similar temperature elevation in voided urine compared with the oral temperature. Although a hot drink can quickly increase oral temperature up to 2° C, 5 minutes later the increase is only 0.3° C.²

The pattern of the fever spikes should also be assessed; patterns include intermittent (returning to normal each day), sustained (with minor daily variation [i.e., <0.3° C] suggesting gram-negative infections or pneumonia), remittent (varying >0.3° C each day but not returning to normal), and relapsing (febrile and afebrile days suggesting the Pel-Ebstein fever of Hodgkin disease, *Borrelia* infections, or episodic cholangitis caused by a mobile common bile duct stone). Once-daily spikes (quotidian fever) occur with liver abscesses or acute cholangitis, whereas twice-daily spikes (double quotidian fever) suggest gonococcal endocarditis. Prolonged fever despite antibiotic therapy can also occur with connective tissue disorders, drug fever, neoplasm, abscess, or antibiotic-resistant organisms and superinfection.

The presence of hypothermia (oral temperature <35° C (<95° F)) requires confirmation. Drinking ice water reduces the oral temperature up to 0.6° C (1° F) for 5 minutes.² False-negative hypothermic readings can also occur with ear temperatures taken in the presence of cerumen and oral temperatures recorded in the presence of tachypnea. Confirmed hypothermia requires the assessment of a patient's temperature with a rectal thermometer (which averages approximately 0.6° C (1° F) higher than the oral temperature). The differential diagnosis of true hypothermia includes ambient cold exposure, submersion, hypothyroidism, hypoglycemia, sepsis, and adrenal insufficiency. With hypothermia from submersion or exposure, warming to room temperature is necessary for adequate assessment of end-organ and neurologic function.

Respiration

The respiratory effort, rate, and pattern should be assessed in ventilated and nonventilated patients. Accessory muscle use is common with pulmonary edema, chronic obstructive pulmonary disease (COPD), asthmatic exacerbations, and pneumonia. It may be detected visually or by palpation over the sternocleidomastoid or intercostal muscles. With acute tachypnea (a respiratory rate >25 breaths/min), an immediate assessment should be performed to distinguish peripheral cyanosis (dusky or bluish tinge to the fingers and toes without mucosal or buccal changes) from central hypoxemia (associated with a bluish tinge to the lips or mucosa under the tongue). Peripheral cyanosis may occur with or without hypoxemia, such as in the case of severe peripheral vasoconstriction. This condition is accompanied by cold extremities and compromised capillary refill.

Tachypnea (>25 breaths/min), when secondary to hypoxia, should nearly always be associated with a reflex tachycardia. Although resting tachypnea may occur with cardiopulmonary disease, it may also be present in response to fever, pain, anemia, hyperthyroidism, abdominal distention, respiratory muscle paralysis, obesity, or metabolic acidosis. When tachypnea accompanies chest pain or collapse, acute pulmonary embolism should be included in the differential diagnosis. When tachypnea is present with a history of orthopnea, it suggests the presence of pulmonary edema, pleural effusion or both. When tachypnea is present in a patient being weaned from a ventilator, tachypnea predicts weaning failure.³

Hypopnea is defined as less than 10 shallow or slow breaths per minute. It may be due to severe cardiopulmonary failure, sepsis, central nervous system (CNS) depressants (e.g., sedative-hypnotics, narcotics, and alcohol), or CNS disease (e.g., cerebrovascular accident, meningitis). Hypopnea may also occur secondary to factors that limit inspiration, such as pericarditis or pleuritis, or in the postoperative period.

Breathing patterns can reveal underlying pathology (Table 4-1). Exaggerated deep and rapid respirations were noted by Kussmaul to imply the presence of diabetic ketoacidosis because most causes of hypoxia usually result in *shallow* and rapid respirations. Apneic episodes with snoring suggest obstructive sleep apnea, a potentially treatable contributor to hypertension

Table 4-1. Breathing Patterns

Respiratory Pattern	Consider	Eponym/Classification
Deep and rapid	Diabetic ketoacidosis	Kussmaul respiration
Snoring with episodic apnea	Obstructive sleep apnea	
Waxing and waning tachypnea/hypopnea alternating with apnea	Oversedation Heart failure Severe CNS process Respiratory failure Renal disease (uremia)	Cheyne-Stokes breathing
Irregularly irregular (yet equal) breaths alternating with periods of apnea	Damage to the medulla oblongata (intracranial disease)	Biot breathing
Completely irregular breaths (pauses with escalating periods of apnea)	Severe damage to the medulla oblongata	Ataxic respiration
No breaths or occasional gasps	Severe cardiovascular or neurologic disease	Agonal breathing

CNS, central nervous system.

and right heart failure. Cheyne-Stokes breathing, in which periods of waxing and waning tachypnea and hyperpnea alternate with apnea, occurs in various cardiac, neurologic, and pulmonary disorders or with simple oversedation. When Cheyne-Stokes breathing occurs in the setting of uremia or heart failure, it portends a poor prognosis. Biot breathing is characterized by irregularly irregular breaths of equal depth that are associated with periods of apnea. It can be seen in patients with intracranial disease affecting the medulla oblongata. More severe damage to the medulla oblongata results in ataxic respiration, the complete irregularity of breathing, with irregular pauses and increasing periods of apnea. As this breathing pattern deteriorates further, it merges with agonal respiration.

Orthopnea (shortness of breath while supine) is most commonly present in patients with heart failure and pleural effusion, but also can occur with ascites, morbid obesity, and diaphragmatic paralysis. Alternatively, platypnea (shortness of breath when assuming the upright position) suggests the right-to-left shunting that occurs with an atrial septal defect or intrapulmonary shunt. Trepopnea (shortness of breath while lying on one side) occurs with a right pleural effusion or with unilateral lung or diaphragm disease when the healthy lung is down.^{4,5}

Pulse

The pulse should be assessed bilaterally for presence, rate, volume, contour, and regularity. An initial examination should always contain a description of the radial and carotid arteries, in addition to the brachial, femoral, popliteal, and pedal pulses. This examination is important for patients with hypotension, claudication, arterial insufficiency, or cerebrovascular accident, or after intra-aortic balloon pump insertion. Assessing the pulse for 30 seconds is more accurate than counting for only 15 seconds.⁶

A discrepancy in bilateral upper extremity pulses (especially with decreases in rate or volume on the left side) raises the possibility of aortic dissection, subclavian narrowing secondary to atherosclerosis or congenital webs. If such a discrepancy is present, the examiner should search for evidence of a subclavian steal phenomenon, detected as a decrease in pulse amplitude after raising or exercising the affected arm for approximately 45 seconds (the left side is affected 70% of the time; the reduction in systolic blood pressure is >20 mm Hg 94% of the time).⁷ Aortic dissection is suggested by the presence of a pulse deficit, focal neurologic signs, and mediastinal widening on the chest radiograph.⁸ Diminished lower extremity pulses are consistent with coarctation of the aorta or atherosclerotic disease of the abdominal aorta. Although the detection of low femoral pulse amplitude (or its absence) is crucial for assessing the risk-to-benefit ratio in patients who may require vascular access or device implantation, its diminution or absence after catheterization or intra-aortic balloon pump implantation requires urgent intervention.

When tachycardia (a heart rate >100 beats/min) is present, the regularity of the rhythm offers important diagnostic clues. Regular rhythm rates between 125 beats/min and 160 beats/min suggest sinus tachycardia, the presence of atrial flutter with 2:1 block, or ventricular tachycardia. The presence of intermittent cannon A waves in the neck veins is highly sensitive, whereas a changing intensity of the first heart sound (S_1) is highly specific for the detection of ventricular tachycardia.⁹ Atrial flutter may be accompanied by rapid undulations in the jugular venous pulse (flutter waves or F waves). Because sinus tachycardia may

be due to correctable causes, such as hypovolemia, hypoxia, infection, hyperthyroidism, anemia, or anxiety, or may be due to the pathologic adaptation occurring with chronic heart failure or myocardial ischemia, integration of these clinical suspicions with the nature of the underlying rhythm is important. The use of vagal maneuvers may help differentiate the causes of narrow-complex tachycardia.

The Valsalva maneuver, performed by asking the patient to bear down as if "having a bowel movement" or pushing up the abdomen against the examiner's hand placed on the middle of the abdomen, seems to be more effective than carotid sinus massage, performed by pressing on the neck at the bifurcation of the carotid artery just below the angle of the jaw, at terminating supraventricular tachycardia^{10,11} in 50% of cases. Paroxysmal supraventricular tachycardia (nodal re-entry and reciprocating tachycardias) may be interrupted with enhanced vagal tone. Sinus tachycardia, atrial flutter, and atrial fibrillation usually slow only transiently (but may reveal the underlying rhythm), although an abrupt halving of the rate may occur with atrial flutter. Detection of an irregular tachycardia on physical examination suggests atrial fibrillation, atrial premature beats, or ventricular premature contractions. In atrial fibrillation, assessment of the apical rate (counting heartbeats via auscultation) is more accurate than counting the radial pulse, accounting for a "pulse deficit."¹²

Bradycardia (heart rate <50 beats/min) may be appropriate in trained athletes, but should be asymptomatic and associated with a gradual increase in heart rate with exercise.¹³ Detection of a regular-rhythm bradycardia in a patient with fatigue, mental status changes, or evidence of impaired peripheral perfusion or pulmonary congestion raises the possibility of pharmacologic toxicity (digoxin, β blockers, or calcium channel blockers), hypothermia (owing to hypothyroidism or exposure), or an atrioventricular nodal or ventricular escape rhythm that occurs with complete heart block or sick sinus syndrome.

Appreciation of the pulse volume and contour is also informative (Table 4-2). Tachycardia with a bounding pulse is present with septic shock (owing to the acute reduction in afterload), hyperthyroidism, or the sudden collapse of the pulse with chronic aortic insufficiency (a water-hammer pulse). Consistent with the presence of chronic aortic insufficiency is the accentuation of the radial pulse when the examiner lifts the whole arm above the patient's head (Mayne's sign). A weak and thready pulse may be

Table 4-2. Pulse Characteristics

Pulse Description	Consider
Bounding	Septic shock, hyperthyroidism, chronic AI
Weak and thready	Severe LV dysfunction, hypovolemia, severe MR, complete heart block, pericardial effusion
Slow rising and weak	Severe AS
Alternating between strong and weak	LV dysfunction, pericardial tamponade
Double tap (pulsus bisferiens)	Hypertrophic cardiomyopathy, AS with AI

AI, aortic insufficiency; AS, aortic stenosis; LV, left ventricular; MR, mitral regurgitation.

present with severe left ventricular dysfunction, hypovolemia, severe mitral regurgitation, or complete heart block. A slow rising and weak carotid pulse (*pulsus parvus et tardus*) is consistent with a diagnosis of severe aortic stenosis, whereas a regular pulse that alternates between weak and strong (*pulsus alternans*) occurs with left ventricular dysfunction or pericardial tamponade. A “double tap” during systole (*pulsus bisferiens*) can occur with either hypertrophic cardiomyopathy or the combination of aortic stenosis and aortic insufficiency.^{14,15} In the presence of a *bisferiens* pulse, two soft and rapid sounds can be auscultated with each cardiac cycle as the brachial artery is compressed by a blood pressure cuff proximally.¹⁶

Irregular rhythms are classified as either *regularly irregular*, where the irregular beat can be anticipated at a fixed interval, or *irregularly irregular*, where the irregular beat occurs without predictability. A regularly irregular pulse commonly occurs with second-degree atrioventricular block (either Mobitz I or II, depending on whether the P–R interval is constant or lengthening before the dropped beat) or with interpolated ventricular premature beats. On the physical examination, the P–R interval can be visualized as the distance between the a wave and c wave on the jugular venous pulse (JVP). This distance, before and after the dropped beat, can be diagnostic when the electrocardiogram is unable to differentiate between Mobitz type I and II second-degree block. When an interpolated ventricular premature beat is present, it may be accompanied by a weakened pulse (owing to inadequate ventricular filling) that occurs at a fixed interval from the regular pulse.

An irregularly irregular pulse implies that the examiner cannot anticipate when the next beat will occur, and may be due to ventricular premature beats, atrial premature beats, multifocal atrial tachycardia, or atrial fibrillation. Although ventricular premature beats and atrial fibrillation are associated with a pulse deficit (where the auscultated apical rate is greater than the palpable radial pulse), the pulse that follows a ventricular premature beat should be stronger. It is clinically relevant to realize that significant numbers of ventricular premature beats can compromise cardiac output. Alternatively, if the beat following a ventricular premature beat is diminished (Brockenbrough sign), hypertrophic cardiomyopathy or severe left ventricular dysfunction should be considered. No pulse deficit (or compensatory pause) should be present with atrial premature beats or multifocal atrial tachycardia. The physician can differentiate atrial premature beats from ventricular premature beats by tapping out the rhythm with his or her hand. Atrial premature beats result in a beat that occurs while the physician's hand is “up.” Although a ventricular premature beat also occurs with the hand in the “up” position, the pulse resumes on the second down-beat after the compensatory pause.

Blood Pressure

In the ICU, there is no rule defining “normal blood pressure.” *Adequate* blood pressure varies by patient and clinical status, but is generally believed to consist of a mean perfusion pressure of at least 60 mm Hg and the absence of end-organ hypoperfusion. For accurate assessment, an adequately sized blood pressure cuff must be used (there are lines on all blood pressure cuffs to indicate adequate sizing) and should be correctly situated around the bicep (and not over clothing). A blood pressure obtained with a cuff that is too short or narrow, especially if the patient is obese or has an enlarged upper arm, may result in a factitiously elevated blood pressure.^{17,18}

Although palpation of pulses is commonly used in emergency situations to estimate systolic blood pressure (i.e., palpation of a radial pulse suggests a minimum systolic blood pressure of 80 mm Hg; a femoral pulse, a blood pressure of at least 70 mm Hg; and a carotid pulse, a blood pressure of at least 60 mm Hg), the overall accuracy of this estimation has been questioned.¹⁹ To obtain the palpable systolic blood pressure, the cuff should first be inflated until the radial pulse is no longer palpable (usually 150 to 200 mm Hg) and then slowly deflated (2 to 3 mm Hg per second) until the pulse returns.

For the auscultatory blood pressure, inflation should be repeated (inflate the cuff to 10 mm Hg above the palpable systolic blood pressure) and listen for the first and fifth (last audible) Korotkoff sounds during slow cuff deflation. The diastolic blood pressure may be difficult, if not impossible, to appreciate in the presence of fever, severe anemia, aortic insufficiency, thyrotoxicosis, vitamin B₁ deficiency, or Paget disease. For patients in atrial fibrillation or with significant ventricular arrhythmias, a relatively accurate blood pressure assessment is obtained by averaging three individual readings.

In patients with left ventricular systolic dysfunction, multiple etiologies of hypotension require assessment during the physical examination. Although hypotension may be caused by overly aggressive diuresis, it may also occur because of volume overload. The presence of a tachycardia with orthostatic hypotension (a blood pressure decrease of >20 mm Hg systolic or >10 mm Hg diastolic when the patient is assessed first in the supine position and then again after 2 minutes with the patient standing or sitting with legs dangling) is consistent with volume depletion. The differential diagnosis of hypotension includes factors that reduce systemic vascular resistance (e.g., infection, inflammation, adrenal insufficiency, anesthetic agents, atrioventricular malformations, and vascular insufficiency), stroke volume (e.g., hypovolemia, aortic stenosis, severe mitral regurgitation, ventricular arrhythmias, and left ventricular dysfunction owing to infarction, ischemia, or a cardiomyopathy), and heart rate (e.g., heart block or pharmacologic bradycardia).

Hypotension without a concomitant increase in the pulse rate (in the absence of medications that can blunt a heart rate response) raises the possibility of autonomic dysfunction. The presence of a *pulsus paradoxus* (a >10 mm Hg decrease in systolic blood pressure occurring at end-expiration with the patient breathing *normally*) can occur with cardiac tamponade (very sensitive when occurring with tachycardia, jugular venous distention, and an absent y descent),^{20,21} constrictive pericarditis (occurring with jugular venous distention that persistently augments with inspiration, a pericardial knock, hepatomegaly, and an exaggerated y descent),²² severe hypertension, pulmonary embolism, COPD, and severe obesity.

With appropriate clinical scenarios, blood pressure should also be assessed in both arms and one leg. Leg blood pressure can be assessed by placing the blood pressure cuff around the calf and using the dorsalis pedis pulse for auscultation or Doppler interrogation. A systolic blood pressure difference greater than 10 mm Hg between arms suggests aortic dissection, proximal aortic aneurysm, or subclavian artery stenosis. With coarctation of the aorta, arm blood pressures are greater than blood pressures in the legs (this may also be accompanied by underdeveloped lower extremity musculature compared with upper extremity musculature). Leg blood pressure that is more than 15 mm Hg higher than arm blood pressure suggests aortic

dissection, aortic insufficiency, or a proximal vasculitis (i.e., giant cell or Takayasu arteritis).

The pulse pressure ([systolic blood pressure – diastolic blood pressure] may also be informative. A low pulse pressure may be present with the decreased stroke volume of hypovolemia, tachycardia, severe aortic or mitral stenosis, pericardial constriction, or cardiac tamponade. With appropriate clinical suspicion, it has a high sensitivity and specificity to predict a cardiac index less than 2.2 L/min/m² when the pulse pressure divided by the systolic pressure is less than 0.25. A wide pulse pressure (>60 mm Hg) can be seen with hyperthermia, but may also suggest greater than moderate chronic aortic insufficiency or high output failure owing to severe anemia, thyrotoxicosis, atrioventricular malformation, sepsis, vitamin B₁ deficiency, or Paget disease. If the wide pulse pressure is present in just one arm, a search for an atrioventricular fistula distal to the site of blood pressure cuff should be undertaken.

Weight

The daily weight is an important vital sign. It often proves to be especially significant for patients in whom volume overload or hypovolemia subsequently complicates the clinical picture. When a weight appears inconsistent with prior weights or the clinical history, the clinician should not hesitate to have the patient reweighed. Noting an increase in weight may be crucial to discern the presence of volume overload in a patient with shortness of breath, whereas loss of weight should occur in patients being diuresed. A weight gain despite the presence of effective diuresis suggests increased fluid intake, either orally or via the intravenous route.

Head, Eyes, Ears, Nose, and Throat Examination

In the presence of an endotracheal or nasogastric tube, the physician first should ensure that the tube is not causing a pressure injury. If the patient has a neck or subclavian central line or Swan-Ganz catheter, the physician must ensure it is secured and uninfected. The head, eyes, ears, nose, and throat examination can also suggest the presence of several syndromes.

In adults, a large skull suggests Paget disease (with associated high output failure) or acromegaly (with frontal bossing and large features). A high arched palate, associated with a wide pulse pressure and pectus excavatum, is consistent with Marfan syndrome. Coarse hair texture or hair loss from the head, axilla, or pubic region suggests hypothyroidism. Temporal artery tenderness suggests the presence of temporal arteritis.

Eyelid xanthelasma or a corneal arcus or both may occur with either hypercholesterolemia or diabetes mellitus. Yellowed sclera are seen with hyperbilirubinemia, whereas blue sclera can be seen in Marfan and Ehlers-Danlos syndromes. Dry, puffy, and sunken (enophthalmic) eyes are consistent with hypothyroidism, whereas exophthalmic eyes with lid lag (white sclera visible between the margin of the upper eyelid and the corneal limbus with the patient looking downward) associated with a lid lag (an immobility or lagging of the upper eyelid on downward rotation of the eye) and lid retraction (widening of the palpebral fissure) are associated with hyperthyroidism. Periorbital edema is seen with the hypoalbuminemia of hepatic disease, a protein-losing nephropathy, or the superior vena cava syndrome.

The lack of periorbital edema with diffuse peripheral edema is a distinguishing feature of a cardiac versus hepatic or renal cause of peripheral edema; it is due to the inability of patients with heart failure and severe volume overload to elevate their upper torso to breathe more comfortably. Conjunctival pallor is a very specific sign of anemia, and this diagnosis is reinforced by the presence of concomitant palmar and palmar crease pallor.²³

When firmly palpating the patient's thyroid gland with the neck flexed (to relax the sternohyoid and sternocleidomastoid muscles), significant findings can include an enlarged thyroid (size appreciated larger than an inch) and the presence of nodules (4% prevalence; most are benign). It is important to note the size and site of these nodules for follow-up examinations.²⁴ During swallowing, the thyroid gland rises upward with the trachea to allow location of a neck mass either within or outside the thyroid gland.

Jugular Venous Pulse and Abdominojugular Reflux

The internal jugular venous pulse (JVP) is useful manometer for right atrial pressure. However, it is only accurate in indicating intravascular volume status and pulmonary capillary wedge pressure in the absence of tricuspid stenosis, right ventricular dysfunction, pulmonary hypertension, and a restrictive or constrictive cardiomyopathy. The JVP should be sought by first asking the patient to lift their chin up and turn to the left against the resistance of the examiner's right hand. Within the triangle formed by the visible heads of the sternocleidomastoid muscle and the clavicle, the examiner should then search with the neck muscles relaxed, for the weak impulses of the jugular vein along a line from the jaw to the clavicle. Shining a tangential light from slightly behind the neck can accentuate the visibility of the transmitted venous impulses. Simultaneous palpation of the radial pulse, assuming the patient is in sinus rhythm, allows detection of a neck pulsation (a wave) immediately preceding the peripheral pulse (Fig. 4-1). Alternatively, one can visualize the x descent as an inward movement along the line of the jugular vein that occurs simultaneously with the peripheral pulse.

In patients with presumed volume overload, jugular venous distention may be best assessed with the patient sitting upright

Figure 4-1. Timing of jugular venous pressure. ECG, electrocardiogram.

at 90 degrees, a position in which the clavicle is approximately 7 to 8 cm above the right atrium (equivalent to the upper limit of normal for right atrial pressure, 5 to 7 mm Hg). The 7 to 8 cm is added to the maximal vertical distance at which any venous pulsations are seen above the clavicle to estimate the right atrial pressure. If the JVP cannot be appreciated in the upright position, an attempt can be made to visualize it sequentially with the upper body at a 45-degree angle (where only 4 to 5 cm is needed to the distance above the clavicle where the venous pulsations were seen). If venous pulsations are still difficult to discern, either of two extremes may be present: either the lack of elevation of the right atrial pressure or jugular venous distention above the angle of the jaw, even in the upright position.

A low right atrial pressure may be investigated further by increasing right atrial filling (i.e., with deep inspiration or passive leg elevation). The left internal jugular vein is less useful than the right internal jugular vein for estimation of the JVP because of the presence of valves impeding venous return or compression of the innominate vein. When it must be used, right atrial pressure should be considered approximately 1 cm lower than the visualized left internal jugular pulse.^{25,26} Likewise, the external jugular veins should be avoided in assessing the JVP because of the extreme angle with which they contact the superior vena cava, and their occasional absence or diminution in the presence of elevated catecholamine levels.²⁷

Although the value of sequential assessment of the JVP has been confirmed by studies of patients with left ventricular dysfunction,²⁸ patients undergoing cardiac catheterization for dyspnea or chest pain,²⁹ and patients with suspected chronic heart failure,³⁰⁻³² it is important to confirm these findings with additional signs of volume overload in the acute setting.^{33,34} When an increasing creatinine value is seen despite the presence of an elevated JVP (with or without diuresis), the differential diagnosis includes refractory left ventricular dysfunction requiring inotropic support, severe right ventricular dysfunction, restrictive or constrictive cardiomyopathy or right heart failure, or underlying renal dysfunction or renovascular disease. With right ventricular dysfunction, the assessment of JVP as a measure of pulmonary capillary wedge pressure becomes progressively less accurate.

Abdominojugular reflux is deemed present when the height of the neck vein distention, visualized with the patient's neck at a 45-degree angle, is increased by at least 3 cm (and maintained for approximately 15 seconds) during a steady pressure of approximately 20 to 35 mm Hg applied over the right upper quadrant or midabdomen (you can learn what exerting 20 to 35 mm Hg of pressure feels like by compressing an inflated blood pressure cuff against a flat surface until the sphygmomanometer reads 30 mm Hg). It is important to instruct patients not to hold their breath because the Valsalva maneuver negates the effect of abdominal pressure. The increased abdominal pressure on the mesenteric or splanchnic veins increases venous return to the right ventricle. With right or biventricular heart failure (and the limited ability to increase right and left ventricular output), distention of the internal jugular vein occurs. A positive abdominojugular reflux effect may also occur with tricuspid stenosis, tricuspid insufficiency, constrictive pericarditis, restrictive cardiomyopathy, pulmonary hypertension, and mitral stenosis. Although limited data are available in the ICU setting, abdominojugular reflux in patients presenting to the emergency department had a low sensitivity (33%) but a high specificity (94%; $P = .028$) for the diagnosis of heart failure. However,

its sensitivity significantly increases in patients with known chronic congestive heart failure,³² when abdominojugular reflux is absent it cannot be taken as evidence *against* the diagnosis of heart failure.³⁵

Chest and Lung Examination

The thorax should first be examined for the presence of an old sternotomy (suggesting prior coronary artery bypass grafting, valve replacement, or congenital heart disease) or thoracotomy scars (suggesting prior pulmonary pathology). If the patient is intubated, the physician needs to ensure that both sides of the chest are expanding evenly.

Although Laënnec's invention of the stethoscope rendered obsolete the need for the physician to place the ear directly against the chest wall to appreciate heart and lung sounds, modern technology has yet to replace the need for daily auscultation of the lungs via the stethoscope (Table 4-3). The waning ability of physicians to appreciate reliably abnormalities in the lung examination undoubtedly limits the information available for patient management, however.³⁶ The lung bases should be auscultated in an alternating fashion, beginning at the lateral posterior aspects of the lung fields and following a side-by-side trek up the lung fields. Although the diaphragm of the stethoscope is used to detect most normal and pathologic lung sounds, the bell is more advantageous for detecting the rhonchi associated with primary tuberculosis or fungal disease in the apices.

Crackles (or rales) are discontinuous lung sounds (that sound like Velcro being pulled apart) generated when an abnormally closed airway snaps open, usually at the end of inspiration.³⁷ "Clear lungs" may be present in 25% of patients presenting with heart failure.³¹ The Boston Criteria for Heart Failure gives 1 point if the crackles are basilar and 2 points if they extend further.³⁸ Crackles have a low sensitivity but high specificity to predict the presence of left ventricular dysfunction or an elevated pulmonary capillary wedge pressure.^{29,30,32} Crackles may also be caused by interstitial lung disease, amiodarone toxicity, pulmonary fibrosis, or COPD.³⁹

Table 4-3. Auscultation of the Lungs

Breath Sound	Consider
Rhonchi	
Diffuse	COPD
Localized	Pneumonia, tumor, foreign body
Stridorous	Large airway obstruction
Wheezes	
Expiratory	Reactive small airway obstruction (asthma, allergies, β blockers)
De novo	Nonasthmatic causes (mass, pulmonary embolism, pulmonary edema, aspiration, foreign body)
Crackles or rales	Pulmonary edema, interstitial lung disease, COPD, amiodarone toxicity

COPD, chronic obstructive pulmonary disease.

Rhonchi (coarse, dry, leathery sounds) are present in the setting of large airway (bronchial) turbulent flow caused by inflammation and congestion, and occur in the ICU most commonly with pneumonia or COPD. When detected, it should be noted whether they occur during inspiration or expiration, and if they are generalized or localized. Stridor refers to loud, audible, and inspiratory rhonchi that suggest extrathoracic large airway obstruction. Diffuse rhonchi suggest generalized airway obstruction that occurs with COPD. Localized rhonchi suggest pneumonia or obstruction owing to tumor or a foreign body. Generally, rhonchi caused by mucous secretions subside or altogether disappear with coughing.

The presence of expiratory wheezes (continuous and high-pitched musical sounds) often denotes reactive small airway obstruction. Because airway size is reduced in the recumbent position, wheezing should worsen when lying down. When accompanied by a prolonged expiratory phase, wheezes signify the presence of airflow through a narrowed tract that is often seen with asthma, allergies, or the toxic effects associated with β blockade. In some patients, the presence of pulmonary edema may result in musical breath sounds similar to wheezes, giving rise to the term *cardiac asthma*. When wheezing is detected de novo in an older patient, a search for nonasthmatic causes, including obstructing masses, pulmonary embolism, pulmonary edema, aspiration pneumonitis, and foreign-body obstruction, is warranted.⁴⁰ Decreased or absent breath sounds in a lung field are consistent with atelectasis, pneumothorax, pleural effusions, COPD, acute respiratory distress syndrome, or pleural thickening.

Egophony (when a verbalized “E” is appreciated via auscultation as an “A”) occurs in the presence of a pleural effusion, but can also be heard with lung consolidation and pneumonia. Although not sensitive, egophony is specific for a parapneumonic process.⁴¹ Lung consolidation can be confirmed further by the presence of bronchophony (when “clearer” voice sounds are heard over consolidated lung tissue). Bronchial breath sounds (breath sounds that are louder than normal) are also heard when consolidation of lung tissue is present because solid tissue transmits sound better than tissue filled with air. When bronchial breath sounds are heard and accompany a dull area to percussion at the base of the left scapula, it suggests the presence of a large pericardial effusion (Ewart sign).

Dullness to percussion at the lung base suggests the presence of pleural effusion and rarely lung consolidation. If the percussive dullness responds to postural changes (i.e., diminution in the left lateral decubitus position), a pleural effusion is likely present.⁴² Although left-sided pleural effusions are common after chest surgery (e.g., post-coronary artery bypass graft surgery after left internal mammary artery dissection) and with pancreatitis or pancreatic cancer, bilateral or right-sided effusions are more consistent with heart failure. Pleural effusions may also occur with pneumonia, hypoalbuminemia (seen with nephrotic syndrome or cirrhosis), and nearly all types of malignancy.

Thorax and Heart Examination

The thorax should be appreciated by looking upward at the chest from the foot of the bed. This view may reveal a pectus excavatum (a congenital anterior chest wall deformity producing a concave, or caved-in, appearance that suggests Marfan or Ehlers-Danlos syndrome or right heart failure), pectus carinatum (an outward “pigeon chest,” protrusion of the anterior chest wall associated

with decreased lung compliance, progressive emphysema, and a predisposition to respiratory tract infections), and barrel chest deformities (with increased anteroposterior chest diameters that may be observed with obstructive forms of chronic pulmonary disease such as cystic fibrosis and severe asthma).

When the examiner is positioned on the right side of the patient, visible or palpable precordial pulsations may be appreciated owing to a thin body habitus or secondary to cardiac disease. Pulsations in the second intercostal space to the left of the sternal border suggest an elevated pulmonary artery pressure, whereas pulsations seen in the fourth intercostal space at the left sternal border are consistent with right ventricular dysfunction or an acute ventricular septal defect. Apical pulsations may be secondary to systemic hypertension, left ventricular hypertrophy, hemodynamically significant aortic stenosis, or a left ventricular aneurysm. With the examiner standing on the right side of the patient, the left ventricular apex is palpated by placing the right hand transversely across the precordium under the nipple, and is perceived as an upward pulsation during systole against the examiner's hand. An enlarged apical impulse is variously described as an impulse detected more than 2 cm to the left of the midclavicular line in the fifth intercostal space or as greater than the size of a quarter and palpable in at least two interspaces. Recognition may be enhanced with the patient in the left lateral decubitus position or when sitting up and leaning slightly forward.

Detection of left ventricular enlargement is a function of age (it increases steadily for men and women, occurring in 66% of men and 58% of women in the 65- to 69-year age range and 82% of men and 79% of women >85 years).⁴³ It has a sensitivity of approximately 65% and a specificity of 95%, with a negative predictive value of 94% for predicting left ventricular systolic dysfunction.³⁰ Although obesity may limit the detection of the left ventricular apical impulse, a displaced impulse is effective in suggesting the diagnosis of heart failure, even in patients with COPD.⁴⁴ Fluid or air in the right pleural cavity, a depressed sternum, and secondary retraction of the left lung and pleura all can result in an apparent augmentation of the left ventricular impulse, however.⁴⁵ Left ventricular enlargement is suggested further by the presence of a sustained apical impulse (persisting more than halfway between S1 and S2 during simultaneous auscultation and palpation). If the left ventricular apical impulse is detectable at end-systole, a dyskinetic ventricle is most likely. If the apical impulse seems to retract during systole, the presence of constrictive pericarditis or tricuspid regurgitation should be considered.

All auscultatory fields should be palpated with the fingertips to detect a thrill (establishing the presence of a grade IV/VI murmur). In addition, the presence of a palpable P2 (an upward pulsation during diastole in the pulmonic position) suggests the presence of either secondary (acute pulmonary embolism, chronic mitral regurgitation or stenosis) or primary pulmonary hypertension. When a pulsation is palpable in the aortic position during systole, it suggests either hypertrophic cardiomyopathy or severe aortic stenosis, whereas its presence over the left sternal border in the fourth intercostal space, especially in the setting of an acute myocardial infarction, raises the possibility of a ventricular septal defect. A presystolic impulse (correlating with the a wave and equivalent to an audible S₄) suggests ventricular noncompliance, and may be present with myocardial ischemia or infarction or with left ventricular hypertrophy secondary

to hypertension, aortic stenosis, acute mitral regurgitation, or hypertrophic cardiomyopathy.

Auscultation of the Heart

Cardiac auscultation in the acute care setting allows for the detection of common holosystolic (mitral regurgitation and ventricular septal defect), systolic ejection (aortic stenosis or hypertrophic cardiomyopathy), and diastolic (aortic insufficiency and mitral stenosis) murmurs that can precipitate or exacerbate a decompensation in the ICU or the presence of abnormal heart sounds indicating underlying pathology (Table 4-4). Rapid assessment can often be lifesaving, but it should not replace a more systematic investigation when acute stabilization has occurred.

S_1 , best appreciated as a high-pitched and split sound at the cardiac apex, is produced at the time of mitral (M_1) and tricuspid (T_1) valve closure, and occurs before the upstroke of the peripheral pulse. An accentuated S_1 is present when the mitral or tricuspid valves are widely separated in diastole (i.e., with atrial fibrillation, with a shortened P–R interval, or in the presence of an obstructing myxoma) or with mitral or tricuspid valves that are difficult to open (i.e., mitral or tricuspid stenosis when the valves have become calcified). When a stenotic valve becomes nearly immobile, however, the intensity of S_1 decreases. A soft S_1 may be present when the valves are already nearly closed at the onset of systole, as occurs with moderate to severe aortic insufficiency, with advanced heart failure, with a prolonged P–R interval, or when the mitral valves are incompetent (owing to

papillary muscle dysfunction, ventricular dilation, or myxomatous degeneration).

S_2 , which occurs at the time of closure of the semilunar aortic (A_2) and pulmonary (P_2) valves, is probably caused by the deceleration of blood in the root of the pulmonary artery and aorta at end-systole. It is best appreciated in the second intercostal space, midclavicular line (pulmonic position) using the diaphragm of the stethoscope. Normally, the intensity of A_2 exceeds the intensity of P_2 . A soft A_2 can occur in the setting of incompetent aortic valves (e.g., aortic insufficiency), a decrease in the distance that the valves have to traverse (e.g., severe aortic stenosis), or a decreased diastolic pressure closing the aortic valve (e.g., with sepsis or an atrioventricular fistula), or secondary to physical muffling of heart sounds that occur with the air trapping of COPD. An accentuated S_2 may be caused by a loud A_2 (e.g., severe systemic hypertension or aortic dilation) or a loud P_2 (e.g., pulmonary hypertension). During auscultation, an accentuated P_2 is said to occur when the pulmonary component of S_2 is louder than S_1 in the fourth to sixth intercostal spaces. Associated findings may include a prominent a wave, an early systolic click (caused by the sudden opening of the pulmonary valve against a high pressure), and a left parasternal lift signaling the presence of right ventricular hypertrophy.

The timing of S_2 splitting into A_2 and P_2 components should be described. Normally, A_2 precedes P_2 . *Wide splitting* of S_2 (when P_2 is delayed relative to A_2) occurs with early aortic valve closure (e.g., severe mitral regurgitation) or delayed pulmonic valve closure (e.g., right bundle branch block, with a secundum atrial septal defect or with pulmonary hypertension). *Paradoxical splitting*, when A_2 occurs after P_2 , may occur because of early pulmonary valve closure (e.g., severe tricuspid insufficiency or with pre-excitation with early right ventricular contraction); delayed activation of the left ventricle (e.g., left bundle branch block); or the prolongation of left ventricular contraction that occurs with hypertension, aortic stenosis, or severe systolic dysfunction. *Fixed splitting*, when the time interval between A_2 and P_2 is not increased during inspiration, may be due to a large atrial septal defect and severe right ventricular failure. Currently, no evidence-based assessments of these findings in the critical care setting are available.

S_3 , which occurs early in diastole, is best appreciated at end-expiration with the bell near the apex and with the patient in the left lateral decubitus position. This low-pitched sound occurs approximately 0.16 second after S_2 . Although often normal when detected in children and young adults, S_3 in patients older than age 40 implies an increase in the passive diastolic filling of either the right (RVS_3) or the left (LVS_3) ventricle. LVS_3 may be detected in patients with heart failure; hypertrophic cardiomyopathy, left ventricular aneurysm; or with hyperdynamic states (e.g. thyrotoxicosis, arteriovenous fistula, hyperthermia, and sepsis). A retrospective analysis of the SOLVD database noted that the presence of LVS_3 in patients with symptomatic chronic left ventricular dysfunction was associated with an increased risk of hospitalization for heart failure and death from pump failure.²⁸ The presence of S_3 in patients with advanced heart failure had 68% sensitivity and 73% specificity for detecting a pulmonary capillary wedge pressure greater than 18 mm Hg.³² RVS_3 is best appreciated with the patient in the supine position, while listening over the third intercostal space at the left sternal border. It is accentuated during inspiration because of rapid

Table 4-4. Clinical Auscultation of S_1 , S_2 , S_3 , and S_4

Heart Sound	Consider
S_1	
Accentuated	Atrial fibrillation, mitral stenosis
Soft	Immobile mitral valves, MR or severe AI
S_2	
Accentuated	(P_2) Pulmonary hypertension; (A_2) Systemic hypertension; Aortic dilation
Soft	(A_2) AI, sepsis, AV fistula
A_2-P_2 splitting	
Wide	Severe MR, RBBB, atrial septal defect (secondary), pulmonary hypertension
Paradoxical	Severe TR, WPW, LBBB, severe hypertension or AS
Fixed	Large atrial septal defect, severe RV failure
S_3	
Present	Heart failure, HOCM, thyrotoxicosis, AV fistula, sepsis, hyperthermia
S_4	
Present	Ischemic or infarcted LV, hypertrophic, dilated or restrictive cardiomyopathy

AI, aortic insufficiency; AS, aortic stenosis; AV, atrioventricular; HOCM, hypertrophic obstructive cardiomyopathy; LBBB, left bundle branch block; MR, mitral regurgitation; RBBB, right bundle branch block; TR, tricuspid regurgitation; WPW, Wolff-Parkinson-White.

right ventricular filling, and occurs with severe tricuspid insufficiency or right ventricular failure.

S_4 is a low-pitched sound best heard with the bell of the stethoscope at the apex in the left lateral decubitus position. It occurs just before S_1 and can be readily distinguished from a split S_1 by its ability to be extinguished by firm pressure on the bell. S_4 is believed to be due to the vigorous atrial contraction necessary to propel blood into a stiffened left ventricle (and is absent in atrial fibrillation). The stiffened left ventricle may be present with an ischemic or infarcted left ventricle or with hypertrophic, dilated, or restrictive cardiomyopathy. Because diastolic and systolic defects can result in S_4 , its presence does not contribute to their differentiation.⁴⁶ Similar to RVS_3 , RVS_4 increases in intensity with inspiration. When LVS_3 and LVS_4 are appreciated, usually in the setting of tachycardia with systolic dysfunction, a summation gallop is said to be present.

Three additional diastolic sounds should be sought during routine evaluation. (1) A high-pitched early diastolic click is caused by abnormal semilunar valves (bicuspid aortic valve or pulmonic stenosis), dilation of the great vessels (aortic aneurysm or pulmonary hypertension), or augmented flow states (truncus arteriosus or hemodynamically significant pulmonic stenosis). (2) A mid-diastolic opening snap, occurring approximately 0.08 second after S_2 and best appreciated in the fourth intercostal space at the left sternal border or apex, is caused by the opening of a stenotic (although pliable) mitral valve. The opening snap disappears when the valve becomes severely calcified. Shortening of the interval from S_2 to the opening snap occurs as the left atrial pressure increases, and indicates progressive disease severity. The opening snap of a stenotic mitral valve can be differentiated from a split S_2 by a widening of the S_2 –opening snap interval that occurs when a patient with mitral stenosis stands up. (3) A dull-sounding early diastolic to mid-diastolic knock suggests the abrupt cessation of ventricular filling that occurs secondary to a noncompliant and constrictive pericardium.

Heart Murmurs: Static and Dynamic Auscultation

Heart murmurs are appreciated as systolic, diastolic, or continuous, and should be described further according to their location, timing, duration, pitch, intensity, and response to dynamic maneuvers (Table 4-5). Although the gradations I–III are arbitrary (grade I, very faint, difficult to hear; grade II, faint, but readily identified; and grade III, moderately loud), the presence of a grade IV murmur always denotes the presence of an associated palpable thrill. Grade V is a louder murmur with a thrill, whereas grade VI occurs when the murmur is heard with the stethoscope physically off the chest wall.

Holosystolic murmurs, with a soft or obliterated S_2 , occur with tricuspid regurgitation, ventricular septal defects, and mitral regurgitation. Tricuspid regurgitation is suggested when the holosystolic murmur is best appreciated in the fourth intercostal space along the left sternal border and augments on inspiration, with passive leg elevation, and with isometric handgrip. The presence of pulsations in the fourth intercostal space at the left sternal border suggests either a ventricular septal defect or concomitant right ventricular dilation or dysfunction. In the setting of an acute inferior wall or extensive anterior wall myocardial infarction, the presence of a new holosystolic murmur occurring with a palpable right ventricular lift requires that an acute ventricular septal defect be excluded. The holosystolic murmur of mitral regurgitation is best appreciated at the apex during end-expiration in the left lateral decubitus position, and is associated with a soft S_1 . With severe mitral regurgitation, it may be associated with a slowly increasing peripheral pulse owing to partial runoff of the left ventricular volume into the left atrium.

With acute mitral regurgitation, the murmur may be absent or may appear earlier or later in systole. When mitral regurgitation is severe, evidence of pulmonary hypertension may also be present. Posterior mitral leaflet involvement results in a murmur that radiates anteriorly, whereas posterior radiation into the axilla suggests anterior mitral valve leaflet dysfunction. In more stable patients in whom positional changes are possible,

Table 4-5. Dynamic Cardiac Auscultation

Maneuver	Physiology	TR	PS	VSD	MR	AS	HOCM	AI
Inspiration	Increased venous return and ventricular volume	↑	↑		nc*/↑			
Expiration	Brings heart closer to the chest wall	↑			nc/↑			
Leg elevation	Increased SVR; increased venous return						↓	
Mueller maneuver	Decrease CVP/BP/SNA (10 sec), then increase in BP/SNA (5 sec) and surge in BP/decrease SNA with release	↑						
Valsalva maneuver	Decreased venous return and ventricular volumes (phase 2)		↓		↓	↓	↑	↓
Squatting to standing	Decreased venous return and volume	↓	↓	↓	↓	↓	↑	
Standing to squatting	Increased venous return; increased SVR			↑	↑	↑	↓	↑
Handgrip	Increased SVR; increased CO; increased LV filling pressures			↑	↑	↓	↓	↑

Note: Inspiration also increases the murmur of tricuspid stenosis and pulmonary regurgitation.

*nc, no changes.

AI, aortic insufficiency; AS, aortic stenosis; BP, blood pressure; CO, cardiac output; CVP, central venous pressure; HOCM, hypertrophic obstructive cardiomyopathy; LV, left ventricular; MR, mitral regurgitation; PS, pulmonary stenosis; TR, tricuspid regurgitation; SNA, sympathetic nerve activity; SVR, systemic vascular resistance; VSD, ventricular septal defect.

prompt squatting from a standing position results in a rapid increase in venous return and peripheral resistance that causes the murmur of mitral regurgitation (and aortic insufficiency) to grow louder. A similar phenomenon occurs with isometric handgrip, although the exact mechanism is unknown.

The harsh systolic ejection murmur of aortic stenosis begins shortly after S_1 , peaks toward midsystole, and ends before S_2 (crescendo-decrescendo). It is best appreciated in the second intercostal space to the right of the sternal border and radiates into the right neck. The absence of this radiation should bring the diagnosis into question. A systolic thrill may be palpable at the base of the heart, in the jugular notch and along the carotid arteries. Associated findings include an ejection click (occurring with a bicuspid valve, which disappears as the stenosis becomes more severe) and, with increasing severity, a slow increase and plateau of a weak carotid pulse (pulsus parvus et tardus).⁴⁷ The severity of the obstruction is related to the duration of the murmur to its peak and not its intensity. An early-peaking murmur is usually associated with a less stenotic valve, whereas a late-peaking murmur, suggesting a longer time for the ventricular pressure to overcome the stenosis, suggests a more severe stenosis. A nearly immobile and stenotic aortic valve can result in a muted or absent S_2 . The high-pitched, diastolic blowing murmur of aortic regurgitation frequently occurs with aortic stenosis.

Hypertrophic cardiomyopathy is also associated with a crescendo-decrescendo systolic murmur. It is best appreciated *between* the apex and left sternal border, however, and although it radiates to the suprasternal notch, it does *not* radiate to the carotid arteries or neck. The murmur of hypertrophic cardiomyopathy can also be distinguished from aortic stenosis by an increase in murmur intensity (when the outflow tract gradient is increased) that occurs during the active phase of the Valsalva maneuver, when changing from sitting to standing (the left ventricular volume abruptly decreases) and with the use of vasodilators. Hypertrophic cardiomyopathy may also be accompanied by the holosystolic murmur of mitral regurgitation owing to the anterior motion of the mitral valve during systole.

Although S_3 and S_4 are common with hypertrophic cardiomyopathy, they lack prognostic significance. Additional findings include a laterally displaced double apical impulse (resulting from the forceful contraction of the left atrium against a non-compliant left ventricle) or a triple apical impulse (resulting from the late systolic impulse that occurs when the nearly empty left ventricle undergoes near-isometric contraction). Similarly, a double carotid arterial pulse (pulsus bisferiens) is common because of the initial rapid increase of blood flow through the left ventricular outflow tract into the aorta, which declines in midsystole as the gradient develops, only to manifest a secondary increase during end-systole. The jugular venous pulse reveals a prominent a wave owing to the diminished right ventricular compliance associated with septal hypertrophy.

Diastolic murmurs are caused by insufficiency of the aortic or pulmonary valves or stenosis of the mitral or tricuspid valves. Chronic aortic insufficiency is heralded by a high-frequency, early diastolic decrescendo murmur, best appreciated in the second to fourth left intercostal space with the patient sitting up and leaning forward. As aortic insufficiency becomes more severe, the murmur takes up more of diastole. When left ventricular dysfunction results in restrictive filling, the murmur of aortic regurgitation may shorten and become softer.

Moderate to severe aortic insufficiency may also be accompanied by an Austin Flint murmur, a low-frequency, mid-diastolic to late diastolic murmur best appreciated at the apex caused by left atrial flow into an “overexpanded” left ventricle.⁴⁸ As Austin Flint reported, “In some cases in which free aortic regurgitation exists, the left ventricle becoming filled before the auricles contract, the mitral curtains are floated out, and the valve closed when the mitral current takes place, and, under these circumstances, this murmur may be produced by the current just named, although no mitral lesion exists.” Aortic insufficiency may be accompanied by a soft S_1 , prominent S_3 , and diastolic rumble. The apical impulse in chronic aortic insufficiency, which is frequently hyperdynamic and diffuse, is also often displaced inferiorly and leftward.

Severe aortic insufficiency is associated with wide pulse (i.e., systole >100 mm Hg and diastole <60 mm Hg) pressure and a multitude of eponym-rich clinical findings, including a Corrigan or water-hammer pulse, de Musset sign (a head bob with each systole), Müller sign (systolic pulsations of the uvula), Traube sign (“pistol-shot” systolic and diastolic sounds heard over the femoral artery), Hill sign (when the popliteal cuff systolic pressure exceeds the brachial cuff pressure by >60 mm Hg), and Quincke sign (capillary pulsations seen when a light is transmitted through a patient’s fingernail). Duroziez sign is elicited as an audible systolic murmur heard over the femoral artery when the artery is compressed proximally along with a diastolic murmur when the femoral artery is compressed distally.

Other diastolic murmurs include the following. (1) Pulmonary regurgitation is a diastolic decrescendo murmur that is localized over the second intercostal space. When it is due to dilation of the pulmonary valve annulus, it produces the characteristic Graham-Steele murmur. (2) Mitral stenosis is a mid-diastolic rumble that is appreciated with the bell as a low-pitched sound at the apex, immediately after an opening snap, which increases in intensity with exercise. (3) Anatomic or functional tricuspid stenosis (the latter with the delayed opening of the tricuspid valve seen with large atrial or ventricular septal defects) is associated with a mid-diastolic rumble or with the aforementioned Austin Flint murmur of aortic insufficiency. Mitral stenosis can be differentiated from tricuspid stenosis by the localization of the latter to the left sternal border and its augmentation with inspiration.

Finally, the superficial, high-pitched or scratchy sound of a pericardial friction rub is best heard with the patient in the sitting position while leaning forward at end-expiration. This murmur may be systolic, systolic and diastolic, or triphasic, and should be suspected in the postinfarction or acute pericarditis setting with pleuritic chest pain and diffuse ST segment elevations on electrocardiogram.

Abdominal Examination

Examining the abdomen on admission and daily during hospitalization can unify diagnoses and potentially identify common in-hospital abdominal complications. Pancreatitis, cholecystitis, and ischemic bowel all can manifest *de novo* in a patient days after admission to the ICU. If a wound or dressing is present, the physician should put on gloves and carefully take the dressing down (or request to be present at the time of dressing change) to examine the site. The abdomen should be inspected for obesity, cachexia, and distended or bulging flanks (the last-mentioned

may be due to ascites, organomegaly, colonic dilation, ileus, or a pneumoperitoneum). A search for the stigmata of liver disease (i.e., spider angiomas and caput medusae), signs of intra-abdominal hemorrhage such as flank (Grey Turner sign) or periumbilical (Cullen sign) ecchymosis, hernias, and surgical scars should also be performed. Abdominal striae and bruises, in addition to moon facies and central obesity, may be caused by excess glucocorticoids owing to exogenous administration or endogenous overproduction (e.g., Cushing syndrome secondary to pituitary, lung, adrenal, or carcinoid tumors). Visible peristalsis and a distended abdomen argue for bowel obstruction as the cause of abdominal pain and should complement the finding of hyperactive bowel sounds.⁴⁹

Auscultation with the diaphragm of the stethoscope should be performed over each major vascular territory in the abdomen for high-pitched systolic bruits suggesting renal artery stenosis, aortic aneurysm, hepatic or splenic vascular lesions, or the potential cause of mesenteric ischemia. An abdominal bruit may be present in 80% to 85% of patients with renal artery stenosis. Venous (continuous) hums, associated with portal venous hypertension, are best appreciated with the bell of the stethoscope, usually in the right upper quadrant.

In the ICU, it is important to assess the change in bowel sounds over time. Bowel sounds should be sought with the diaphragm of the stethoscope; although loud, high-pitched, and hyperactive bowel sounds may herald the presence of an obstructed bowel, they may also be present with gastroenteritis, inflammatory bowel disease, or gastrointestinal bleeding. Bowel sounds are considered absent only after listening for at least 3 minutes in each quadrant. Absent or decreased bowel sounds suggest the presence of a paralytic ileus (common after surgery or in the presence of hypokalemia, opiates, constipation, and hypothyroidism) or mesenteric thrombosis. Special attention should be paid to “crampy” and diffuse or periumbilical abdominal pain that progressively increases. If pain is accompanied by decreased or absent bowel sounds, distention, guarding, or rebound, the probability that ischemic or obstructive bowel disease is present is significantly increased. A succussion splash, defined as a palpable or audible “splash” elicited by applying a firm push to the abdomen, occurs when a hollow portion of the intestine or an organ/body cavity contains a combination of free fluid, air, or gas. A succussion splash is commonly caused by intestinal or pyloric obstruction (e.g., pyloric stenosis or gastric carcinoma) or a hydropneumothorax over a normal stomach. In critically ill patients, catastrophic intestinal rupture, bowel strangulation, or infarct must also be considered.

Palpation may reveal the presence of peritoneal signs (rebound or involuntary guarding) that are best assessed by watching the patient’s facial expression during light, followed by progressively deeper, palpation. Voluntary guarding is the defensive posture patients use to avoid palpation by contracting their abdominal musculature. This is not considered a peritoneal sign and may be avoided either by distracting the patient or performing repeated examinations of the abdomen to acclimate the patient to touch. Involuntary guarding is the reflex contraction of abdominal muscles, often owing to peritoneal inflammation. Rebound tenderness occurs when the patient reports augmentation in abdominal pain after abrupt release of pressure exerted with deep palpation at the site of abdominal tenderness. Although additive to the examination, this sign is neither specific nor sensitive for peritonitis, and may cause undue patient discomfort

without cause. Peritoneal signs in a critically ill patient should provoke an immediate search for evidence of organ perforation, an ischemic bowel, or peritonitis.

Envisioning the underlying structures is also helpful in determining potential causes of pain on palpation. Right upper quadrant tenderness is commonly associated with hepatic (e.g., hepatitis, hepatic congestion from heart failure) or gallbladder (e.g., acute cholecystitis, biliary colic) disease, a duodenal ulcer, or right lower lobe pneumonia. A positive Murphy sign (an inspiratory pause during palpation of the right upper quadrant) is a specific, but not sensitive, indicator of gallbladder disease. Right lower quadrant pain on palpation shifts the focus to the ascending colon (e.g., appendicitis or cecal diverticulitis) and tubulo-ovarian structures (e.g., ectopic pregnancy, tubo-ovarian abscess, ruptured ovarian cyst, and ovarian torsion). Appendicitis is also suggested by the presence of McBurney sign, tenderness located two thirds the distance from the anterior iliac spine to the umbilicus on the right side.

Left upper quadrant pain suggests pancreatic (e.g., acute pancreatitis or pancreatic tumor) or splenic (e.g., splenic congestion, splenomegaly, or infarction) disease or left lower lobe pneumonia. Left lower quadrant pain occurs with sigmoid and descending colon disease (e.g., diverticulitis) or left-sided tubulo-ovarian pathology. Midline or periumbilical discomfort on palpation occurs during early appendicitis, gastroenteritis, or pancreatitis. Pancreatitis may be associated with epigastric tenderness, guarding, hypoactive bowel sounds, fever, and hypotension. Flank pain should also raise the possibility of an abdominal aortic aneurysm, pyelonephritis, and renal colic. Lower abdominal or suprapubic pain occurs with nephrolithiasis, cystitis, ectopic pregnancy, and pelvic inflammatory disease.

The discovery of an abdominal mass during palpation should include a complete description of its size, consistency (hard, soft, or nodular), and pulsatility. Not all abdominal masses indicate tumors; bowel obstruction, inflammatory bowel disease, an enlarged left lobe of the liver, and abdominal aortic aneurysm are some examples of nontumorous masses. A pancreatic mass is rarely palpable.

Percussion may reveal localized abdominal dullness suggesting organomegaly, stool, or the presence of an abdominal mass, whereas generalized abdominal dullness is often associated with ascites. With a suspicion of ascites, noting whether dull areas shift with changes in patient position can be informative. This shift can be detected most easily by the presence of dullness in areas of prior tympany when the patient’s abdomen is percussed in the recumbent position and after the patient has been rolled approximately 30 degrees away from the examiner.

Percussion can be used to detect hepatomegaly. The lower edge of the liver can be detected by placing the right hand in the right lower quadrant of the abdomen and gently moving toward the lower rib margin, approximately 2 cm with each gentle breath of the patient. If the edge is not felt, no further examination is required. If the edge is appreciated, the superior border of the liver should be determined by percussion, starting in the third intercostal space and moving down one interspace at a time until the note changes from resonant to dull. In obese patients, “scratching” with auscultation for the change from tympany to dull on superior and inferior aspects of the liver may be performed. Hepatomegaly is said to be present if the liver span is appreciated for greater than 12 cm (although the actual mean liver span along the midclavicular line is apparently 7 cm

in women and 10.5 cm in men). Splenomegaly may be present if the spleen is detected while advancing the examining hand upward toward the left upper quadrant during exhalation with palpating for the spleen edge during inspiration. Percussive dullness over the spleen in the midaxillary line during inspiration also suggests splenomegaly. Finally, a rectal examination should be performed to search for potential causes of urinary tract obstruction (e.g., benign prostatic hypertrophy) or infection (e.g., prostatitis), and to evaluate the stool for gross or occult blood.

Neurologic Examination

One third of patients admitted to the ICU have neurologic complications that may double the length of a hospital stay and increase the likelihood of death.⁵⁰ Depressed consciousness is a major contributor to prolonged ventilation. Careful attention and notation should be made on the initial examination and with changes in neurologic state.

The neurologic examination should begin with an assessment of sensorium (dementia or delirium) and the level of consciousness. Level of consciousness has been described as alert, lethargic (easily aroused with mild stimulus), somnolent (easily aroused, but requires stimulation to maintain arousal), obtunded/stuporous (arousable only with repeated and painful stimuli), and comatose (unarousable despite vigorous stimulation with no purposeful movements). If comatose, the depth of the coma can be assessed by the degree of corneal reflex loss. A continuous performance test (asking the patient to raise a hand) can be used to evaluate alertness in noncomatose patients, but a formal Glasgow Coma Scale score should be routinely monitored, along with brainstem reflex assessment, in all unresponsive or minimally responsive patients.

Frontal release signs (forced grasping) and perioral primitive reflexes (snout and pout) are found in diffuse structural and metabolic disease. Flexor and extensor postures can occur in traumatic and metabolic coma (e.g., secondary to hypoxia, ischemia, hypoglycemia, or uremia). Upper motor neuron disease (destructive, pharmacologic, infectious, or metabolic) can be implied by the coexistence of a positive Babinski response, indicated by an upward movement of the great toe (instead of a normal downward turn) in response to a forceful stroke along the lateral plantar surface of the foot from the heel toward the toes. "Fanning" of the toes is a normal phenomenon.

Delirium is an acute and reversible confusional state, occurring in 20% of all hospitalized elderly patients.⁵¹ It can be assessed by formal screening tools that focus, at any altered level of consciousness, on an acute change in mental status from a patient's baseline that is fluctuating, with difficulty focusing attention or disorganized thinking or both.⁵² Assessment of dementia is impossible in a patient who is delirious.

Pupil asymmetry, alterations in size, or poor reactivity (i.e., dilated and fixed) suggests a history of cerebral anoxia, intracranial vascular events, masses, or metabolic or drug abnormalities. Although patients in a coma usually have closed eyelids, tonic lid retraction or reopening after forced closure may be present with pontine disease. The brainstem can also be examined more formally using oculocephalic maneuvers or oculovestibular testing. The presence of hand tremors can suggest thyrotoxicosis or parkinsonism (associated with a pill-rolling phenomenon); hand tremors that occur with purposeful

movement suggest cerebellar pathology (e.g., alcoholism or cerebrovascular accident). In patients with evidence of diabetic neuropathy or parkinsonism, autonomic dysfunction should be suspected. Myoclonus (brief, often asymmetric, generalized body jerks lasting <0.25 second) may appear as a result of cerebral hypoxia or ischemia.

Cranial nerves should be assessed grossly or more intently with active neurologic insults. The optic nerve (CN II) is assessed by confirming visual acuity. Pupillary reactions to light (CN III) are examined by shining a bright light obliquely into each pupil in turn, looking for papillary constriction in the ipsilateral (direct) and contralateral (consensual) eye. A decreased direct response (or dilation) indicates an afferent pathway defect (Marcus Gunn pupil) such as occurs with optic neuritis, ischemic optic neuropathy, or severe retinal disease. Fixed and dilated pupils are associated with brainstem injury, but may also be due to a recent dose of atropine. A pupil that is capable of accommodation but does not respond to light (Argyll-Robertson pupil) is associated with tertiary syphilis (and should be considered if the differential diagnoses include aortic dissection or aortic insufficiency), neurosarcoidosis, and Lyme disease.⁵³ Anisocoria (pupil inequality = 1 mm) suggests a CNS mass or bleed, and may explain the precordial T wave inversions seen in a comatose patient without evidence of cardiomyopathy, myocarditis, or electrolyte abnormalities. Simple anisocoria (>0.4 mm difference between eyes) is present in nearly 40% of healthy individuals, however.⁵⁴

Pupillary accommodation may be tested by holding a finger approximately 10 cm from the patient's nose and, while observing the pupillary response in each eye, asking the patient to alternate looking into the distance and at the finger. Narrowing should occur with focus on the near finger, whereas dilation should occur when focusing afar. The presence of eyelid ptosis may also suggest a defect in the third cranial nerve or the presence of a posterior communicating artery aneurysm. Old age, trauma, chronic inflammation, neoplasms, and thyroid abnormalities are more commonly the cause, however.

Extraocular movements should be assessed by asking the patient to follow the examiner's finger with the eyes (without moving the head) and checking gaze in the six cardinal directions using a cross or "H" pattern (CN III, IV, and VI). The examiner should pause during upward and lateral gaze to check for nystagmus.

Trigeminal nerve (CN V) motor function can be assessed by palpating for temporal or masseter muscle strength while asking the patient first to open the mouth and then to clench the teeth. The three sensory components of the trigeminal nerve can be tested by assessing the response on both sides of the face to a sharp and blunt object lightly placed against the forehead, cheeks, and jaw. An intact corneal reflex (eye blink when the cornea is touched by a cotton wisp) tests the sensory component of the fifth cranial nerve and the motor component of the seventh cranial nerve. Facial asymmetry or droop is also present with seventh cranial nerve injury (e.g., secondary to Bell palsy, cerebrovascular accident, or trauma). Bell palsy can be differentiated from stroke by the ability of a patient with Bell palsy to close his or her eye or wrinkle the forehead. Less common causes of seventh cranial nerve injury include sarcoidosis and Lyme disease.

The eighth cranial nerve can be coarsely assessed by having the patient, with the eyes closed, detect the sound of fingers lightly rubbing together alternatively next to each ear. Sensorineural hearing loss can be associated with a genetic form

of dilated cardiomyopathy.⁵⁵ A hoarse voice may be caused by tenth cranial nerve abnormalities, such as compression of the recurrent laryngeal nerve motor branch by the marked left atrial enlargement that can occur with severe mitral stenosis. The motor strength of the eleventh cranial nerve is assessed by asking the patient to shrug the shoulders against resistance. Finally, the hypoglossal nerve (CN XII) is assessed by asking the patient to protrude the tongue and move it side to side.

Assessment for sensory deficits, abnormal peripheral reflexes, and muscle strength may help guide the evaluation of patients with possible systemic neurologic or myopathic disease. The sensory examination requires the attention, participation, and understanding of the patient. Light touch is tested by touching the skin with a wisp of cotton or a tissue and asking the patient to acknowledge the feeling while not looking. Pain sensation can be elicited using a sharp object; temperature sensation can be grossly ascertained using cold and warm objects. Vibration is tested with a tuning fork and needs to be compared bilaterally. Sensory deficits can offer important clues regarding the systemic, central, or peripheral location of underlying lesions. Diabetes mellitus is suggested by a “stocking-glove” distribution of sensory defects; focal hyperesthesia or anesthesia can occur with the dry beriberi of vitamin B₁ deficiency (high output cardiac failure occurs in wet beriberi). The presence of hand tremors can suggest thyrotoxicosis or parkinsonism (associated with a pill-rolling phenomenon), whereas hand tremors that occur only with purposeful movements suggest cerebellar pathology (e.g., alcoholism or cerebrovascular accident). Delayed ankle reflexes in a patient with cool, dry, and coarse skin with bradycardia is highly suggestive of hypothyroidism.^{56,57}

Motor deficits may be difficult to evaluate in the ICU, but should be initially sought in all major muscle groups by having the patient move each muscle group against resistance. Motor strength is reported as 5/5 (normal strength), 4/5 (movement against resistance, but less than normal), 3/5 (movement against gravity, but not against added resistance), 2 (movement at the joint, but not against gravity), 1/5 (visible muscle movement, but no movement at the joint), and 0/5 (no muscle movement). Motor deficits may be present with a cardiomyopathy in patients with Duchenne or Becker muscular dystrophy, whereas the presence of motor and conduction defects can occur with myotonic dystrophy. Focal muscle weakness raises the possibility of a new or old upper motor neuron lesion (e.g., multiple sclerosis, intracranial mass, or cerebrovascular accident) or mononeuropathy. Symmetric proximal weakness can occur with numerous myopathies, whereas symmetric distal weakness can occur with polyneuropathy, amyotrophic lateral sclerosis, and Guillain-Barré syndrome. Statins and alcohol can affect either distal or proximal muscle groups.

Vascular Examination

The vascular examination may begin with the auscultation of both flanks for the presence of a bruit suggestive of renal artery stenosis. Angiographically significant renal artery stenosis may be present in nearly 60% of patients with peripheral arterial disease. The aorta can often be assessed on deep palpation of the central abdomen. A pulsatile pulse immediately above the level of the umbilicus is a nonsensitive sign of an abdominal aortic aneurysm and is most readily detected in men older than 60 years. Auscultation of both abdominal flanks may detect

the presence of renal artery stenosis. In patients complaining of exertional or positional leg pain, the absence of a pulse or the presence of arterial ulcers is often diagnostic for vascular insufficiency. In the setting of an intra-aortic balloon pump or after a catheter-based coronary artery assessment or intervention, particular attention has to be paid to following the pulses sequentially on the investigated limb.

Musculoskeletal and Integument Examination

The musculoskeletal examination should begin with a general assessment for global or focal muscle wasting or atrophy. During lung auscultation, one can simultaneously inspect the spine for scoliosis, lordosis, or kyphosis. Each spinous process should be inspected for focal areas of tenderness. Holt-Oram syndrome, associated with atrial and ventricular septal defects, usually manifests with upper limb skeletal deformities, including unequal arm lengths; anomalous development of the radial, carpal, and thenar bones of the hand; triphalangeal or absent thumbs; or phocomelia. Arachnodactyly (long spidery fingers) may be found in patients with Marfan syndrome. Capillary pulsations under the fingernails may be evident with aortic regurgitation, sepsis, or thyrotoxicosis whereas splinter hemorrhages also raise the possibility of bacterial endocarditis. The presence of Osler nodes (painful reddish papules approximately 1 cm on the fingertips, palms, toes, or soles of the feet) also suggests endocarditis.

The joints should be felt for crepitus during passive motion, and in the setting of fever or focal neurologic symptoms, the neck should be assessed for evidence of nuchal rigidity. The extremities should be assessed for unilateral or bilateral edema (suggestive of heart failure, hypoproteinemia, or vein thrombosis), cellulitis, phlebitis, or ischemic extremities. While evaluating the legs, the clinician should check if subcutaneous anticoagulation or compression boots are necessary.

Skin erythema and warmth suggest inflammation, including soft tissue swelling or focal areas of tenderness. Specific skin patterns may suggest particular diseases and may prove critical to the care of patients in the ICU. A rash typically found on the palms, soles, dorsum of the hands, and extensor surfaces that begins as macules that develop into papules, vesicles, bullae, urticarial plaques, or confluent erythema is consistent with Stevens-Johnson syndrome. Other skin findings associated with disease include the malar flush (mitral facies) of mitral stenosis, brick-red coloring seen with polycythemia, bronze coloring associated with hemochromatosis, oral hyperpigmentation and brown coloring with Addison disease, “moon facies” of Cushing disease, and a butterfly rash across the nose consistent with systemic lupus erythematosus.

Approximately 4 to 5 g/dL of unoxygenated hemoglobin in the capillaries generates the blue color appreciated clinically as central cyanosis.⁵⁸ For this reason, patients who are anemic may be hypoxemic without showing any cyanosis. Central cyanosis (involving the mucous membranes of the lips, tongue, and earlobes) with warm extremities strongly suggests right-to-left shunting (usually the shunt is >25% of the total cardiac output), severe anemia (hematocrit <15%), severe hypoxia, or concomitant lung disease. Cyanosis may also occur in the presence of increased amounts of methemoglobin (e.g., with use of dapsone,

nitroglycerin, or topical benzocaine) or sulfhemoglobin. Pseudocyanosis, a blue color to the skin without deoxygenated hemoglobin, may occur with the use of amiodarone, phenothiazines, and some metals (especially silver and lead). Central cyanosis often improves with supplemental oxygen. Clubbing suggests central cyanosis, right-to-left shunting with or without congenital heart disease, or bacterial endocarditis. Cyanosis in the presence of normal oximetry suggests anemia, poor cardiac output, or hypercapnia. If the lower limbs are cyanosed, but the upper limbs are not, a patent ductus arteriosus should be expected. Peripheral cyanosis with cool extremities suggests the presence of low cardiac output, hypovolemia, or peripheral vasoconstriction. Warming the extremity often improves cyanosis.

Jaundice, which may be present with hepatitis, alcoholic liver disease, choledocholithiasis, pancreatic cancer, or metastatic liver disease, can be differentiated from other causes of yellow skin by the concomitant “yellowing” of mucous membranes under the tongue or in the conjunctiva of the eye. The presence of spider angiomas, palmar erythema, dilated abdominal veins, and ascites increases the likelihood of a hepatocellular cause of the jaundice.⁵⁹ The finding of a palpable gallbladder (Courvoisier sign) is highly suggestive of extrahepatic obstruction.

Conclusion

The physical examination offers much to help hone and optimize diagnostic and therapeutic paradigms. In the hands of the astute clinician, the physical examination offers timely keys for the successful management of critically ill patients in the ICU.

Scientific Foundation of Cardiac Intensive Care

SECTION

Role of the Cardiovascular System in Coupling the External Environment to Cellular Respiration

CHAPTER

Peter D. Wagner

**Cardiovascular Function and Pulmonary
Gas Exchange**

**Cardiovascular Function and Systemic
Gas Exchange**

THE CARDIOVASCULAR system exists primarily to transport O_2 and nutrients to the various body tissues and to transport CO_2 and other waste products from the tissues to the lungs, kidneys, or liver for disposal. This system is a component of the O_2 transport pathway, linking the environment, via the lungs and chest wall, to tissue cells, via the heart and the vascular network.

This chapter focuses on cardiovascular function as it affects O_2 transport between the environment and the tissue cells. Total cardiac output and its distribution among and within organs are crucial aspects of O_2 transport efficiency in health and disease. Although the principles of O_2 exchange and transport in the lungs and tissues are fundamentally similar, it is worthwhile to discuss pulmonary and tissue O_2 transport separately. Normal physiologic processes are described first, followed by pathophysiologic consequences of disease, from the point of view of cardiac function.

Cardiovascular Function and Pulmonary Gas Exchange

Cardiac function is important to O_2 exchange in the lungs in many ways. First, total pulmonary blood flow, which is normally equal to cardiac output, affects PO_2 of venous blood entering the lungs. Although in health this is of little significance, it is of

major importance in disease. Second, the relationship between total pulmonary blood flow and the volume of blood in the pulmonary capillaries determines red blood cell exposure (or transit) time in the lungs. In resting normal humans, transit time is much greater than what is needed; this may not be the case during exercise or in disease. Third, the distribution of pulmonary blood flow among the 300 million alveoli cannot be perfectly matched to the ventilation of the alveoli. This causes ventilation-perfusion ($\dot{V}_A/\dot{Q}$) mismatch, which interferes with arterial oxygenation. This $\dot{V}_A/\dot{Q}$ mismatch is of little consequence in health, but is of major importance in disease of the cardiopulmonary system. Fourth, any dysfunction of the left ventricle that increases diastolic filling pressure has the potential for causing pulmonary edema, especially if pulmonary capillaries have been damaged by disease. Pressures are sufficiently low in health that edema does not occur at rest. With heavy exercise, mild interstitial edema can occur, but the effects are subtle. The importance of left ventricular dysfunction increases dramatically when filling pressures exceed 20 to 25 mm Hg.¹ Pulmonary microvessels may undergo a degree of physical disruption at very high vascular pressures.² Fifth, right ventricular hypertrophy from pulmonary diseases can impair left ventricular function, effectively decreasing left ventricular compliance through mechanical interdependence of the heart chambers. These five concepts are now discussed.

Total Pulmonary Blood Flow and Oxygen Exchange

Pulmonary O_2 exchange under steady-state conditions obeys mass balance principles. Corresponding equations can be written to describe O_2 uptake from respired air and into the pulmonary circulation.³ These equations are:

$$\dot{V}O_2 = \dot{V}_I \cdot F_{IO_2} - \dot{V}_A \cdot F_{AO_2} \quad [1]$$

$$\dot{V}O_2 = \dot{Q}[CaO_2 - C\bar{v}O_2] \quad [2]$$

where $\dot{V}O_2$ is whole-body O_2 consumption, $\dot{V}_I$ and $\dot{V}_A$ are inspired and expired alveolar ventilation, F_{IO_2} and F_{AO_2} are inspired and expired alveolar O_2 fractional concentrations, $\dot{Q}$ is total pulmonary blood flow, and CaO_2 and $C\bar{v}O_2$ are arterial and pulmonary arterial (mixed venous) O_2 concentrations. These two equations embody the principle of taking the difference between the O_2 flow rate into and out of the lungs, expressed for ventilation (Equation 1) or blood flow (Equation 2). Although not completely correct, it is reasonable for clinical purposes to assume that $\dot{V}_I$ equals $\dot{V}_A$ to simplify Equation 1. Strictly, $\dot{V}_A = \dot{V}_I - \dot{V}O_2 + \dot{V}CO_2$, where $\dot{V}CO_2$ is CO_2 output by the lungs. If the respiratory quotient (R) equals 1, $\dot{V}O_2 = \dot{V}CO_2$, and $\dot{V}_A = \dot{V}_I$. Normally, $\dot{V}O_2$ exceeds $\dot{V}CO_2$ so that R is, on average, 0.8. Under these conditions, $\dot{V}_A$ is about 1% less than $\dot{V}_I$, an unimportant difference.

In healthy lungs, alveolar PO_2 , which is proportional to F_{AO_2} in Equation 1, is tightly related to CaO_2 in Equation 2 by the O_2 -hemoglobin (Hb) dissociation curve. CaO_2 can be directly computed using alveolar PO_2 and the O_2 -Hb dissociation curve.⁴ This is not true in lung disease, where for Equation 1, F_{AO_2} is mean alveolar $[O_2]$ averaged over the 300 million alveoli, weighted by the ventilation of each, and CaO_2 is arterial $[O_2]$, similarly averaged but weighted by blood flow to each of the alveoli. When ventilation or blood flow is distributed in a nonhomogeneous manner in lung disease, the PO_2 corresponding to mean alveolar gas is often much higher than that of arterial blood corresponding to CaO_2 . CaO_2 cannot be accurately calculated from F_{AO_2} and the O_2 -Hb dissociation curve.

In the normal lung, it is clear from Equation 1 that alveolar $[O_2]$, F_{AO_2} , is a direct function of $\dot{V}O_2$, F_{IO_2} , and alveolar ventilation only; so too is arterial $[O_2]$, CaO_2 . The important conclusion is that changes in cardiac output ($\dot{Q}$) have no influence on arterial $[O_2]$ or PO_2 in normal lungs, so long as CaO_2 is a direct function of F_{AO_2} . An increase in cardiac output per se with anxiety or fever would not affect arterial PO_2 in a normal lung if $\dot{V}O_2$, F_{IO_2} , and ventilation remained unchanged. A decrease in cardiac output from dehydration, blood loss, or myocardial infarction also would not affect arterial PO_2 under the same assumptions in a normal lung.

Equation 2 shows that the sole influence of cardiac output on gas exchange in a normal lung is to affect mixed venous $[O_2]$ and PO_2 . As cardiac output decreases, so too does $C\bar{v}O_2$, and as cardiac output increases, so too does $C\bar{v}O_2$. Although, as stated, this does *not* affect arterial $[O_2]$ or PO_2 in the normal lung, this is not the case in lungs with diseases associated with ventilation–blood flow mismatch or right-to-left shunting. In such diseases, it is still true that $C\bar{v}O_2$ must increase and decrease with cardiac output just as in health, if other influences are constant; however, because arterial blood is the mixture of blood from all lung regions, a shunt or areas of low $\dot{V}_A/\dot{Q}$ ratio mix in blood from such regions having lower $[O_2]$ than normal, reducing mixed arterial $[O_2]$ and PO_2 . As cardiac output decreases, the $[O_2]$ and PO_2 of such shunts or low $\dot{V}_A/\dot{Q}$ regions decrease because

Figure 5-1. Effect of changes in cardiac output on arterial PO_2 in normal and diseased lungs. In this example, the diseased lung contains a 25% right-to-left shunt. Arterial PO_2 is essentially independent of cardiac output in health, but depends significantly on cardiac output in disease.

such pathways essentially fail to oxygenate flowing blood above mixed venous levels.

The contribution of such regions to arterial blood, being tightly coupled to mixed venous $[O_2]$, is closely dependent on cardiac output. The end result is more severe arterial hypoxemia as cardiac output decreases, and less severe hypoxemia as cardiac output increases. This situation is illustrated in Figure 5-1, in which a normal lung and a lung containing as an example of disease a 25% right-to-left shunt are compared as cardiac output changes. Arterial O_2 saturation, a better reflection of the O_2 concentration of the blood, follows changes in PO_2 (Fig. 5-2). Mixed venous PO_2 (Fig. 5-3) changes similarly in both cases according to Equation 2, but arterial PO_2 and O_2 saturation vary with cardiac output only in the abnormal lung. The clinical message is clear—the degree of arterial hypoxemia in a given patient depends not only on how much shunt or $\dot{V}_A/\dot{Q}$ mismatch is present, but also on cardiac output. If arterial PO_2 were to decrease in such a patient, changes in cardiac output should be excluded if the arterial PO_2 change is to be interpreted as a change in health of the lung. Application of the classic shunt or venous admixture equation^{5,6} illustrates this principle dramatically:

$$\dot{Q}_{VA}/\dot{Q}_T = 100 \cdot [C_{IO_2} - CaO_2]/[C_{IO_2} - C\bar{v}O_2] \quad [3]$$

where $\dot{Q}_{VA}/\dot{Q}_T$ is venous admixture as a percentage of the cardiac output and C_{IO_2} is essentially the $[O_2]$ of normal end-capillary blood in nonshunted, normal $\dot{V}_A/\dot{Q}$ regions of the lung.

When $\dot{Q}_{VA}/\dot{Q}_T$ is computed over the range of cardiac output values and for the examples in Figure 5-1, assuming $C\bar{v}O_2$ stays constant ($P\bar{v}O_2$ constant at the normal value of 40 mm Hg for $\dot{Q}_T = 6 \text{ L} \cdot \text{min}^{-1}$ in each case, rather than the *actual* $C\bar{v}O_2$ associated with each cardiac output), it can be seen (Fig. 5-4) how badly $\dot{Q}_{VA}/\dot{Q}_T$ is overestimated when actual cardiac output is low, and underestimated when cardiac output is high. Neither of the extremes of cardiac output in Figure 5-4 (i.e., $3 \text{ L} \cdot \text{min}^{-1}$ and $12 \text{ L} \cdot \text{min}^{-1}$) is beyond the range of common experience in the intensive care unit. Apparent shunt ($\dot{Q}_{VA}/\dot{Q}_T$) would be about twice the actual value when cardiac output is reduced by 50%, and half the real value when cardiac output is doubled if venous $[O_2]$ is assumed to be at normal levels.

Figure 5-2. Effect of cardiac output on arterial oxygen saturation, from the same calculations as used in Figure 5-1. Saturation varies considerably with cardiac output in diseased, but not in normal, lungs.

Figure 5-3. Change in mixed venous PO_2 with cardiac output for the conditions of Figures 5-1 and 5-2. Mixed venous PO_2 changes similarly with cardiac output in health and disease. Absolute PO_2 is slightly higher in health at a given cardiac output.

Pulmonary Transit Time

The preceding section assumes sufficient time for O_2 to equilibrate fully across the blood gas barrier; that is, PO_2 in the capillary blood has increased from mixed venous levels all the way to alveolar PO_2 within the available red blood cell contact time. Average red blood cell contact time normally appears to be about 0.75 second. This estimate is the ratio of resting capillary blood volume (75 mL, measured by the carbon monoxide technique⁷) to the corresponding cardiac output (6 $L \cdot min^{-1}$). Figure 5-5 indicates the normal PO_2 profile calculated along the pulmonary capillary and shows full equilibration in about 0.25 second, leaving 0.5 second in reserve.⁸ Although transit times in different alveoli are not uniform,⁹ the variance in such times is still small enough that full equilibration occurs at rest, even in channels with the shortest transit and even during moderate exercise. Only during heavy exercise does failure of equilibration occur in healthy individuals.¹⁰ At high altitudes, diffusion limitation is seen with even light to moderate exercise and becomes a major factor reducing arterial $[O_2]$ under such conditions.¹¹

Figure 5-4. Calculated or apparent shunt as a percentage of cardiac output, when the assumption is made that oxygen concentration in mixed venous blood is constant, equaling that seen when cardiac output is 6 $L \cdot min^{-1}$. This assumption leads to large errors in calculated shunt when cardiac output is reduced or increased. The dashed lines indicate conditions under which the assumption is correct, so that calculated shunt is also accurate, but only at that point.

Figure 5-5. Time course of PO_2 change along the pulmonary capillary as oxygen moves from alveolar gas into the flowing capillary blood. Starting at a mixed venous PO_2 of 40 mm Hg, full equilibration with alveolar gas is reached in about 0.25 second, leaving a large reserve in transit time under normal conditions.

In cardiopulmonary diseases, diffusion limitation in the lung rarely occurs, even when patients are well enough to exercise. The exception is interstitial pulmonary fibrosis. Here, diffusion limitation is usually seen during exercise, which aggravates hypoxemia.¹² Diffusion limitation can also occur at rest in such patients.¹³ Pulmonary diffusing capacity must be less than about 60% of normal, however, before diffusion limitation is seen because of previously described reserves in red blood cell transit time.¹³ Hypoxemia in cirrhosis of the liver seems to have a small component of diffusion limitation as well.

In severe cardiopulmonary diseases, such as acute pulmonary edema from left ventricular failure or acute respiratory distress syndrome, conditions develop that reduce O_2 diffusing capacity. In particular, the normally thin (0.5- μm) blood-gas barrier separating alveolar gas from capillary blood can become edematous; however, it is thought that this does not produce

measurable O_2 diffusion limitation. In more advanced disease, there is alveolar filling with edema fluid, cellular debris, or both, which abolishes all ventilation of affected alveoli and produces what is more commonly termed *shunt* (i.e., perfusion of unventilated alveoli). It could be argued that such alveoli are completely diffusion-limited because no O_2 exchange occurs at all. This becomes a semantic issue and should not detract from the more important problem of understanding the pathologic and physiologic changes that occur with these diseases.

Distribution of Blood Flow within the Lungs

In normal lungs, output from the right ventricle is not equally distributed among the 300 million alveoli. Gravity affects blood flow distribution; more blood flows through dependent than nondependent alveoli because of the weight of the blood.¹⁴ There are nongravitational influences on blood flow distribution as well. The fractal branching nature of the vascular tree produces nonuniform distribution,¹⁵ and the lack of perfect anatomic symmetry perturbs flow patterns further.¹⁶ There may also be greater perfusion of central (proximal) than peripheral (distal) lung regions,¹⁷ although this has not been resolved. As a result of all of these independent sources of nonuniformity, a substantial degree of nonhomogeneous blood flow distribution exists. It seems, however, that the distribution of ventilation is largely matched to that of blood flow, so that ventilation and blood flow are each greatest and least in the same areas.¹⁸ This matching is imperfect, but interferes only trivially with O_2 transport in the normal lung. If the ideal lung produces an arterial PO_2 of 100 mm Hg, the real lung in young healthy subjects produces an arterial PO_2 of 90 to 95 mm Hg. Because of the flat O_2 -Hb dissociation curve at this PO_2 , the effect on arterial $[O_2]$ of this 5- to 10-mm Hg decrease is negligible.

Equations 1 and 2, although used previously for considering the whole lung, can be applied at the local alveolar level, where the terms now reflect local alveolar and end-capillary O_2 levels and local $\dot{V}O_2$. Still assuming equality of $\dot{V}_I$ and $\dot{V}_A$ at this level and setting Equations 1 and 2 equal to one another yields a new relation:

$$\dot{V}_A [FIO_2 - FAO_2] = \dot{Q} [C\bar{c}O_2 - C\bar{v}O_2]$$

or

$$\dot{V}_A / \dot{Q} = [C\bar{c}O_2 - C\bar{v}O_2] / [FIO_2 - FAO_2] \quad [4]$$

where $C\bar{c}O_2$ is the standard term for end-capillary $[O_2]$ in a local lung region.

Equation 4 shows that within such a local lung region, alveolar (and end-capillary) $[O_2]$ is a unique function of the $\dot{V}_A / \dot{Q}$ ratio and the so-called boundary conditions (i.e., the inspired and mixed venous O_2 levels). A third factor implicit to Equation 4 is the PO_2 - $[O_2]$ relation defined by the O_2 -Hb dissociation curve.

Equation 4 points out how changes in the local $\dot{V}_A / \dot{Q}$ ratio are key factors affecting local gas exchange and arterial PO_2 and $[O_2]$.^{3,5,6} Figure 5-6 shows how local PO_2 depends on the $\dot{V}_A / \dot{Q}$ ratio for room-air breathing and a range of three mixed venous PO_2 levels. At $\dot{V}_A / \dot{Q}$ ratios in the normal range (about 0.3 to 3),¹⁹ local PO_2 varies considerably with $\dot{V}_A / \dot{Q}$ and PvO_2 . At lower $\dot{V}_A / \dot{Q}$ ratios typical of most cardiopulmonary diseases (i.e., below the normal range), local PO_2 is tied to PvO_2 , and is virtually independent of the $\dot{V}_A / \dot{Q}$ ratio. As cardiac output and PvO_2 change, low $\dot{V}_A / \dot{Q}$ regions closely reflect these changes, affecting arterial PO_2 as mentioned previously. The quantitative

Figure 5-6. Alveolar PO_2 in small lung regions as a function of local $\dot{V}_A / \dot{Q}$ ratio. The normal $\dot{V}_A / \dot{Q}$ range is shown. The most important observation to be made is that when $\dot{V}_A / \dot{Q}$ ratio is reduced below normal, alveolar PO_2 is tied closely to PO_2 in the mixed venous blood.

manner in which blood flow is distributed within the lungs, and how this relates to the distribution of ventilation and of $\dot{V}_A / \dot{Q}$ ratios are major factors in gas exchange and in arterial oxygenation.

In cardiopulmonary disease, areas of low or zero $\dot{V}_A / \dot{Q}$ ratio are commonly seen and are responsible for hypoxemia.²⁰ In most cases, areas of low or zero $\dot{V}_A / \dot{Q}$ ratio are generated by abnormalities in local ventilation, not blood flow, although the alveolar edema underlying such effects may have its origins in primary cardiac disease. Local reduction in ventilation from airway obstruction or alveolar filling with cell debris or fluid is the usual mechanism. There are some specific situations in which hypoxemia seems to be the result of primary vascular changes. The hypoxemia of chronic liver disease is the result of pulmonary vascular malformations that mostly act as right-to-left shunts; the blood in these malformations does not participate in gas exchange.²¹⁻²³ Pulmonary thromboembolic disease, by obstructing some pulmonary arteries, results in overperfusion of nonembolized areas. This overperfusion reduces the local $\dot{V}_A / \dot{Q}$ ratio of nonembolized alveoli and is a primary reason for hypoxemia when it occurs in such patients.²⁴

Of particular relevance to cardiovascular state in the context of pulmonary gas exchange is a curious, poorly understood, but reproducible phenomenon whereby, as total blood flow through the lung (usually cardiac output) increases or decreases, so too does fractional shunt or venous admixture.²⁵ Figure 5-7 is a dramatic example of this phenomenon in a patient with lung disease on variable right heart bypass.²⁶ As pulmonary blood was mechanically varied from 1 to 5 L/(min · m²), percentage of shunt increased from 15% to 40% of the cardiac output. To underline the magnitude of this effect, absolute shunt perfusion increased from 0.15 L/(min · m²) to greater than 2 L/(min · m²), a more than 10-fold increase. Because these changes are rapidly reversible within minutes, it seems unlikely that the greater blood flow is actually causing more damage and shunt on this basis.

There is probably some systematic change in blood flow distribution between ventilated, normal regions and the unventilated alveoli causing the shunt to change with total blood flow.²⁷ This change generally occurs regardless of the anatomic distribution

Figure 5-7. Dependence of percentage shunt through the lungs on pulmonary blood flow in a single patient with acute respiratory distress syndrome. In this patient on partial right heart bypass, pulmonary blood flow varied between $1 \text{ L} \cdot (\text{min} \cdot \text{m}^2)^{-1}$ and $5 \text{ L} \cdot (\text{min} \cdot \text{m}^2)^{-1}$. Shunt varied between 15% and 40% in a linear manner.

of disease and seems to be unrelated to lung structure in any systematic way. Numerous animal studies done under many circumstances mirror the human experience, regardless of whether the cardiac output is manipulated mechanically or pharmacologically.²⁸ The finding that the increase in percent of shunt with cardiac output is far greater in animals breathing pure O_2 than room air, and greater than in animals breathing a hypoxic gas mixture points to an interaction between hypoxic pulmonary vasoconstriction and blood flow as the basic mechanism.²⁹

At low blood flow rates while breathing 100% O_2 , unventilated alveoli are greatly vasoconstricted by hypoxia, whereas ventilated units have little or no vascular tone. Any increase in total blood flow is directed mostly to the unventilated units because the higher pressure of high blood flow can overcome hypoxic vasomotor tone, whereas little additional blood flow can be accommodated by already relaxed, well-ventilated regions. From the clinical standpoint, it is important to be aware of the shunt–total blood flow relationship when interpreting pulmonary gas exchange as cardiac output varies.

Closely related to the previously described phenomenon is the effect of systemic vasodilators, which are sometimes given to patients in left heart failure to reduce afterload. When such patients have pulmonary gas exchange abnormalities, often as a result of pulmonary edema from the heart failure itself, there are areas of low or zero $\dot{V}_A/\dot{Q}$ ratio as a result of edema of the alveolar wall, alveolar gas space, or both.²⁰ Consequently, these regions are subject to hypoxic pulmonary vasoconstriction. Administration of a systemic vasodilator (e.g., nitroprusside) dilates not only the systemic vasculature, but also the pulmonary vasculature. The latter is particularly evident in the most vasoconstricted areas having a low $\dot{V}_A/\dot{Q}$ ratio. The result is increased blood flow through these areas (i.e., an increase in shunt or venous admixture).²⁰ Such changes act to worsen arterial hypoxemia. A reduction in arterial PO_2 is not often seen, however, because the simultaneous increase in cardiac output seen with vasodilators increases mixed venous PO_2 . As described in previous arguments (see Figs. 5-1 and 5-6), arterial PO_2 would be increased by this mechanism. The two opposing influences tend to balance, with no net change in arterial oxygenation.²⁰

Despite no change in arterial $[\text{O}_2]$, if cardiac output increases, total O_2 transport (the product of cardiac output and arterial $[\text{O}_2]$) also increases. This increase may be beneficial to cellular O_2 metabolism because it may increase O_2 availability to cells.

Left Ventricular Dysfunction and Lung Fluid Exchange

Another point of interaction among the heart, the lungs, and O_2 transport occurs when left ventricular filling pressures increase for any reason (e.g., myocardial or valvular disease). The potential problem is pulmonary edema. The lungs normally allow a steady flux of water and proteins from the capillaries to the interstitial space. This lymph finds its way in peribronchial lymphatic channels from peripheral to central lung regions and exits the hilum of the lungs in lymph ducts that drain into the superior vena cava. Transcapillary fluid flux is described by the Starling equation:

$$J = K[(P_{MV} - P_{INT}) - \sigma(\Pi_{MV} - \Pi_{INT})] \quad [5]$$

where J is fluid flux across the capillary wall, K is an overall filtration coefficient proportional to permeability and surface area of the microvascular network, and σ is a reflection coefficient for proteins. The latter is 0 when the wall is freely permeable to proteins and 1 when completely impermeable; σ must be low because albumin levels in pulmonary lymph are approximately 70% to 90% of those in capillary plasma.^{30,31} P_{MV} and P_{INT} are intracapillary microvascular and extracapillary interstitial hydrostatic pressures. Π_{MV} and Π_{INT} are the protein osmotic pressures in the same regions.

The equation sums the intracapillary and extracapillary hydrostatic and osmotic forces. The net result is positive¹ so that normally about 0.25 to 1 mL of lymph is transported across the capillary each minute. The lymphatic drainage system can easily handle this load. Its drainage efficiency is increased by one-way valves that make use of the respiratory excursions in intrathoracic pressure to pump lymph from alveoli centrally to the lymph ducts for return to the venous system.

For a structurally normal capillary, microvascular pressures must exceed 25 mm Hg before the rate of fluid movement out of the capillaries exceeds drainage capacity, and edema develops.¹ Normal microvascular pressures are 5 to 10 mm Hg. If capillary permeability is increased by capillary damage in disease, or if plasma protein levels are very low, alveolar edema occurs at pressures much lower than the expected 25 mm Hg.

When left ventricular dysfunction from any cause elevates pulmonary microvascular pressures sufficiently, the stage is set for clinical pulmonary edema, which causes reduced local ventilation, sometimes to the point of abolition of local gas exchange, resulting in areas of low $\dot{V}_A/\dot{Q}$ ratio and shunt. The mechanisms involved may include alveolar wall interstitial edema that reduces alveolar compliance and ventilation; compression of conducting airways, blood vessels, or both by fluid moving centrally as lymph, increasing resistance and decreasing gas or blood flow; or alveolar flooding with edema, abolishing ventilation and gas exchange in these alveoli completely. Left ventricular dysfunction is discussed further elsewhere in this text.

Ventricular Function and Lung Disease

Increasing evidence suggests that primary lung disease causing chronic pulmonary hypertension and resulting in right ventricular hypertrophy impedes left ventricular filling^{32,33}; this is functionally equivalent to increased diastolic stiffness

of the left ventricular wall. Left ventricular filling pressures are increased, and this increase is transmitted back through the pulmonary microvascular bed. As pressure in that bed is increased, transcapillary fluid flux tends to increase, increasing the risk of edema discussed previously. Further retrograde pressure transmission elevates pulmonary artery pressure, worsens the load on the right ventricle, and sets up a potential vicious cycle of events impeding cardiac and pulmonary function.

Although the importance of this mechanism in clinical disease states remains to be determined, there is some evidence of its pertinence to a specific human disorder: high-altitude pulmonary edema.³⁴ Susceptible individuals develop patchy pulmonary edema after rapid ascent and vigorous effort at altitudes of 9000 feet above sea level and higher. Although such individuals are known to have an exaggerated pulmonary vasoconstrictor response to hypoxia,³⁵ they also have higher left ventricular filling pressures (as estimated by pulmonary artery occlusion pressures) during exercise than do subjects resistant to high-altitude pulmonary edema.³⁴ Although this observation may reflect intrinsic variance in left ventricular stiffness per se, it is also compatible with the interdependent ventricular effects described previously, whereby right ventricular hypertension reduces effective left ventricular compliance.

Another type of cardiac complication of lung disease comes from ventilator strategies used in patients on assisted ventilation in the intensive care unit. High respiratory inflation pressures are commonplace to overcome loss of pulmonary compliance as a result of fluid and cell buildup in the alveolar region. Positive airway pressure is also commonly maintained at end-expiration to prevent alveolar collapse. When these strategies overinflate less affected alveoli, their capillaries are stretched and compressed, which increases pulmonary vascular resistance. This increased pulmonary vascular resistance combined with the positive intrathoracic pressures as a result of positive end-expiratory pressure impairs venous return and right and left ventricular function, and cardiac output is reduced, often by surprisingly large amounts.³⁶

Balancing ventilatory strategies to maintain alveolar gas exchange while minimizing undesirable cardiovascular consequences is a classic and difficult problem in management of acutely ill patients, and guidelines are continually being revised for optimal ventilatory care.³⁷ Until the consequences of such strategies on O₂ transport to critical organs including the heart can be assessed accurately, it will be difficult to rationalize the use of a particular approach. As positive end-expiratory pressure is increased, arterial [O₂] may improve as a result of alveolar re-expansion of previously atelectatic regions, but at the cost of diminished cardiac output and organ blood flow.³⁸ O₂ transport, the product of arterial [O₂] and blood flow to each organ, may increase, remain the same, or decrease in ways that are difficult to measure, let alone understand in terms of metabolic consequences. Optimal ventilatory care remains a critical area of clinical and basic research.

Cardiovascular Function and Systemic Gas Exchange

After O₂ exchange between alveolar gas and capillary blood has occurred, oxygenated arterial blood must be transported to the various organs and tissue beds of the body. After reaching the

microvasculature of each bed, O₂ is moved from its intraerythrocytic location bound to Hb through a series of steps to reach intracellular mitochondria.³⁹ Most O₂ taken in at the lungs is used at the mitochondrial level to produce adenosine triphosphate (ATP) for energy and heat needs of the organs.

The O₂ unloading pathway in a typical tissue traverses the following sequential steps.³⁹ First, O₂ must chemically dissociate from the Hb molecule. In vitro studies of this reaction suggest that when a person is at rest, there is sufficient unloading time for this dissociation to proceed to completion, but during intense exercise, this may not be the case. Next, O₂ molecules in solution must diffuse out of the red blood cell, into the microvascular plasma, and through the capillary endothelial wall. The amount of capillary surface area available within an organ is thought to be a critical variable, which under some conditions (e.g., in muscle during exercise, possibly in multiple organ failure in several capillary beds) is a limiting component to the movement of O₂ from red blood cell to mitochondria.^{40,41} The final step for O₂ is intracellular movement to reach mitochondria.

All of these transport steps rely on passive diffusion; there are no active (i.e., energy-requiring) O₂ transport processes. In muscle, intracellular O₂ movement is considered to be uniquely accelerated, however, by the binding of O₂ to myoglobin.^{42,43} This binding of O₂ to myoglobin reduces intracellular Po₂, maintaining a large Po₂ difference between the red blood cell and the muscle cytoplasm, which facilitates O₂ diffusion by Fick's law of diffusion. Myoglobin molecules can move freely in cytoplasm, and this aids O₂ transport further. Because of the great metabolic need for O₂ during exercise, this mechanism is considered important. Without myoglobin, aerobic ATP production might be significantly reduced by the lower O₂ transport rate. Finally, in muscle and other tissues, there may be a high concentration of mitochondria close to the cell wall, particularly near capillaries.³⁹ Whether this association facilitates O₂ movement directly to mitochondria or serves some other purpose, such as to facilitate metabolic clearance of waste products, is unknown.

This basic process of tissue O₂ transport is common to all tissues. Quantitative features depend on individual anatomic factors that determine microvascular richness and diffusion distances. Just as in the lungs, this diffusive system is generally adequate in all organs in normal humans at rest; however, during exercise in healthy states and possibly also in disease states, diffusive conductance may be limited to the point of constraining O₂ flux to the mitochondria and local metabolic rate. Maximal O₂ consumption is determined in part by the finite nature of the overall muscle diffusive conductance between the red blood cells and the mitochondria.⁴⁴ The decrease in maximal $\dot{V}O_2$ with hypoxia and increase in hyperoxia are further compatible with this notion. Behavior of O₂ consumption as O₂ transport to tissues is varied at rest or in disease is also compatible with a limited, finite O₂-diffusing conductance and pathway, although other factors may be responsible (discussed later).

Another important concept in O₂ transport to different organs and within organs is heterogeneity. In an ideal organism, blood flow and O₂ transport to each tissue would be precisely matched to local metabolic need. The organs with more O₂ would generally receive correspondingly more blood flow. Organs with a need for high blood flow based on other functions (e.g., kidney, liver) disrupt this ideal. Consequently, [O₂]

of venous blood from various organs differs in accord with the relationship between O_2 and blood flow ($\dot{Q}$), as Equation 2 would dictate. Even within organs, local heterogeneity may exist such that some regions are overperfused, whereas others are underperfused. Underperfused regions may be unable to achieve their normal metabolic rate because of lack of O_2 , and cellular dysfunction may result.

There is blood flow heterogeneity within all organs. This has been repeatedly shown using tracer (washout or microsphere) studies.^{45,46} This technique and the related method of radioactive tracer washout can measure only the distribution of blood flow, however, *per unit mass of tissue*. No technology is available that can measure regional blood flow in relation to O_2 consumption ($\dot{V}O_2$). Unless local O_2 consumption and local tissue mass are tightly correlated, tracer techniques cannot give us the desired information: how uniform (or nonuniform) is the local $\dot{V}O_2$ -blood flow relation? It is by no means necessary that tissue mass and $\dot{V}O_2$ are closely related. If local $\dot{V}O_2$ depends on O_2 delivery to the region, a close relationship cannot exist; local $\dot{V}O_2$ changes with blood flow, regardless of tissue mass. This is a serious technologic limitation on the understanding of O_2 transport-metabolism heterogeneity. This technologic limitation is partly why clinical application of principles of O_2 transport in the intensive care unit has been frustrating and has not produced improvement in patient care. Only when techniques are developed that assess patients' heterogeneity of $\dot{V}O_2$, blood flow, and cellular metabolism in the critical organs (e.g., brain, heart, kidney, gut) can proper use be made of the theoretical understanding of O_2 transport.

In addition to finite diffusive conductance and heterogeneity, a third physiologic phenomenon may interfere with O_2 transport within organs: the diffusive shunt for O_2 .^{47,48} To the extent that thin-walled precapillary and postcapillary blood vessels containing arterial and venous blood are physically juxtaposed in a tissue bed, there may be some direct diffusive escape of O_2 from the precapillary vessel into the postcapillary vessel. Although the existence of this phenomenon has been shown, its quantitative importance is probably small. Frozen tissue spectroscopy (measuring red blood cell Hb- O_2 saturation) in cross sections of such vessel pairs fails to yield evidence of this, at least in myocardium.⁴⁸

Another factor that can also interfere with O_2 transport out of the microcirculation is anatomic, non-nutritive, vascular arteriovenous connections or shunts.⁴⁹ Although anatomic studies show the existence of such pathways, their functional significance in health, let alone in disease, remains to be firmly established. Mathematical models of O_2 transport⁵⁰ suggest that experimental data are compatible with such shunts, but the key question of whether the same data can also be explained *without* invoking such shunts has not been answered.

With this introduction, the relationship between O_2 transport and O_2 consumption can be discussed. As recently as 1985, in a 600-page book devoted to acute respiratory failure in acute respiratory distress syndrome, less than one paragraph was devoted to this critical topic.⁵¹ In a more recent book on the subject, the area merited an entire chapter⁵²; at more recent international critical care meetings, symposia have regularly addressed the problem, and attempts have been made to tailor clinical care to maximizing O_2 transport.

In the healthy state, variations in total-body O_2 transport ($\dot{Q}O_2$) can be produced by varying cardiac output ($\dot{Q}T$),

Figure 5-8. Effect of total oxygen transport (cardiac output $\times$ arterial oxygen concentration) on total body oxygen uptake in the anesthetized dog. Above point C, at about $10 \text{ mL} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ O_2 transport, oxygen uptake is essentially independent of oxygen transport. To the left of point C, oxygen uptake falls toward the origin almost in proportion to reduced O_2 transport.

Hb concentration ($[Hb]$), or arterial O_2 saturation (SaO_2). $\dot{Q}O_2$ is essentially the product of these three variables:

$$\dot{Q}O_2 = k \cdot \dot{Q}T \cdot [Hb] \cdot SaO_2 \quad [6]$$

where k is the stoichiometric binding constant for O_2 and Hb; it is the number of milliliters of O_2 that can be bound by 1 g of Hb. Theoretically, k is 1.39, but it may be only 1.34 in practice because of small amounts of methemoglobin or carboxyhemoglobin. Equation 6 ignores the normally insignificant amounts of physically dissolved O_2 in the blood, which amount to only 1.5% of total arterial $[O_2]$ in healthy individuals.

When in normal animals $\dot{Q}O_2$ is varied over a reasonable range by manipulating $\dot{Q}T$, $[Hb]$, or SaO_2 , total-body O_2 consumption ($\dot{V}O_2$) is usually found to be constant (i.e., independent of $\dot{Q}O_2$). As $\dot{Q}O_2$ is reduced further, however, $\dot{V}O_2$ begins to decrease, and when $\dot{V}O_2$ is plotted against $\dot{Q}O_2$, the decreasing relation is essentially linear and heads toward the origin. Figure 5-8 shows an example of this pattern in a normal dog.⁵³ The biphasic $\dot{V}O_2$ - $\dot{Q}O_2$ relation shown in Figure 5-8 exemplifies the flat region of the curve where $\dot{V}O_2$ is not dependent on $\dot{Q}O_2$, and the portion at low $\dot{Q}O_2$ where, as $\dot{Q}O_2$ decreases, so does whole-body $\dot{Q}O_2$.

Figure 5-8 is from well-controlled studies in which, as a result of constant body temperature, muscle paralysis, and mechanical ventilation, overall cellular metabolic need for O_2 can reasonably be assumed to be constant. Under such conditions, the approximate (and difficult to identify precisely) junction (see point C in Fig. 5-8) of the independent and dependent portions of the curve is termed the *critical point*, and the associated $\dot{Q}O_2$ is termed the *critical O_2 transport (or delivery) value*. In the literature, DO_2 is often used instead of O_2 . The accepted interpretation of the dependent region (below point C in Fig. 5-8) is that mitochondrial O_2 supply has been reduced sufficiently by the severe reduction in $\dot{Q}O_2$ that mitochondrial O_2 needs cannot be fully met. As a result, $\dot{V}O_2$ decreases. A key observation is that at and below the critical point, mixed venous PO_2 has *not* fallen to zero. An apparent paradox exists: a decrease in $\dot{V}O_2$, yet failure to extract all of the O_2 out of the blood, which, had that been

possible, would have at least maintained $\dot{V}O_2$ down to a lower value of $\dot{Q}O_2$. It is therefore concluded that there is a physical limit to O_2 transport between blood and mitochondria.

Two competing but not mutually exclusive hypotheses based on reduced O_2 supply have been advanced to explain $\dot{V}O_2$ dependency on $\dot{Q}O_2$.⁵⁴ The first is heterogeneity. As the transport of O_2 molecules into the arterial tree is progressively reduced, but above the critical point C (see Fig. 5.8), sufficient O_2 flux to every organ exists. The system simply extracts the same amount of O_2 per unit time from a diminishing arterial supply, in concert with mass balance principles (see Equation 2), resulting in a mixed venous $[O_2]$ that decreases progressively with $\dot{Q}O_2$. Below the critical point, O_2 extraction no longer can be maintained because as a result of complex regulatory processes controlling blood flow between and within organs, some organs or cells within organs are deprived of flow and O_2 , to ensure survival of more critical organs and cells.

The second possibility is that tissue O_2 diffusive conductance, in excess above the critical point, is insufficient to move O_2 molecules from the tissue microvascular red blood cells to the mitochondria.⁵⁵ This is not because O_2 diffusive conductance suddenly decreases when $\dot{Q}O_2$ is reduced below the critical value, but because O_2 flux from red blood cells to mitochondria by diffusion depends on the product of the diffusive conductance, DO_2 , and the PO_2 difference between the red blood cells (P_{RBC}) and the mitochondria (P_{MITO}) according to Fick's law of diffusion:

$$\dot{V}O_2 = DO_2 [P_{RBC} - P_{MITO}] \quad [7]$$

Above the critical point, P_{RBC} and P_{MITO} are much greater than zero, or the minimal mitochondrial PO_2 necessary to sustain mitochondrial respiration (about 0.5 mm Hg according to in vitro studies). At the critical point, with no change in DO_2 implied, P_{RBC} and P_{MITO} have decreased as $\dot{Q}O_2$ is reduced and venous PO_2 decreases (discussed previously), and P_{MITO} has reached the critical mitochondrial value (0.5 mm Hg) for sustaining mitochondrial O_2 . As $\dot{Q}O_2$ is reduced below the critical value, P_{RBC} decreases even further; P_{MITO} cannot be sustained, and $\dot{V}O_2$ must decrease as a result of mitochondrial O_2 supply limitation. Both hypotheses could be simultaneously correct and interactive; more research is needed to clarify these and any other possibilities.

A third possible factor should be mentioned. Rather than $\dot{V}O_2$ passively decreasing as a result of limited O_2 supply from either heterogeneity or diffusion limitation, intracellular sensors of O_2 could mediate a protective reduction in metabolic O_2 requirements. An example is the behavior of renal $\dot{V}O_2$ as renal blood flow is reduced.⁵⁶ Because most of renal O_2 consumption goes into active Na^+Cl^- reabsorption from tubular fluid, and the salt load depends on glomerular filtration and on blood flow, renal $\dot{V}O_2$ decreases with renal blood flow and with renal $\dot{Q}O_2$ because the metabolic demands on the kidney decrease. This is a special case and mechanism, and is not thought to reflect behavior of the other organ systems.

The preceding has not differentiated among the three possible means of reducing $\dot{Q}O_2$ mentioned at the outset: manipulating blood flow, [Hb], or SaO_2 . Classic studies comparing these strategies have revealed that reducing SaO_2 or [Hb] produces the same critical point C (see Fig. 5-8) when expressed as the value of $\dot{Q}O_2$ at which $\dot{V}O_2$ begins to decrease.⁵⁷ $\dot{V}O_2$ begins to decline at a higher venous PO_2 , however, when O_2 transport is reduced

by anemia rather than by hypoxia. This action is consistent with an effect of anemia reducing the O_2 diffusional conductance, much as is the case for O_2 diffusing capacity and [Hb] in the lungs, requiring a higher driving pressure (see Equation 7) to maintain $\dot{V}O_2$. Support for this idea comes from exercise studies of maximal $\dot{V}O_2$ as [Hb] is changed, showing [Hb] dependence of muscle O_2 diffusional conductance.^{58,59}

To this point, only whole-organism data have been described, but it is important to explore the $\dot{V}O_2 - \dot{Q}O_2$ relationship in individual organ systems. Similar biphasic $\dot{V}O_2 - \dot{Q}O_2$ curves have been found in several organ systems: skeletal muscle,⁶⁰ liver,⁶¹ and intestine.⁶² Although critical values of organ $\dot{Q}O_2$ may be different, the research conditions under which they have been measured are difficult to compare, and to a rough approximation, the whole-body data seem to reflect these individual organ results reasonably. The implication is that to the extent that heterogeneity of O_2 transport is important to the $\dot{V}O_2 - \dot{Q}O_2$ relationship, this is likely to be based more on intraorgan than interorgan differences in O_2 flow; however, this area needs more investigation.

It seems that when $\dot{V}O_2$ is O_2 supply-dependent (below point C; see Fig. 5-8), cellular metabolism and integrity are threatened. The physician's natural therapeutic reaction would be to increase $\dot{Q}O_2$ by manipulating blood flow or [Hb] or arterial O_2 saturation, and this reaction has found its way into the critical care arena. This is not a trivial undertaking; of the three components of $\dot{Q}O_2$ potentially subject to manipulation, arterial O_2 saturation is of limited availability in most critically ill patients because of their lung disease. Hyperoxia provides only a small improvement in O_2 saturation, and renders the lungs vulnerable to O_2 toxicity. Shunt reduction by ventilating the lungs with high pressures reduces cardiac output and may offset the gains in O_2 saturation. Increasing [Hb] may produce viral contamination of blood; as [Hb] is increased, cardiac output may decline, also offsetting the gains in overall $\dot{Q}O_2$. This leaves enhancing cardiac output as the remaining major possibility. The hearts in such patients are usually already under stress and pumping two to three times the usual resting volume per minute in response to the high tissue metabolic needs associated with tissue repair and fever.⁶³

Cardiac function may be impaired by high respiratory pressures (discussed previously); the myocardium may be damaged by the systemic disease processes of critically ill patients (e.g., patients with acute respiratory distress syndrome); and coronary blood flow may be compromised as a result of prior coronary artery disease or aggressive ventilator strategies. Encouraging greater cardiac function with various inotropic or sympathomimetic agents (e.g., dopamine, dobutamine) carries significant risk under these circumstances and cannot be universally recommended until the physicochemical basis of O_2 supply dependency of $\dot{V}O_2$ in these patients is fully understood.

There are two additional significant caveats to the entire $\dot{V}O_2 - \dot{Q}O_2$ issue. The first is delineating signal from noise. $\dot{V}O_2$ is the product of blood flow and arteriovenous $[O_2]$ difference, whereas $\dot{Q}O_2$ is the product of blood flow and arterial $[O_2]$. Unless $\dot{V}O_2$ and $\dot{Q}O_2$ are measured by technically independent techniques, there is major covariance between $\dot{Q}O_2$ and $\dot{V}O_2$ as a result of the use of blood flow and arterial $[O_2]$ in $\dot{V}O_2$ and $\dot{Q}O_2$. Measurement errors in blood flow and arterial $[O_2]$ must give an apparent correlation between $\dot{V}O_2$ and $\dot{Q}O_2$ (i.e., data compatible with O_2 supply dependency)⁶⁴; however, this

would be clearly a false-positive outcome. This issue is particularly a problem for sequential measurements in a given individual. This problem also occurs in comparing patients of different size or $\dot{V}O_2$ on a plot of $\dot{V}O_2$ versus $\dot{Q}O_2$; a small patient generally shows lower values for both variables than a large patient. Normalization for body size must be performed before interpretation. Cross-sectional surveys of single datum points from many subjects may not be particularly useful in understanding the phenomenon further. Before accepting data supporting a dependency of $\dot{V}O_2$ on $\dot{Q}O_2$, it is essential to ensure that appropriate methods and statistical treatment of the data have excluded false-positive correlations between $\dot{V}O_2$ and $\dot{Q}O_2$.^{40,41}

The second difficulty in understanding the $\dot{V}O_2 - \dot{Q}O_2$ relationship is a physiologic one. In the preceding discussion, it is assumed that cellular O_2 requirements are constant as $\dot{Q}O_2$ is manipulated by the investigator. This requirement is obvious; if a patient is studied first while skeletal muscles are active and then again when paralyzed by a muscle relaxant and on a ventilator, total-body O_2 requirements would be reduced. Just as during normal exercise, O_2 transport, cardiac output in particular, is regulated by O_2 requirements. In the previous comparison, $\dot{V}O_2$ and $\dot{Q}O_2$ would be greater before paralysis, and a $\dot{V}O_2 - \dot{Q}O_2$ plot would suggest O_2 supply dependence of $\dot{V}O_2$. It is critical to understand the difference; a change in $\dot{V}O_2$ caused by a change in $\dot{Q}O_2$ constitutes true O_2 supply dependence of $\dot{V}O_2$, whereas a change in activity of cells or tissues requiring more O_2 is generally reflected by an increase in $\dot{Q}O_2$ to meet these needs.⁵⁶ This is an appropriate response that should not be regarded as O_2 supply dependence of $\dot{V}O_2$ in the previous context; yet, on a diagram relating $\dot{V}O_2$ and $\dot{Q}O_2$, both scenarios look the same.

In critically ill patients, $\dot{V}O_2$ is sometimes found to vary with O_2 transport ($\dot{Q}O_2$) under conditions and at $\dot{Q}O_2$ levels that would not produce changes in $\dot{V}O_2$ in health. The physician must first ensure these changes are real and not the result of covariance and errors. The physician must ascertain, if possible, whether the relationship is driven by a change in O_2 requirement (i.e., false O_2 supply-dependent relationship) or a change in O_2 availability (i.e., true O_2 supply-dependent relationship). Only if the latter is established can the physician begin to consider the pros and cons of manipulating O_2 transport variables; however, even then, options are limited, as previously explained. Because the various intraorgan relationships between cellular metabolic normalcy and O_2 supply in critically ill patients is poorly understood, it is likely to be some time before the necessary technologies are developed to allow physicians to make rational use of these undoubtedly important concepts.

Mixed venous O_2 saturation ($S\bar{v}O_2$) may be used in assessing cardiovascular sufficiency in critically ill patients.⁶⁵ The attractiveness of continuous, accurate, real-time measurements of $S\bar{v}O_2$ using a Swan-Ganz catheter with fiberoptics allowing external spectrophotometric determination of Hb saturation has brought this issue into prominence. A rearrangement of Equation 2 and the previous discussion provide a rational basis for interpretation of $S\bar{v}O_2$. Because

$$\dot{V}O_2 = \dot{Q}T[CaO_2 - C\bar{v}O_2] \quad [2]$$

the right side can be re-expressed so that:

$$\dot{V}O_2 = 1.34 \cdot \dot{Q} \cdot [Hb] \cdot [SaO_2 - S\bar{v}O_2] \quad [8]$$

This transformation assumes negligible contribution of dissolved O_2 (see Equation 6). By rearrangement of Equation 8:

$$S\bar{v}O_2 = SaO_2 - \dot{V}O_2 / [1.34 \cdot [Hb] \cdot \dot{Q}T] \quad [9]$$

Provided that arterial saturation (SaO_2), $\dot{V}O_2$, and $[Hb]$ remain constant, a decrease in $S\bar{v}O_2$ indicates a decrease in $\dot{Q}T$, and this can be useful as a cardiac output monitor. A decrease in SaO_2 or $[Hb]$ or an increase in $\dot{V}O_2$ also reduces $S\bar{v}O_2$; these variables must be assessed independently to interpret $S\bar{v}O_2$. An increase in $S\bar{v}O_2$ can occur from an increase in cardiac output, but is also seen if, as a result of peripheral tissue heterogeneity, O_2 diffusion limitation, or both, $\dot{V}O_2$ was reduced. Therapeutically beneficial and harmful phenomena can move $S\bar{v}O_2$ in the same direction, obscuring interpretation of $S\bar{v}O_2$. A further transformation of Equation 9 yields:

$$S\bar{v}O_2 = SaO_2 [1 - \dot{V}O_2 / \dot{Q}O_2] \quad [10]$$

Looking at Figure 5-8, it would be expected that along the flat portion of the relation, above the critical point C, $S\bar{v}O_2$ must decrease as $\dot{V}O_2$ stays constant while $\dot{Q}O_2$ is reduced; this is clear from Equation 10. Below the critical point C, if the $\dot{V}O_2 - \dot{Q}O_2$ relation is truly a straight line passing through or near the origin, the ratio $\dot{V}O_2 / \dot{Q}O_2$ may be essentially constant while $\dot{V}O_2$ and $\dot{Q}O_2$ are decreasing. If SaO_2 is constant under such conditions, $S\bar{v}O_2$ also is constant. It is possible that under the very conditions the physician wants to identify (i.e., O_2 supply dependency of $\dot{V}O_2$), $S\bar{v}O_2$ could be essentially constant and obscure the presence of the presumed cellular metabolic derangement.

Monitoring of $S\bar{v}O_2$ alone yields data that are open to many interpretations that could have either beneficial or deleterious implications.⁶⁵ Without measures of all the determinants of $S\bar{v}O_2$ (i.e., SaO_2 , $\dot{V}O_2$, $[Hb]$, and cardiac output), unique interpretation is impossible. This conclusion is clouded further by the obvious fact that $S\bar{v}O_2$ is mixed venous O_2 saturation, and its relationship to oxygenation of individual critical organs is, as discussed previously, a major unknown in critically ill patients. $S\bar{v}O_2$ reflects PO_2 of the venous blood, not of the intracellular environment. When O_2 transport between blood and mitochondria is compromised in disease, venous PO_2 is likely to exceed PO_2 at the mitochondria considerably. This situation is analogous to lung disease, in which alveolar PO_2 can greatly exceed arterial PO_2 ; the alveolar value is not used as an index of arterial PO_2 in this setting because they move in opposite directions as disease worsens.

The medical community has a long way to go before a clear understanding of the role of the cardiovascular system in O_2 transport in critically ill patients can be obtained. Technologic advances in assessing cellular metabolic function in critical organs in the context of O_2 supply and at a level that can assess functional heterogeneity within and between organs are the key to success in this regard.

Arteriovenous Oxygen Difference
Reflex Control of Cardiac Output
Left Ventricular Performance
End-Systolic Pressure-Volume Relationship

Application of the Pressure-Volume Approach
to Pathologic Conditions
Limitation of the Pressure-Volume Approach
Conclusion

THE CARDIOVASCULAR system supplies the tissues with oxygen and metabolic substrates and removes carbon dioxide and other waste products. The integration of all its components (venous circulation, right heart, lungs and pulmonary vascular system, and left heart and arterial circulation) results in the cardiac output.

The cardiac output is readily measured in the clinical setting using indicator dilution techniques. A common approach is to inject a cold solution into the right atrium, and measure the resulting blood temperature transient by using a thermistor on the tip of a catheter positioned in the pulmonary artery. An alternative approach is to measure cardiac output using the Fick principle. The rate of oxygen consumption of the patient is measured by collection of expired gases or, less accurately, assumed using a standard nomogram based on the patient's height, weight, and age. The difference in arterial and pulmonary venous oxygen content (A-VO₂ difference) is measured. Cardiac output is calculated as:

$$\text{Cardiac output} = \text{O}_2 \text{ consumption} / \text{A-VO}_2 \text{ difference} \quad [1]$$

Cardiac output is usually normalized for body surface area and expressed as the cardiac index. The normal range for the cardiac index at rest is wide, 2.5 to 4.2 L/min/m², and cardiac output can decline by almost 40% without deviating from normal limits. A low cardiac index of less than 2.5 L/min/m² usually indicates a marked disturbance in cardiovascular performance and is almost always clinically apparent. Although the resting cardiac output or index is an insensitive measure of cardiovascular performance, it is clinically valuable in critically ill patients.

Arteriovenous Oxygen Difference

The provision of adequate tissue oxygenation depends on the integrated function of the heart, peripheral and pulmonary vasculature, lungs, blood, and peripheral metabolism.¹ According to the Fick principle, the oxygen consumed by the body is equal to the product of the cardiac output and the A-VO₂ difference. Under normal circumstances at rest, oxygen delivery exceeds consumption, so that adequate tissue oxygenation is provided with an A-VO₂ difference of 40 ± 10 mL/L. If arterial oxygen tension and serum hemoglobin are normal, this results

in a mixed venous oxygen saturation of 70% or more. If cardiac output decreases, the tissues extract a greater fraction of oxygen from the arterial blood, and mixed venous oxygen saturation decreases. A mixed venous oxygen saturation of 70% or more indicates that oxygen delivery and cardiac output are sufficient to meet the needs of the body.²

A wide A-VO₂ difference and reduced mixed venous oxygen saturation may result from an abnormality of cardiovascular function that has resulted in a reduced cardiac output, a defect in blood oxygen-carrying capacity, or pulmonary disease. When the ability of the tissue to increase its extraction of oxygen is exhausted, tissue hypoxia results. In these conditions, anaerobic metabolism is heralded by a precipitous increase in venous lactate levels.³

During exercise, oxygen consumption can increase 18-fold. This increase in O₂ demand is met partly by an increase in cardiac output up to sixfold (from 3 to 18 L/min/m²), and partly by a threefold increase in the A-VO₂ difference (from 40 to 120 mL/L), with a decrease in mixed venous oxygen saturation from 75% to 25%.

The myocardium nearly maximally extracts oxygen from blood at rest. The coronary sinus oxygen saturation is low (<40%), and the myocardium cannot use an increase in oxygen extraction as a compensatory mechanism for inadequate coronary flow.

Reflex Control of Cardiac Output

Under normal conditions, the heart has a large functional reserve; it is not the limiting factor in determining cardiac output. The arterial (perfusion) pressure and the cardiac output are adjusted to meet the needs of the body as they vary with posture and activity. The regulatory mechanisms involve sensory and effector components. The sensory components include peripheral receptors that react to changes in blood pressure (e.g., baroreceptors in aortic arch and carotid sinuses), blood volume (e.g., stretch receptors in the atria, Bainbridge reflex), and ventilation (e.g., carotid chemoreceptors). In addition there are loci in the cortex, hypothalamus, and diencephalon of the brain that react to emotions, anxiety, anticipation, exercise, hypoxia, and temperature. Cardiac output is modulated through changes in heart rate, stroke volume, and vasomotor tone that are mediated by

direct parasympathetic and sympathetic neural pathways and by circulating catecholamines. Other humoral factors, such as adrenocortical steroids, thyroid hormones, insulin, and glucagons, have been shown to have an effect on cardiac function, but the importance of these hormones for regulation of cardiac output is unclear.

Direct sympathetic neural stimulation and circulating catecholamines exert a powerful stimulatory effect, increasing heart rate and contractile state, whereas vagal stimulation results in a decrease in heart rate and contractile state. The sympathetic and parasympathetic systems interact with each other in a complex fashion to influence cardiovascular performance. Generally, two types of interactions exist: accentuated antagonism and reciprocal excitation.⁴ Accentuated antagonism refers to the finding that the negative inotropic and chronotropic effects of vagal stimulation are more pronounced when vagal stimulation occurs in the presence of an increased adrenergic tone. Reciprocal excitation refers to the paradoxical effects of stimulation by one division on the autonomic nervous system, which results in effects normally expected from stimulation by the opposite autonomic division. The most common example of this is the production of positive inotropic effects by vagal stimulation or acetylcholine administration under experimental conditions.⁴

The factors that help regulate cardiac output are summarized in Table 6-1. The regulation system of cardiac output can become dysfunctional and result in syncope as a result of enhanced atrial and peripheral baroreceptor sensitivity, autonomic dysfunction, or complete heart block. In a critically ill cardiac patient, the normal regulatory mechanisms are usually saturated by maximal sympathetic and catecholamine stimulation. Under these conditions, the major determinants of cardiac output are no longer the neurohormonal pathways that regulate the normal cardiovascular system, but rather the interaction between the heart and the peripheral vasculature. The mechanical determinants of ventricular pump function are of paramount importance.

Table 6-1. Factors That Influence Cardiac Output

	Effects
Sympathetic tone	↑ contractile state, ↑ heart rate
Vagal tone	↓ contractile state
Right vagus	↓ sinus node activity, sinus bradycardia
Left vagus	↓ atrioventricular conduction
Volume load	↑ heart rate (Bainbridge reflex)
Baroreceptor stimulation (aortic arch, carotid sinus)	↓ contractile state
Calcium administration	↑ contractile state
Hormones (epinephrine, glucagon, thyroxine)	↑ contractile state, ↑ heart rate
Drugs	
Positive inotropes	
Phosphodiesterase inhibitors (milrinone, amrinone, theophylline)	↑ contractile state, ↑ heart rate
Digitalis glycosides	↑ contractile state, ↓ atrio- ventricular conduction
Adrenergic stimulants (dopamine, dobutamine)	↑ contractile state, ↑ heart rate
Negative inotropes	
β-adrenergic antagonists	↓ contractile state, ↓ heart rate
Calcium channel blockers	↓ contractile state, ↓ atrio- ventricular conduction

Left Ventricular Performance

Pressure-Volume Loop

Although the integrity of left ventricular and right ventricular function and pulmonary and peripheral circulations is important, most cardiovascular dysfunction in adults is the result of impaired left ventricular function. The performance of the left ventricle can be understood by examining the relationship between left ventricular pressure and volume during a single beat in the pressure-volume plane (Fig. 6-1). Instantaneous intraventricular pressure is plotted on the *y* axis, and instantaneous ventricular volume is plotted on the *x* axis. At end-diastole (point *a*), ventricular pressure is relatively low, and ventricular volume is relatively high. The segment *ab* represents isovolumic contraction, with an increase in intraventricular pressure, but no ejection. Point *b* represents the start of ejection, coincident with the opening of the aortic valve when ventricular pressure exceeds aortic pressure. At end-systole (point *c*), the aortic valve closes, and a period of isovolumic relaxation commences (segment *cd*). The mitral valve opens at point *d*, when ventricular pressure decreases to less than atrial pressure, and ventricular filling commences.

The difference between the end-diastolic and end-systolic volumes represents the volume ejected in that beat (stroke volume), and the ratio of stroke volume to end-diastolic volume

Figure 6-1. For a single cardiac cycle, instantaneous left ventricular (LV) pressure is plotted against LV volume. Point *a* represents end-diastole and the start of isovolumic contraction. Ventricular pressure increases without any change in volume until ejection starts at point *b*, which represents the opening of the aortic valve. During ejection, ventricular volume decreases. Point *c* represents end-systole and the start of isovolumic relaxation. Aortic valve closure occurs near end-systole. Ventricular pressure continues to decrease until ventricular filling starts with the opening of the mitral valve at point *d*. Ventricular pressure increases very slightly during diastolic filling.

Figure 6-2. Three different pressure-volume (PV) loops are shown representing beats at three different preloads. Control conditions are represented by the shaded PV loop. An increase in preload (e.g., a large volume load) is associated with an increase in diastolic filling and a shift in the end-systolic PV point to the left. The added stretch causes a stronger contraction and an increase in the pressure developed during systole and in stroke volume. The PV loop is larger and shifted to the right (*broken lines*). Conversely, a decrease in preload, such as a loss of blood volume, results in a smaller PV loop which is shifted to the left (*broken lines*). The end-systolic points of the three variably loaded beats fall on a straight line. This line represents the end-systolic pressure-volume relationship (ESPVR). A similar but curvilinear relationship is formed by the end-diastolic PV points—the end-diastolic pressure-volume relationship (EDPVR).

is the ejection fraction. In the absence of aortic stenosis, the ventricular pressure at end-systole is the same as the pressure in the proximal aorta, and approximates systolic blood pressure (actually the pressure at the diastolic notch in the aortic pressure-time course). Cardiac output is the product of stroke volume and heart rate. The pressure-volume loop provides a useful way to analyze the effects of contractile state, preload, and afterload on cardiac output.

Effect of Alterations in Preload on the Pressure-Volume Loop

Preload is defined as the stretch of the myocardium before activation and is readily indexed by end-diastolic volume. Within physiologic ranges, the greater the stretch on the myocardium, the stronger the ensuing contraction; this is known as the Frank-Starling relationship.⁵ From studies in isolated heart preparations in which preload, afterload, and contractile state were controlled, it has been shown that an increase in preload, produced by an increase in end-diastolic volume, results in an increase in the end-systolic pressure and the stroke volume of the ensuing beat.⁶⁻⁸

Three pressure-volume loops under three different preload conditions are shown in Figure 6-2. For the purpose of illustration, it is assumed that heart rate, contractile state, and afterload remain constant. Baseline conditions are represented by the shaded loop. A decrease in preload as a result of loss of blood volume, if not associated with any other change in afterload or contractile state, results in a smaller end-diastolic volume and a smaller pressure-volume loop that is shifted to the left. Conversely, a volume load results in a larger pressure-volume loop that is shifted to the right. An isolated increase in preload without any change in afterload or contractile state results in increases

in stroke volume and end-systolic pressure if heart rate, afterload, and contractile state are unchanged. These conditions do not apply precisely in vivo. Isolated changes in preload, afterload, contractile state, or heart rate occur rarely because these changes are usually a response to, or in themselves result in, compensatory neurohormonal reflexes, which influence all these variables in a complex fashion. It may be useful, however, for an understanding of cardiovascular dynamics to analyze these factors separately.

End-Systolic Pressure-Volume Relationship

In Figure 6-2, the end-systolic points of all three pressure-volume loops fall on a straight line. This line is termed the *end-systolic pressure-volume relationship* (ESPVR) and is constant for a given contractile state.⁹ A similar but nonlinear relationship can be constructed for the end-diastolic points—the end-diastolic pressure-volume relationship (EDPVR). The ESPVR and EDPVR have been shown to be relatively load independent at a given contractile state^{10,11}; however, the ESPVR is not absolutely load independent, probably because of the positive and negative inotropic effects of ejection.¹²⁻¹⁴ For practical purposes, at a given contractile state, the cardiac pressure-volume loop is always bound by the ESPVR and the EDPVR. For a given contractile state, the ESPVR can conveniently be expressed as follows (see Fig. 6-2):

$$P_{es} = E_{es} (V_{es} - V_o) \quad [2]$$

where P_{es} is end-systolic pressure, V_{es} is end-systolic volume, V_o is the volume axis intercept, and E_{es} is the slope of the ESPVR.^{6,9,15} Because of its relative load independence, E_{es} has been proposed as an index of contractile state.⁹ V_o represents the volume at which the ventricle can no longer generate force. This dead volume is a function of heart size. A smaller heart can contract down to a smaller volume than a large heart.

Effect of Changes in Contractile State

The contractile state of the heart refers to the intrinsic ability of the myocardium at a given load to generate force during contraction. Myocardial contractile state is influenced by several endogenous and exogenous factors (see Table 6-1). In the pressure-volume plane, an increase in myocardial contractile state results in an increase in force development at any given ventricular volume. Conversely, the “dead volume” of the ventricle is unchanged because heart size has not changed. These changes manifest in the pressure-volume plane as an increase in the slope of the ESPVR without a change in V_o .⁹ In Figure 6-3, preload, afterload, and heart rate are assumed to be constant. Under these conditions, an increase in contractile state results in an increase in stroke volume and end-systolic pressure. Conversely, in the absence of any compensatory mechanisms, a reduction in myocardial contractility results in a reduction in systolic pressure and stroke volume. Some common compensatory mechanisms are discussed later; first, the effect of changes in afterload must be considered.

Effect of Changes in Afterload

Afterload is the load the ventricle must overcome to eject volume, and, in the absence of valve disease, is determined mainly by the properties of the arterial system. An increase in afterload results in an increase in end-systolic pressure at the expense of ejection.

Figure 6-3. The effect of an increase in contractile state on the pressure-volume loop and the end-systolic pressure-volume relationship is shown.

Figure 6-4. The effect of changes in afterload is shown in three beats at different afterloads. An increase in afterload results in an increase in end-systolic pressure, but a decrease in stroke volume. A decrease in afterload has opposite effects. The end-systolic pressure-volume points do not deviate significantly from the end-systolic pressure-volume relationship (ESPVR). The ESPVR is insensitive to changes in afterload.

The effect on the pressure-volume loop is shown schematically in Figure 6-4. Stroke volume, ejection fraction, and, assuming no change in heart rate, cardiac output are decreased despite a constant contractile state. This is a good illustration of the load dependence and limitations of cardiac output and ejection fraction as clinical indices of contractile state. As shown in Figure 6-4, an increase in afterload, without a change in contractile state, results in changes in the shape of the pressure-volume relationship, but the end-systolic points do not deviate significantly from the ESPVR. This is an idealized figure; as stated previously, the end-systolic points are load dependent,^{12,14} but a simplified view suffices for illustration and allows the conceptual expression of the interaction between left ventricular function and the arterial system.

To understand ventriculoarterial coupling, it is useful to view the arterial system also in terms of pressure-volume or pressure-stroke volume relationships, as proposed by Sunagawa

Figure 6-5. The systolic pressure-volume relationship of the arterial system. The volume of this system at any given time is a function of the stroke volume, which determines the volume increase during systole, and of the vascular resistance to blood flow out of the arterial system and into the venous system. The change in pressure for a given change in volume is a function of the effective compliance of the arterial system. For a given cardiac cycle and assuming constant afterload, aortic end-systolic pressure (AoP_{es}) is linearly related to stroke volume. The slope of this relationship is termed the arterial elastance (E_a) and is an index of afterload.

Figure 6-6. The arterial elastance (end-systolic pressure divided by stroke volume) is superimposed on the pressure-volume loops for three variably afterload beats. An increase in afterload is represented by an increase in the slope of the arterial elastance (E_a).

and colleagues.¹⁶ In this study, the relationship between stroke volume and arterial end-systolic pressure is linear, and it is assumed that the relationship passes through the origin (Fig. 6-5). The slope of this relationship is termed the *arterial elastance* (E_a), and is the end-systolic pressure divided by the stroke volume. E_a can be expressed in the ventricular pressure-volume plane (Fig. 6-6). E_a is represented by the slope of a line connecting end-diastolic volume on the volume axis and the upper left corner of the pressure-volume loop. This approach is simplified and not absolutely correct because the arterial pressure-volume relationship probably does not truly pass through the origin.¹⁷ The concept of arterial elastance and the ESPVR can be used, however, to predict analytically the effect of changes in afterload on end-systolic pressure and cardiac output.

Figure 6-7. Acute myocardial infarction results in a reduction in contractile state owing to a loss of muscle mass. This results in a decrease in the slope of the end-systolic pressure-volume relationship (ESPVR). The volume axis intercept (V_0) increases by the theoretical volume enclosed by the dead muscle, shifting the ESPVR to the right. Compensatory mechanisms result in an increase in end-diastolic volume and afterload. These changes result in a reduction in stroke volume and an increase in filling pressures.

Application of the Pressure-Volume Approach to Pathologic Conditions

Acute Systolic Dysfunction

The framework of the pressure-volume approach as described previously allows the conceptualization of the interaction among cardiac function, preload, and afterload. Figure 6-7 represents a hypothetical situation in a patient with an acute myocardial infarction. Acute myocardial infarction results in the loss of a segment of functioning myocardium, while the rest of the heart is preserved. Assuming for simplicity that ischemia or neurohormonal stimuli do not alter the contractile state of the surviving myocardium, the ventricle can be modeled as two compartments: one with a normal ESPVR and one with an ESPVR that approximates the EDPVR.¹⁸ The combined effect is to reduce the slope of the ESPVR (E_{es}), representing a reduction in overall myocardial contractility, and an increase in the volume intercept (V_0). The increase in V_0 represents the contribution of the volume of the nonfunctioning segment of the ventricle to the “dead volume.”

As a result of these changes, the heart is able to maintain an adequate systemic perfusion pressure, but at the expense of an increase in end-diastolic volume and end-diastolic pressure. The increases in end-diastolic volume and pressure are mediated by neurohormonal reflexes, which result in fluid retention and an increase in vascular resistance. The increase in vascular resistance is reflected in the pressure-volume plane as an increase in arterial elastance (E_a). The clinical syndrome of heart failure as a result of acute systolic dysfunction results from the increase in end-diastolic filling pressure, which causes pulmonary congestion or peripheral edema, and the reduction in stroke volume, which is the result of the decrease in E_{es} and the increase in E_a . To some extent, an increase in heart rate may compensate for the reduction in stroke volume to maintain cardiac output.

Figure 6-8. Diastolic dysfunction resulting from impaired distensibility manifests in the pressure-volume plane as an increase in the slope or leftward shift of the end-systolic pressure-volume relationship (ESPVR). The ventricle requires a higher filling pressure to distend sufficiently to receive an adequate end-diastolic volume.

Diastolic Dysfunction

Inasmuch as left ventricular systolic function represents the ejection of adequate volume, diastolic function can simply be viewed as the process of filling of the left ventricle. Normal diastolic function is defined as adequate filling of the left ventricle, without exceeding a pulmonary venous pressure of 12 mm Hg.¹⁹ From the pressure-volume approach, it is clear that the end-diastolic pressure is a function of end-diastolic volume and EDPVR. Systolic dysfunction, resulting in an increase in end-diastolic volume and end-diastolic pressure, also meets this definition. In this case, the abnormality is primarily in systole, however, if systole is defined as adequate ejection, given adequate filling.

Isolated diastolic dysfunction commonly can result from impaired ventricular distensibility, external compression of the left ventricle, or obstruction to filling of the left ventricle.²⁰⁻²² Impaired distensibility as a result of chronic hypertension is a common cause of diastolic dysfunction and is represented in the pressure-volume plane as a steep or left-shifted EDPVR (Fig. 6-8). With significant diastolic dysfunction, adequate filling sufficient to maintain stroke volume is achieved only at the expense of an elevated end-diastolic filling pressure. Diastolic dysfunction, without any systolic dysfunction, can produce symptoms of pulmonary congestion and congestive heart failure.^{21,23} The effect of external compression such as pericardial tamponade or constriction similarly results in a leftward shift of the EDPVR by reducing capacitance.

Aortic Stenosis

Aortic stenosis is a special form of systolic dysfunction. The stenosed aortic valve imposes a resistance to ejection that must be overcome by the ventricle to maintain an adequate stroke volume and systemic perfusion pressure. The resistance to ejection results in a pressure gradient across the valve. The effect on the ventricle is an increase in the effective arterial elastance, which in this case incorporates the stenotic valve and does not reflect pure arterial properties. The increase in end-systolic pressure results in an increase in end-systolic ventricular wall stress. Over time, the ventricle compensates by concentric hypertrophy, which reduces the wall stress. The effect of this hypertrophy is to shift the ESPVR to the left. Concentric hypertrophy is also a common cause of diastolic dysfunction that manifests as an elevated EDPVR (Fig. 6-9).^{24,25}

Figure 6-9. Aortic stenosis imposes an added afterload on the left ventricle, which must generate an increased end-systolic pressure to overcome the aortic valve gradient. Concentric left ventricular hypertrophy results in a leftward shift in the end-systolic pressure-volume relationship (ESPVR) with a small increase in the slope of the ESPVR (E_{es}). Hypertrophy also results in diastolic dysfunction, with a steeper end-diastolic pressure-volume relationship (EDPVR). These changes result in a reduction in stroke volume and an increase in filling pressures.

Figure 6-10. Mitral stenosis imposes a resistance to left ventricular filling. This results in a diastolic pressure gradient between the left atrium and left ventricle. Adequate ventricular filling is maintained at the expense of an increase in left atrial end-diastolic pressure (LAEDP). LVEDP, left ventricular end-diastolic pressure.

Mitral Stenosis

Mitral stenosis is a special form of diastolic dysfunction. The stenotic mitral valve imposes a resistance to left ventricular filling, which results in a pressure gradient between the left atrium and the left ventricle. The increased atrial pressure is reflected into the pulmonary venous system, and can result in symptoms of pulmonary congestion and congestive heart failure. This is best visualized in the pressure-volume plane by plotting end-diastolic left atrial pressure superimposed on the ventricular pressure (Fig. 6-10). Atrial pressure exceeds ventricular diastolic pressure throughout diastole by an amount that depends on the effective mitral valve area and the flow across the valve.²⁶

Valvular Regurgitation

Mitral and aortic regurgitation result in increased ventricular filling in diastole, with an increase above normal in end-diastolic volume that results in an increase in total stroke volume. The

Figure 6-11. Chronic mitral or aortic regurgitation imposes a chronic volume load on the left ventricle owing to the added burden of the regurgitant volume (RV). The increase in preload results in an increase in total stroke volume, although effective stroke volume usually is unchanged. In acute regurgitation, filling pressures are markedly increased, but with chronic regurgitation, the ventricle dilates, and the end-systolic pressure-volume relationship (ESPVR) and end-diastolic pressure-volume relationship (EDPVR) shift to the right, enabling the heart to accommodate the added volume load with smaller increases in filling pressures.

effective stroke volume is the difference between total stroke volume and regurgitant volume. In acute valvular regurgitation, the increase in ventricular filling results in high filling pressures as the ventricle is forced to operate on the steep portion of its EDPVR; this can result in acute pulmonary edema. Over time, the ventricle adapts its systolic and diastolic properties and dilates to accommodate the increase in end-diastolic volume, while limiting the increase in filling pressure. This activity results in a right shift in the ESPVR and EDPVR.²⁴ Figure 6-11 shows these effects for compensated, chronic valvular regurgitation. Ventricular dilation results in an increase in V_0 . In the compensated phase, contractile state is preserved, and the slope of the ESPVR does not change significantly, but shifts to a higher operating volume range. Chronic severe regurgitation, if uncorrected, can lead to systolic dysfunction, resulting in a dilated cardiomyopathy.

Dilated Cardiomyopathy

Chronic, severe systolic dysfunction can result from coronary ischemia, valvular regurgitation or other causes of chronic volume overload, and intrinsic myocardial processes. The common pathophysiology is that the ventricle dilates to compensate for chronic volume overload. The ventricular dilation, imposed by regurgitation, shunts, or other abnormalities of the peripheral circulation or in primary myocardial disease, is the only way that the heart can maintain an adequate perfusion pressure. The changes in the pressure-volume plane are characterized by a reduction in the slope of the ESPVR as a result of a decrease in contractile state, and a right shift in the ESPVR and EDPVR secondary to dilation of the left ventricle (Fig. 6-12).²⁷

Figure 6-12. Severe chronic systolic dysfunction results in the development of a dilated cardiomyopathy. The slope of the ESPVR (E_{es}) is reduced, and the end-systolic pressure-volume relationship (ESPVR) and end-diastolic pressure-volume relationship (EDPVR) are displaced to the right because of ventricular dilation.

Limitation of the Pressure-Volume Approach

For clinicians, the real value of the pressure-volume approach lies in its use as a conceptual model to understand the physiologic and pathologic determinants of cardiac function and hemodynamics. Invasive and noninvasive determination of the ESPVR and EDPVR in conscious animals and humans has been described,^{6,27-29} but has not been implemented routinely in clinical diagnosis or therapy for several reasons. In a single heart, it is simple to interpret a change in the baseline ESPVR, but comparisons between populations or individuals are difficult because the slope and intercept of the ESPVR depend on cardiac size.

The lack of a universally acceptable correction for cardiac size makes it difficult to define a normal range for the E_{es} . This difficulty is compounded by the fact that V_o cannot be measured directly in vivo, but is determined by extrapolation and is subject to large errors.³⁰ In addition, the timing of end-systole is not always clear-cut. End-systole is defined as the upper left corner of the pressure-volume loop, but this does not always correspond with either aortic valve closure or maximal ventricular elastance, especially in mitral regurgitation.³¹ Apart from difficulties in comparing pressure-volume relationships, the determination of these relationships in vivo requires alterations in loading conditions over a wide range. The changes in loading conditions themselves may directly affect the slope of the ESPVR through reflex alterations in contractile state and heart rate.

Lastly, ESPVR is depicted in this chapter as a linear relationship with a slope and an intercept that are readily determined. Several studies have suggested, however, that the ESPVR becomes nonlinear at high contractile states and with heart failure.³²⁻³⁵ This nonlinearity may make a slope measurement sensitive to the range of data collection and complicate comparison. These limitations do not diminish the effectiveness of the pressure-volume relationship as an analytical tool to understand the physiologic and pathophysiologic determinants of cardiac output.

Conclusion

The function of the cardiovascular system is to provide adequate tissue oxygenation by the circulation of oxygenated blood. Mixed venous oxygen saturation is determined by the balance between oxygen delivery and oxygen consumption. Under normal conditions, the heart has a large functional reserve, and cardiac output is regulated by neurohormonal mechanisms to meet the needs of the body as they change with posture and activity, so that at rest mixed venous oxygen saturation is at least 70%. Left ventricular dysfunction is a common cause of cardiovascular insufficiency. In this setting, regulatory mechanisms are saturated by maximal sympathetic autonomic stimulation, and cardiac output becomes limited by left ventricular performance. Ventricular performance and its coupling to the vasculature can be analyzed within the pressure-volume plane. This approach provides a clinically useful, mechanistic framework for understanding integrated cardiovascular function in critically ill patients.

Coronary Physiology and Pathophysiology

Andrew Peter Selwyn

CHAPTER

7

Determinants of Myocardial Oxygen Consumption Vessel Wall and Local Control of Coronary Blood Flow

Pathophysiology

A CLEAR UNDERSTANDING of the physiologic control of coronary blood flow is essential to considering and treating the underlying pathophysiology in patients who are acutely ill in a cardiac intensive care unit.

Determinants of Myocardial Oxygen Consumption

The working myocardium requires a coronary blood flow of 70 to 90 mL/100 g of myocardium per minute to provide for an oxygen consumption of 8 to 15 mL/100 g of tissue per minute at rest for contraction and relaxation. This figure rapidly increases fivefold to sixfold with exercise or sympathetic arousal. At rest, the heart consumes most of the oxygen contained in its blood supply. Any increase in demand must be met by an increase in blood flow. An understanding of the control of coronary blood flow in physiologic and pathologic states is essential.

With each beat, developed muscle tension requires oxygen, and total tension developed in unit time is directly proportional to the oxygen needs of the working myocardium. The frequency of developed tension (heart rate) is also quantitatively important with regard to oxygen consumption, whereas stroke volume (muscle shortening) has a smaller impact on the needs for oxygen and blood supply. Excitation and contraction coupling and changes in calcium flux influence contractility, which also has an important impact on the demands for oxygen and blood flow.

Myocardial demand for oxygen and blood is determined by developed systolic wall tension, heart rate, and contractility. Coronary blood supply is determined by metabolic demands, autoregulation, blood oxygen-carrying capacity, diastolic time, neurohumoral factors, and extravascular compressive forces (Fig. 7-1). The following sections discuss the dominating controlling influences of metabolic regulation and autoregulation.

Metabolic Control

The myocardium operates by using aerobic metabolism, and the prevailing tissue oxygen level provides a powerful signal for the control of coronary resistance vessels and blood flow to regulate oxygen supply and maintain tissue oxygen tension. Within each

beat, the tissue oxygen level exerts the most powerful effect on coronary vascular resistance within the myocardium. Coronary occlusion causes instantaneous coronary resistance vessel dilation to facilitate blood flow. Similarly, increases in myocardial work increase oxygen consumption and lead to immediate and precisely regulated dilation of resistance vessels with increases in coronary blood flow to maintain the oxygen supply to tissues. Tissue oxygen tension likely signals the coronary resistance vessels through local mechanisms, such as the release of adenosine, tissue levels of carbon dioxide, pH, nitric oxide, and other substances as discussed later.¹⁻³

Autoregulation

The heart provides pressure and blood flow to many organs (i.e., perfusion), and the vascular resistance in each region of the body varies from minute to minute. As a result, alterations in pressure and flow in the ascending aorta can affect the coronary circulation, which must maintain local perfusion to the myocardium (pressure $\times$ flow per unit of tissue) and meet the local needs of the working heart muscle. Aortic pressure can decrease to approximately 50 mm Hg or increase to approximately 150 mm Hg in health, and the coronary resistance vessels are capable of

Figure 7-1. Control of myocardial blood flow and oxygen consumption and demand. (Adapted from Ardehali A, Ports TA: Myocardial oxygen supply and demand. *Chest* 1990;98:699.)

adapting to maintain a constant and necessary level of coronary blood flow. This autoregulation is a protective mechanism and is probably mediated by the local release of nitric oxide by the endothelium and local constriction of vascular smooth muscle cells with increasing intraluminal pressure (the myogenic reflex). The preceding mechanisms are likely transduced via pressure-sensitive and flow-sensitive channels on the endothelium and vascular smooth muscle cells.²⁻⁴ The presence of atherosclerotic narrowing in epicardial coronary arteries impairs autoregulation, narrowing the range of aortic pressure within which changing coronary resistance can maintain myocardial perfusion at different aortic pressures. Similarly, hypertension and left ventricular hypertrophy also can impair the regulation of myocardial blood flow.

Vessel Wall and Local Control of Coronary Blood Flow

Blood Flow

The coronary vasculature is subject to neural innervation and the effects of circulating mediators such as serotonin, adenosine diphosphate, epinephrine, and vasopressin. These are in addition to the mechanisms that respond to the oxygen and metabolic needs of the heart (see previous sections on metabolic control and autoregulation). The local vascular endothelium seems to transduce many of these physiologic signals, including local shear force, pulse pressure, sympathetic stimulation, and blood flow itself. It responds by exerting its own local control on vascular smooth muscle cells by governing constriction and relaxation. To be specific, vascular endothelial cells possess membrane-associated channels sensitive to many circulating and local regulators, such as shear forces, flow, serotonin, and thrombin. The endothelium is also sensitive to α -adrenergic sympathetic stimulation and aggregating platelets. These signals can cause the endothelium to release locally vasodilators, such as nitric oxide, endothelium-dependent hyperpolarizing factor, and prostacyclin, or vasoconstrictors, such as endothelin-1 and thromboxane. These local responses provide physiologic control in each segment of the coronary circulation.

The healthy coronary arteries maintain the ability to control local vasomotion, maintain an anticoagulant surface, and present a biologic barrier that prevents infiltration and proliferation (Fig. 7-2). These key defensive mechanisms are important in health, and a clear understanding of them is important in the development of diseases such as atherosclerosis.

Epicardial Coronary Arteries

Healthy epicardial arteries offer little resistance to coronary blood flow. The endothelium can respond locally to shear forces, blood flow, and sympathetic stimulation by producing and releasing nitric oxide from L-arginine, prostacyclin, and endothelium-derived hyperpolarizing factor, all of which mediate local vasodilation when required, controlling shear stress and blood velocity, while preserving flow. The coronary endothelium can also mediate constriction through the release of endothelin-1, myogenic reflex, and local release of thromboxane. Other essential and intrinsic properties of the healthy vascular endothelium include the maintenance of an anticoagulant surface, prevention of inflammatory cell infiltration, and the control of cell growth.²⁻⁵

Resistance Vessels

The resistance vessels are subject to the needs of the myocardium for oxygen and are primarily responsible for exerting the metabolic control and autoregulation previously described in detail for the coronary blood supply. Locally, the endothelial release of nitric oxide also mediates dilation of resistance vessels as part of the response to metabolic demand. There is continuous release of nitric oxide to control the basal dilator tone of these vessels.²⁻⁶

Extravascular Compression of Coronary Blood Supply

The intracavity pressure and the vascular compression achieved by contracting heart muscle act to obstruct coronary blood flow during systole, even causing reversed flow in intramyocardial vessels. In health, diastolic driving pressures overcome diastolic compressive forces because the aortic diastolic pressure is higher than the pressure in the coronary sinus or right atrium. Intracavity pressures and vascular compression are important forces influencing flow during systole and diastole. These myocardial or extravascular forces are more prominent in the inner layer of the left ventricle (i.e., the subendocardium). Flow in the epicardium is generally 25% higher than that in the endocardium. Increases in wall stress in health and disease place greater demands for oxygen and blood flow in the subendocardial layers. This layer also exhibits the greatest susceptibility to limitations of flow in disease states, however. Increased wall tension (ventricular hypertrophy) and decreased perfusion pressure (e.g., coronary stenoses and shock) are more likely to jeopardize subendocardial coronary flow.¹

Neural Control and Reflexes

α_1 -Adrenergic and α_2 -adrenergic innervation can produce coronary constriction. This sympathetic stimulation also produces increases in heart rate and myocardial work, increasing myocardial oxygen demand, which leads to the dominating effect of coronary vasodilation through increased metabolic demand. β_2 -Adrenergic stimulation produces coronary dilation, whereas

parasympathetic stimulation dilates only the small coronary arteries. The chemoreceptors can indirectly alter sympathetic stimulation of the heart, affecting developed tension, heart rate, myocardial oxygen demand, and coronary resistance. The carotid sinus nerve mediates sympathetic stimulation and coronary dilation. The sympathetic receptors seem to cause coronary dilation, and there are receptors that can also lead to coronary dilation through muscarinic pathways. Parasympathetic stimulation via the coronary circulation can lead to bradycardia and hypotension (i.e., the Bezold-Jarisch reflex). Finally, continuous modulation of α -adrenergic sympathetic outflow seems to exert a tonic level of constrictor tone on the coronary circulation, which is opposed by the dilator effect of the continuous production of nitric oxide by a healthy endothelium.¹⁻⁵

Pathophysiology

Common cardiovascular risk factors, in particular, hypercholesterolemia, impair the production of an important endothelium-derived relaxing factor, nitric oxide, by the vascular endothelium in the epicardial arteries and the coronary resistance vessels. This impaired production of nitric oxide results in the failure of endothelium-dependent dilation in response to shear stress, blood flow, and the sympathetic stimulation of exercise. The lack of reflex dilation is replaced by abnormal constriction. These risk factors interfere with a wide range of endothelial functions, including nitric oxide production by uncoupling the enzymes that produce nitric oxide, oxidant stress, disabling necessary cofactors, and inhibiting the mRNA that governs the production of nitric oxide by nitric oxide synthase.

Atherosclerosis

Atherosclerosis leads to local accumulation of matrix, inflammatory cells, debris, cholesterol crystals, and smooth muscle cells, which all lead to focal stenoses in epicardial arteries. When stenosis is sufficiently severe, a pressure gradient develops across the lesion, and eventually blood flow decreases as each stenosis progresses. The effect of plaque and stenosis on coronary blood flow depends on the minimum cross-sectional area of narrowing; blood viscosity; vessel wall function; loss of laminar flow; development of turbulence; and the severity, length, and complexity of the lesion. In the presence of stenoses greater than 70%, small increases in blood flow greatly increase the pressure gradient across the stenosis. In the aforementioned circumstances, exercise increases myocardial oxygen demand producing resistant vessel dilation, a decrease in poststenotic pressure and increase in pressure gradient across the stenosis, and a further decrease in poststenotic perfusion pressure to the subendocardium. The minimal cross-sectional area within the stenosis is the most important measure of the lesion's rheologic effect on blood. At this point, small changes in stenosis severity produce exaggerated increases in the pressure gradient to resistance, which jeopardizes coronary blood supply.

Physiologic increases in coronary blood flow are blunted when the stenosis exceeds approximately 45%, and they are abolished when the stenosis exceeds 80%. Resting coronary blood flow declines when the stenosis exceeds 90% to 95%.^{6,7}

Apart from the structural disease and the physical effects of stenosis on flow as described earlier, atherosclerosis is characterized by a dysfunctional endothelium that loses its ability to regulate local vasodilation and permits abnormal and

paradoxical constriction particularly in response to the sympathetic stimulation that occurs during everyday life. This reflex constriction has important consequences at the site of severe stenoses. During physical exercise, exposure to cold, and mental stimulation, sympathetic arousal leads to abnormal or exaggerated reflex constriction stenoses owing to endothelial dysfunction. Worsening resistance and the adverse effects on coronary blood supply contribute to the development of ischemia under these circumstances. In atherosclerosis, the endothelium also loses other healthy functions—the maintenance of an anticoagulant surface, an anti-inflammatory effect, and the local control of growth and cell proliferation. The loss of these functions permits platelet aggregation and thrombus formation locally, infiltration of inflammatory cells, local growth of smooth muscle cells, and extracellular matrix accumulation, all of which contribute to lesion progression.^{1,8}

Collateral Blood Vessels

Preexisting but nonfunctioning vascular channels and collateral blood vessels connect the coronary arteries within the myocardium. If narrowing of large coronary arteries causes a decrease in perfusion pressure, the collateral channels can open immediately, and over a period of days can undergo passive widening to facilitate coronary blood flow between previously unconnected regions of the ventricles. Over weeks, specific cell growth leads to formation of new collateral vessels. This process is stimulated by ischemia, myocardial work, and oxygen demand with growth factors as mediators. Serotonin from platelets can cause opposite effects, such as collateral vessel constriction, and can worsen tissue perfusion. Endothelium-derived relaxing factors such as nitric oxide can dilate collateral vessels and facilitate regional myocardial blood flow.

Preexisting collateral vessels can partially compensate for coronary stenoses and occlusions. If the stimulus for collateral growth is persistent over months, and collateral blood vessels develop, they can become capable of compensating for occlusion of large proximal epicardial arteries. Nevertheless, collateral vessels have limited ability to provide sufficient myocardial perfusion under stress and circumstances of increased demand.

Myocardial Ischemia

Ischemia occurs because myocardial blood flow fails to provide sufficient blood and oxygen to meet the myocardial demand that is required for contraction, relaxation, and cellular metabolism. This failure is commonly caused by decreased blood supply or increased myocardial demand for blood and oxygen when blood supply is fixed by obstructive coronary artery disease. During ischemia, tissue oxygen tension decreases, and aerobic metabolism becomes anaerobic; left ventricular relaxation and then contraction fails within seconds; and there are characteristic changes in the surface electrocardiogram that may or may not be followed by chest tightness (i.e., angina pectoris).

Episodes of transient myocardial ischemia most commonly occur in the presence of one or more atherosclerotic stenoses in the epicardial coronary arteries of 70% or greater. In addition, these atherosclerotic vessels exhibit endothelial dysfunction, and with exercise, mental arousal, or sympathetic stimulation (e.g., cold), their abnormal constriction increases the resistance at stenoses and further limits coronary blood supply, often at a time when there is an increase in myocardial demand for oxygen and blood flow.

In unstable angina and myocardial infarction, coronary blood supply is decreased further by a local procoagulant surface and clot formation at atherosclerotic plaques. Further narrowing can occur, causing occlusion of a diseased epicardial coronary artery.

While abnormal constriction occurs at atherosclerotic stenoses, myocardial demand for oxygen is increased by any increase in heart rate, developed tension, and contractility, often in the presence of some degree of left ventricular hypertrophy or anemia. The mechanisms that lead to transient ischemia often include abnormalities of supply and demand, which coexist and act in concert. During myocardial ischemia, tissue oxygen tension decreases, energy stores decline, inorganic phosphate accumulates, and intracellular calcium can no longer facilitate myocardial relaxation or contraction by myofilaments. There is temporary loss of the healthy transmembrane ion gradients while intracellular pH decreases. Myocardial relaxation fails first, and then contraction fails, followed by characteristic electrocardiogram changes with ST segment depression when there is patchy endocardial ischemia and ST elevation with severe transmural ischemia. If the balance between blood supply and myocardial demand is sustained and severe beyond 20 minutes (with plaque rupture, thrombosis, or sustained stimulation), the above-described myocardial pathology is accompanied by progressive irreversible changes in myocardial membranes, enzymes, and proteins, leading to a central area of myocardial

necrosis that may be a single episode over approximately 6 hours or stuttering and distributed over days. At this stage, the severity of ischemia and the development of necrosis depend almost entirely on the available coronary blood supply.

Atherogenesis
Plaque Disruption
Thrombosis

Integrated Pathogenesis of Acute Coronary
Syndromes
Conclusion

THE ACUTE coronary syndromes (unstable angina, myocardial infarction [MI], sudden cardiac death) are a major cause of morbidity and mortality in developed countries. MI alone is the major cause of death in most Western countries.¹ The rapidly increasing prevalence in developing countries, specifically South Asia and Eastern Europe, coupled with an increasing incidence of tobacco abuse, obesity, and diabetes, is predicted to make cardiovascular disease the major global cause of death by 2020.² Atherosclerotic plaque formation within the coronary arteries with subsequent lesion disruption, platelet aggregation, and thrombus formation is the primary cause of acute coronary syndromes in humans.

During the early 1900s, the first description of the clinical presentation of acute MI was published by Obstrastzow and Straschesko.³ Shortly thereafter, Herrick⁴ associated the clinical presentation of acute MI with thrombotic occlusion of the coronary arteries. Much has been learned since these early observations concerning the pathophysiology of coronary artery disease and the acute coronary syndromes. This chapter reviews the pathogenesis of atherosclerosis and explores the mechanisms responsible for the sudden conversion of stable atherosclerotic plaques into unstable life-threatening atherothrombotic lesions.

Atherogenesis

Development

Atherogenesis, or the development of plaques within the walls of blood vessels, is the result of complex interactions involving blood elements, vessel wall abnormalities, and alterations in blood flow. In addition, several pathologic mechanisms play an important role, including inflammation with activation of endothelial cells and monocyte recruitment,⁵⁻⁹ growth with smooth muscle cell proliferation and matrix synthesis,^{10,11} degeneration with lipid accumulation,^{12,13} necrosis, calcification and ossification,^{14,15} and thrombosis.¹⁶ These diverse processes result in the formation of atheromatous plaques that form the substrate for future acute coronary syndromes.

Fatty Streak

Vascular injury and thrombus formation are key events in the formation and progression of atherosclerotic plaques. Fuster and colleagues¹⁷ proposed a pathophysiologic classification of

vascular injury that divides the damage into three types (Fig. 8-1). Type I injury consists of functional deviations from normal endothelial function without obvious morphologic changes. Type II injury involves a deeper form of vascular damage that includes denudation of endothelial cells and intimal damage with maintenance of an intact elastic lamina. Type III injury is represented by endothelial denudation and damage to the intima and media of the vessel wall.

The earliest finding in spontaneous atherosclerosis is an intimal lesion containing lipid-laden macrophages and a few T lymphocytes.¹⁸ In the “response to injury hypothesis” proposed by Ross¹⁹ and others, these “fatty streaks” are thought to result from chronic injury to the arterial endothelium induced by disturbances in coronary blood flow (type I injury) and an increased vascular permeability to lipids and monocytes (Fig. 8-2). The chronic injury is primarily a disturbance in the pattern of blood flow in certain parts of the arterial tree, such as bending, branch points, or both. Certain factors, such as hypercholesterolemia, tobacco abuse, vasoactive amines, glycosylated products, infection, and immune complexes, may potentiate the effect of type I injury on the endothelium.²⁰ This chronic, low-grade damage leads to the accumulation of lipids and macrophages at the site of injury producing the characteristic fatty streak. These lipid-laden macrophages, also known as foam cells, are derived primarily from tissue macrophages. Foam cells are formed when large amounts of intracellular lipids, mainly from modified low-density lipoprotein (LDL), are taken up via a family of macrophage scavenger receptors and internalized into the macrophage.

There is growing evidence that oxidized LDL is a key active component in the generation of atherosclerosis, rather than a passive substance that accumulates within macrophages. It is hypothesized that oxidized LDL has five potentially atherogenic effects: (1) monocyte chemotactic activity, (2) inhibition of macrophage migration out of the vessel wall, (3) enhanced uptake by macrophages, (4) formation of immune complexes, and (5) cytotoxicity (Fig. 8-3).

In the presence of elevated plasma LDL levels, the concentration of LDL within the intima is increased. By poorly understood mechanisms, which may involve the generation of free radicals by cellular lipoxygenases,^{21,22} the LDL molecule undergoes oxidative modification (peroxidation of polysaturated fatty acids) that alters its metabolism. When the LDL contains fatty acid

Figure 8-1. Classification of vascular injury and vascular response. See text for details. (From Fuster V, Badimon L, Badimon J, Chesebro J: *The pathogenesis of coronary artery disease and the acute coronary syndromes*. N Engl J Med 1992;326:242-248.)

Figure 8-2. Response-to-injury hypothesis. Advanced intimal proliferative lesions of atherosclerosis may occur by at least two pathways. The pathway shown by the *long clockwise arrows* to the right has been observed in experimental hypercholesterolemia. Injury to the endothelium (**A**) may induce growth factor secretion (*short arrows*). Monocytes attach to endothelium (**B**), which may continue to secrete growth factors (*short arrow*). Subendothelial migration of monocytes (**C**) may lead to fatty streak formation and release of growth factors such as platelet-derived growth factor (PDGF) (*short arrow*). Fatty streaks may become directly converted to fibrous plaques (*long arrow* from **C** to **F**) through release of growth factors from macrophages or endothelial cells or both. Macrophages may also stimulate or injure the overlying endothelium. In some cases, plaques may lose their endothelial cover, and platelet attachment may occur (**D**), providing additional sources of growth factors (*short arrows*). Some of the smooth muscle cells in the proliferative lesion itself (**F**) may synthesize and secrete growth factors such as PDGF (*short arrows*). An alternative pathway for the development of advanced atherosclerosis lesions is shown by the *arrows* from **A** to **E** to **F**. In this case, the endothelium may be injured, but remain intact. **A**, Increased endothelial cell turnover may result in growth factor synthesis by endothelial cells. **E**, This may stimulate migration of smooth muscle cells from the media into the intima, accompanied by endogenous production of PDGF by smooth muscle cells and growth factor secretion by the "injured" endothelial cells. **F**, These interactions could lead to fibrous plaque formation and further lesion progression. LDL, low-density lipoprotein. (From Ross R: *The pathogenesis of atherosclerosis: An update*. N Engl J Med 1986;314:458-500.)

lipid peroxides, a rapid propagation amplifies the number of free radicals and leads to extensive fragmentation of the fatty acid chains. These fragments of oxidized fatty acids attach covalently to apoprotein B.^{23,24} By means of specialized receptors, distinct from the LDL receptor, these modified apoprotein B molecules

with the attached fatty acids are recognized by macrophages and taken up by the cell (Fig. 8-4).²⁵ All three major cell types within the artery wall are capable of modifying LDL to a form that is recognizable by a scavenger receptor. In contrast to the LDL receptor, the scavenger LDL receptors are not downregulated in

Figure 8-3. Mechanisms by which the oxidation of low-density lipoprotein (LDL) may contribute to atherogenesis, including the recruitment of circulating monocytes by means of the chemotactic factor present in oxidized LDL, but absent in native LDL (I); inhibition by oxidized LDL of the mobility of resident macrophages and their ability to leave the intima (II); cytotoxicity of oxidized LDL, leading to loss of endothelial integrity (III); and uptake of oxidized LDL by macrophages, leading to foam cell formation (IV). Formation of immune complexes is not shown. (From Quinn MT, Parthasarathy S, Steinberg D: Endothelial cell-derived chemotactic activity for mouse peritoneal macrophages and the effects of low density lipoprotein. *Proc Natl Acad Sci U S A* 1985;82:5949-5953.)

the presence of excess ligand. Cells are able to accumulate large amounts of intracellular lipid.

Oxidized LDL within the intima may play a role in the adhesion of circulating monocytes to the arterial wall. More recent studies have shown that oxidized LDL, but not native LDL, is a powerful chemoattractant for circulating monocytes.²⁶ In addition, oxidized LDL is a potent inhibitor of the migration of macrophages out of the intima. By these two mechanisms, oxidized LDL may serve to attract and retain monocytes and macrophages within the vessel wall.

LDL modification by oxidation causes activation, dysfunction, apoptosis, and necrosis in human endothelial cells.²⁷ Activated endothelial cells express leukocyte adhesion molecules, including vascular cell adhesion molecule 1 and intercellular adhesion molecule-1, causing blood cells to adhere at the sites of activation.²⁷ Monocytes and lymphocytes preferentially adhere to these sites. A potent chemotactic agent, monocyte chemoattractant protein 1, is produced by endothelial cells and smooth muscle cells. This same protein has been found in the intima of atherosclerotic lesions and in foam cells. Secretion of monocyte chemoattractant protein 1 by endothelial or smooth muscle cells may be induced by oxidized LDL, suggesting a possible mechanism whereby lipids induce the recruitment of

Figure 8-4. Mechanisms of oxidative modification of low-density lipoprotein (LDL) by cells. (From Steinberg D, Parthasarathy S, Carew TE, et al: Beyond cholesterol: modification of low-density lipoprotein that increases its atherogenicity. *N Engl J Med* 1989;320:915-924.)

Figure 8-5. Linkage between the lipid infiltration hypothesis and the endothelial injury hypothesis. The lipid infiltration hypothesis (right column) may account for fatty streaks, and the endothelial injury hypothesis (left column) may account for the progression of the fatty streak to more advanced lesions. macrophages leading to the formation of early atherosclerotic lesions.²⁸

Within the vessel wall, monocytes undergo phenotypic modification by macrophage colony-stimulating factor inducing them to differentiate into tissue macrophages. These macrophages are capable of expressing scavenger receptors leading to internalization of oxidized LDL and the creation of foam cells and fatty streaks.

Plaque Formation

With time, fatty streaks progress into mature atherosclerotic plaques (Fig. 8-5). Macrophages recruited into the area may release toxic products that cause further damage leading to denudation of the endothelium and intimal injury (type II injury). This deeper form of injury leads to platelet adhesion. Adherent platelets, along with recruited macrophages and damaged endothelium release growth factors, such as platelet-derived growth factor (PDGF), epidermal growth factor- β , and somatomedin C. These growth factors may lead to migration and proliferation of vascular smooth muscle cells, and stimulate the production of collagen, elastin, and glycoproteins. These proteins provide the connective tissue matrix of the newly formed plaque and give it structural support. Cholesterol, derived from insudated blood lipid or extruded from dying foam cells, becomes entrapped within this matrix. The lipid and connective tissue matrix are covered by a fibromuscular cap consisting of smooth muscle cells, collagen (types I and III), and a single layer of endothelial cells. This complex constitutes the mature atherosclerotic plaque (Fig. 8-6A). Vascular smooth muscle cells synthesize and assemble the collagen fibrils, and furnish the bulk of the noncollagenous portion of the extracellular matrix of the cap. The fibromuscular cap is a dynamic structure undergoing constant remodeling through

the synthesis and breakdown of essential components (Fig. 8-7; see also Plate I).

The microscopic changes that occur in spontaneous atherosclerosis have been described by Stary¹⁸ and modified by the American Heart Association (AHA).²⁹ Using autopsy results from the coronary arteries and aortas of young people, Stary described five distinct lesions. A Stary I lesion, not apparent macroscopically, consists of isolated macrophages or foam cells within the intima of the involved vessel. These lesions are noted in 45% of infants up to 8 months of age, and eventually regress. A Stary II lesion, which is seen in adolescents, is characterized by numerous foam cells, lipid-containing smooth muscle cells, and a minimal amount of scattered extracellular lipid. Macroscopically, with Sudan IV staining, these lesions appear as a flat or raised fatty streak. In some children, more advanced lesions are noted that are characterized by an increased amount of extracellular lipid and the appearance of a raised fatty streak (Stary III) or a single confluent extracellular core (Stary IV). In adults, usually beginning in the third decade of life, two types of lesions are noted in the coronary arteries. Some plaques are mostly fibromuscular, whereas others are fibrolipid with a cap of smooth muscle cells and collagen. These latter lesions are designated as Stary V lesions.

The first three lesion types in the AHA classification are similar to those in the original Stary description. In the AHA classification, a type IV lesion has a predominance of extracellular, mostly diffuse lipid, whereas a type Va lesion has localized lipid content surrounded by a thin capsule. Additionally, type V lesions are classified further according to the amount of stenosis and fibrosis (types Vb and Vc). Type IV or Va lesions may progress slowly over time into more advanced type V lesions or undergo disruption resulting in a type VI lesion represented by a ruptured plaque with overlying thrombus (Fig. 8-8).

The composition of nonruptured atheromatous plaques is highly variable, and the factors controlling this process are poorly understood. Mature plaques consist of two components: soft, lipid-rich, atheromatous gruel and hard, collagen-rich, sclerotic tissue. The relative amounts of each component may differ with the individual plaque, but generally two populations of lesions predominate (see Fig. 8-6B). One group consists of fibrointimal lesions characterized by large amounts of fibrous tissue and relatively little atheromatous gruel. The second population consists of lipid-laden lesions with a cholesterol-rich central core and a thin outer capsule.

Differences in plaque composition have important clinical implications. Plaques causing severe stenosis tend to have a higher fibrous and lower lipid content than less stenotic lesions.³⁰ Several studies have shown, however, the less stenotic, lipid-laden plaques to be the more clinically dangerous lesions.³¹ As discussed in this chapter, the soft atheromatous center may predispose the plaque to rupture, exposing the highly thrombogenic gruel and subintimal elements to blood flow, and leading to the formation of thrombus and acute myocardial ischemia in many cases.

Progression of Atherosclerosis

Atherosclerosis is a dynamic process that, without intervention, is progressive. Serial angiographic studies have shown that atherosclerotic plaques tend to enlarge over time, and that a significant number of lesions progress to total occlusion. The risk of progression to total occlusion seems to be related to

Figure 8-6. Photomicrographs illustrating the relationship between plaque composition and vulnerability. **A**, A mature atherosclerotic plaque consisting of two main components: soft lipid-rich gruel (asterisk) and hard collagen-rich sclerotic tissue (blue). **B**, Two adjacent plaques, one located in the circumflex branch (left) and another in the proximal side branch (right). Although both plaques have been exposed to the same systemic risk factors, the plaque to the left is collagenous and stable, but the plaque to the right is atheromatous and vulnerable, with disrupted surface and superimposed nonocclusive thrombosis (red). **C-E**, Vulnerable plaque containing a core of soft atheromatous gruel (devoid of blue-stained collagen) separated from the vascular lumen by a thin cap of fibrous tissue infiltrated by foam cells that can be seen clearly at high magnification (**E**), indicating ongoing disease activity. Such a thin, macrophage-infiltrated cap is probably very weak and vulnerable, actually disrupted nearby, explaining why erythrocytes (red) can be seen in the gruel just beneath the macrophage-infiltrated cap. **F**, Atherectomy specimen from culprit lesion in non-Q wave myocardial infarction. At high magnification it can be seen clearly that this plaque specimen is heavily infiltrated by red-stained macrophages. **A-E**, Trichrome stain. **F**, Immunostaining for macrophages using monoclonal antibody PG-M1 from Dako. (From Falk E, Shah PK, Fuster V: *Coronary plaque disruption*. *Circulation* 1995;92:657-671.)

the initial severity of the lesion, with more obstructive lesions progressing to total occlusion more frequently than less severe lesions.³² The factors that govern plaque progression are incompletely understood, but two mechanisms have been proposed. One mechanism involves continuation of the myointimal proliferative process produced by the chronic endothelial injury responsible for the early lesions of atherosclerosis.¹⁰ The second mechanism, which may be more important in rapidly growing plaques, involves recurrent minor fissuring of the atheromatous

plaque (type Va lesion undergoing type III injury) with subsequent thrombus formation and fibrotic organization.

Chronic Endothelial Injury

In the “response-to-injury hypothesis,” progression of atherosclerotic lesions occurs via the same mechanisms responsible for the initial myointimal lesion. At least two separate processes seem to be involved. One pathway involves gross endothelial cell damage and monocyte, macrophage, and platelet recruitment

Figure 8-7. Color diagram showing metabolism of collagen and elastin in the plaque's fibrous cap. The vascular smooth muscle cell synthesizes the extracellular matrix proteins, collagen, and elastin. In the unstable plaque, interferon- γ (IFN- γ) secreted by activated T cells may inhibit collagen synthesis, interfering with the maintenance and repair of the collagenous framework of the plaque's fibrous cap. The activated macrophage secretes metalloproteinases that can degrade collagen and elastin. Degradation of the extracellular matrix can weaken the fibrous cap, rendering it particularly susceptible to rupture and precipitating acute coronary syndromes. IFN- γ secreted by T lymphocytes can activate the macrophage. Plaques also contain other activators of macrophages, such as tumor necrosis factor- α (TNF- α), macrophage colony-stimulating factor (M-CSF), and macrophage chemoattractant protein-1 (MCP-1). (From Libby P: *Molecular bases of the acute coronary syndromes*. *Circulation* 1995;91:2844-2850.)

Figure 8-8. Schematic of coronary atherosclerosis progression according to lesion morphology. See text for details. SMC, smooth muscle cells. (From Fuster V: *Mechanisms leading to myocardial infarction: insights from studies of vascular biology*. *Circulation* 1994;90:2126-2146.)

with growth factor secretion leading to the formation and progression of fibrous plaques. A second pathway involves direct stimulation of endothelial cells without obvious injury. This process may increase endothelial cell turnover with increased growth factor production leading to smooth muscle cell migration and increased production of PDGF. Through these interactions, further growth of the initial fibrous plaque may occur (see Fig. 8-2).¹⁰

Recurrent Thrombosis

The second proposed mechanism of atherosclerotic progression involves recurrent minor plaque disruption with subsequent thrombus formation followed by fibrotic organization. Plaque

disruption is a common event, and may be asymptomatic in many patients.³³ As discussed in greater detail later, rupture of lipid-laden plaque exposes the highly thrombogenic atheromatous core and subendothelial components of the arterial wall to the circulation. This exposure results in platelet adhesion and activation with the release of growth factors and the stimulation of the coagulation cascade. This sequence of events results in the formation of thrombus, superimposed on the damaged plaque, which eventually undergoes fibrotic organization with subsequent incremental narrowing of the arterial lumen. In this model, recurrent subclinical events may lead to progressive plaque growth and, ultimately, vessel occlusion.

Several lines of evidence point to an important role of mural thrombus formation in the progression of atherosclerosis. Autopsy studies of coronary artery disease patients who died of cardiac and noncardiac causes reveal the presence of plaques with healed fissures with various stages of thrombus formation and organization and old organized coronary thrombi that are difficult to distinguish from primary atherosclerotic changes seen in the arterial wall.³³⁻³⁵ In situ hybridization techniques and monoclonal antibodies directed at platelets, fibrin, fibrinogen, and their degradation products reveal increased amounts of these substances within the intima, neointima, and deeper medial layer in patients with coronary artery disease.^{36,37} These observations suggest that products of organized thrombus are important in the growth of atherosclerotic plaques.

Platelets and mural thrombi may contribute to the progression of atherosclerosis by mechanisms other than the addition of organized fibrous layers to the plaque. As noted previously, adherent platelets are capable of secreting various mitogenic factors, including PDGF, transforming growth factor- β , and others. These factors may be involved in the proliferation, hypertrophy, and migration of smooth muscle cells, which are important

steps in intimal thickening and plaque growth.¹⁷ Studies from animals with thrombocytopenia or lacking von Willebrand factor (a protein required for platelet adhesion) have shown a reduced amount of atherosclerotic plaque formation and growth. Thrombin produced after vascular injury may become incorporated into the thrombus and extracellular matrix, and may be released slowly over time during periods of spontaneous fibrinolysis or remodeling of the thrombus. Thrombin may bind to platelet receptors and cause platelet activation or to smooth muscle cells resulting in proliferation. Through these mechanisms it is possible that platelets and thrombin play a role in the early and late stages of atherosclerotic progression.

Plaque Disruption

The formation of atherosclerotic plaques within the coronary arteries may gradually impede blood flow by progressive obstruction of the vessel lumen. Initially, these lesions are silent except during periods of increased myocardial oxygen demand. When coronary blood flow cannot be increased to meet the demand of the myocardium, ischemia results and causes characteristic exertional angina. With time, the atherosclerotic plaque may slowly enlarge, producing a greater degree of occlusion that results in symptoms with progressively lesser degrees of exertion.

The pathophysiology of acute coronary syndromes, including unstable angina, MI, and sudden cardiac death, is significantly different. These clinical entities represent a continuum of disease characterized by an *abrupt* reduction in coronary blood flow. Current concepts hold that this abruptly reduced coronary blood flow is caused by atherosclerotic plaque fissuring or rupturing that leads to the formation of thrombus, which, superimposed on a pre-existent lesion, severely limits flow (see Fig. 8-6B).³⁸⁻⁴¹

The risk of plaque fissuring or rupturing is related to the intrinsic properties of individual plaques (vulnerability) and extrinsic factors acting on the plaque itself (rupture triggers). The former predisposes plaques to rupture, whereas the latter may precipitate disruption if vulnerable plaques are present.

Vulnerability

Pathoanatomic examination of intact and disrupted plaques and in vitro mechanical testing of isolated fibrous caps indicate that the vulnerability of a given plaque to rupture depends on several factors: size and consistency of the atheromatous core, thickness and collagen content of the fibrous cap covering the core, the degree of inflammation within the cap, and cap fatigue (see Fig. 8-6C and D).

Core Size and Content

The size and consistency of individual plaques vary greatly from lesion to lesion. As previously described, atherosclerotic plaques are composed of two main components whose ratio may vary within a given plaque. The typical plaque, especially in the most highly stenotic lesions, contains more hard fibrous tissue than soft atheromatous gruel. Plaques containing a larger amount of gruel tend to be identified more often beneath thrombi in acute coronary syndromes, however.³¹ Several investigators have shown that the culprit lesions responsible for acute coronary syndromes tend to have a lipid-laden core occupying greater than 40% of the plaque.⁴²

The composition and size of the atheromatous core are important in determining vulnerability. The core is rich in extracellular lipids, especially cholesterol and its esters.⁴³ Plaques are softened and made more prone to rupture by an increased amount of extracellular lipids in the form of cholesterol esters. Conversely, lipids in the form of cholesterol crystals have the opposite effect on plaque stability.

Cap Thickness and Content

Fibrous caps covering the lipid cores of atherosclerotic lesions vary in thickness, cellularity, matrix composition, and collagen content, all of which are important determinants of plaque stability.⁴⁴ Disrupted caps tend to contain fewer cells that synthesize collagen than intact caps.^{42,45} This lack of collagen may weaken the fibrous cap, leaving the plaque prone to rupturing, which tends to occur in areas where the cap is the thinnest and often most heavily infiltrated by foam cells. In eccentric plaques, rupturing usually occurs in the shoulder region, defined as the junction between plaque and the adjacent, less diseased vessel wall. The cap in these shoulder regions is often thin and heavily infiltrated with macrophages.⁴⁴

Inflammation

The concept that the inflammatory response may play a role in atherosclerosis dates back to Virchow, who postulated that atherosclerosis results from the local reaction of the vessel wall to the insudation of blood products. More recently, a growing body of evidence supports the concept that inflammation is involved in plaque disruption leading to acute coronary syndromes.

Several studies have shown that disrupted fibrous caps are heavily infiltrated by lipid-laden macrophages or foam cells (see Fig. 8-6E and F).³¹ Postmortem examination of thrombosed coronary arteries has shown foam cell infiltration in most plaque rupture sites. Atherectomy specimens from culprit lesions responsible for acute coronary syndromes show significantly increased amounts of macrophages compared with specimens from patients with stable angina. Although the morphology of the plaque itself may vary, the cellular composition at the site of rupture is remarkably consistent with macrophages being the dominant cell.

Experimental evidence from in vitro⁴⁶ and in vivo systems⁴⁴ suggests that the macrophages present in atherosclerotic plaques are involved in active inflammation. Other components of the inflammatory response, including T lymphocytes, mast cells, and neutrophils, have been found in atherosclerotic plaques.⁴⁷ Interferon- γ , a cytokine produced within atheromas by activated T cells,⁴⁸ may play a crucial role in this process. Interferon- γ decreases interstitial collagen synthesis within the fibrous cap, inhibits smooth muscle cell proliferation, activates the apoptosis pathway in smooth muscle cells, and activates macrophages.⁴⁹ Active inflammation in areas of high stress may weaken the fibrous cap further and contribute to plaque rupture.

T-cell cytokines also induce the production of large amounts of molecules downstream in the cytokine cascade resulting in elevated levels of interleukin-6 and C-reactive protein in the peripheral circulation, which amplifies local and systemic inflammation. Elevated levels of C-reactive protein and interleukin-6 in patients with acute coronary syndromes are associated with a worse prognosis.

When activated, macrophages are capable of causing weakening of plaque structure by several mechanisms. These cells may

degrade the extracellular matrix by secreting various proteolytic enzymes. One such group of enzymes is the matrix metalloproteinases (MMPs). The MMPs are a family of zinc-dependent and calcium-dependent enzymes that are important in the resorption of the extracellular matrix in normal and pathologic conditions. These enzymes may be divided into subgroups based broadly on substrate preference.⁵¹ The MMP subgroups include collagenases, gelatinases, stromelysin, and membrane-type MMPs that act on various substrates, including collagen, elastin, proteoglycan, lamin, fibronectin, and basement membrane components. Taken together, these MMPs are capable of completely degrading all extracellular components, and may play a role in atherogenesis and plaque disruption. In addition, MMPs can be proinflammatory by facilitating inflammatory cells.

MMPs are secreted by macrophages, smooth muscle cells, and lymphocytes found within atherosclerotic plaques. Production and secretion of MMPs is a balance between several different factors. Numerous cytokines and growth factors, including interleukin-1, PDGF, and tumor necrosis factor- α , have been shown to induce the synthesis of MMPs. Conversely, several unrelated substances have been shown to inhibit MMP production, including heparin, corticosteroids, and tumor necrosis factor- β . MMPs are secreted as proenzymes or zymogens and require an activation step to become capable of degrading the extracellular matrix. When activated, the effects of the MMPs are controlled by a family of naturally occurring specific inhibitors, the tissue inhibitors of metalloproteinases. Several lines of investigation point to a possible role for MMPs in plaque rupture. Messenger RNA transcripts of one MMP family member, stromelysin, have been identified in macrophages and smooth muscle cells in fibrous and lipid-laden plaques.⁵² Other MMPs have been found in atherosclerotic, but not normal arteries.⁵³ Atherectomy specimens from patients with unstable angina have shown increased intracellular gelatinase B production compared with specimens from patients with stable angina.⁵⁴

Chronic immune stimulation within the atheroma may lead to the elaboration of several factors including cytokines and metalloproteinases that alter the structural integrity of the fibrous cap by inhibiting collagen synthesis and increasing matrix degradation. Taken together, these factors reduce the structural integrity of the plaque, rendering the fibrous cap weak and prone to rupture in a susceptible region of the plaque. More recent studies using in situ zymographic techniques have revealed a net excess of metalloproteinase activity and matrix degradation within fibrous caps, especially at the vulnerable shoulder region of plaques.⁵⁰

Rupture Triggers

Atherosclerotic plaques are constantly exposed to various mechanical and hemodynamic forces that may precipitate disruption of a vulnerable lesion. The importance of several external forces has been shown, including cap tension, cap and plaque compression, intraplaque hemorrhage, circumferential bending, longitudinal flexion, and hemodynamic forces.

Cap Tension

The blood pressure inside the artery exerts radial and circumferential forces across the arterial wall, which must be counteracted by tension within the wall to maintain vessel integrity. The circumferential tension is described by the law of Laplace, which relates intracavity pressure (blood pressure) and lumen radius

(vessel diameter) (Fig. 8-9). The higher the blood pressure or the larger the luminal diameter, the greater the tension is within the wall.⁵⁵ If components within the wall are unable to bear the tension, the stress may be redistributed to the adjacent structures. In coronary artery disease, the soft atheromatous core is unable to bear the imposed load resulting in a shift of these forces to the fibrous cap. Studies using simulated and real plaques have shown that soft eccentric pools of atheromatous gruel lead to the concentration of stress on the adjacent cap, especially near the shoulder region.³⁰ These areas of increased stress correlate with the actual area of plaque rupture in most specimens.⁵⁶

The consistency of the atheromatous gruel and the thickness of the fibrous cap are important determinants of plaque rupture. Atheromatous gruel with increased amounts of extracellular lipid in the form of cholesterol esters tends to be softer. Softer plaques are less able to handle increased wall stress, and redistribute these forces to the fibrous cap predisposing the lesion to rupture. The thickness of the fibrous cap is also an important factor in determining the ability of a given lesion to handle circumferential stress, with the thinner caps developing a greater amount of stress. Mildly to moderately stenotic lesions are associated with greater circumferential wall tension rather than more severe lesions. Active newer plaques are also noted to have positive remodeling of their vessel size as postulated by Glagov⁵⁷ and confirmed by intravascular ultrasound. This increase in vessel diameter can additionally contribute to increased wall stress promoting plaque rupture. These observations, along with several other factors, may help to explain why the less occlusive lesions tend to be the most clinically volatile.

Cap and Plaque Compression

In addition to rupture from the lumen into the plaque, the reverse process of disruption from the interior of the plaque into the vessel lumen may occur. This process is likely to be secondary to an increase in intraplaque pressure caused by vasospasm,

Figure 8-9. Circumferential tension on the fibrous cap of an atherosclerotic plaque containing a lipid pool (hatched area) is determined by the law of Laplace, which relates tension (t) to the intralumen pressure (p) and the lumen radius (r). The mean circumferential stress on the fibrous cap is related to circumferential tension and cap thickness (h). (From MacIsaac A, Thomas JD, Topol EJ: *Toward the quiescent coronary plaque*. *J Am Coll Cardiol* 1993;22:1228-1241.)

intraplaque hemorrhage, plaque edema, and collapse of compliant stenosis.

Vasospasm may rupture plaques by compressing the atheromatous core and blowing the fibrous cap into the lumen.⁵⁸ Intraplaque hemorrhage is an important contributor to the transformation of stable plaques into unstable lesions.⁵⁹ Microvascular incompetence is a likely source of intraplaque hemorrhage, although the exact mechanism is unknown. The rapid accumulation of erythrocyte-derived cholesterol contributes to the expansion of the volume of the necrotic core. In addition, it serves as a potent inflammatory stimulus resulting in greater macrophage density. These factors may increase plaque vulnerability to rerupture. Collapse of a severe but compliant stenosis because of negative transmural pressure may cause buckling of the vessel wall, which may disrupt the plaque.

Circumferential Bending

The propagating pulse wave generated by the systolic contraction of the heart produces changes in the lumen size and shape. The normal cyclic diastolic-systolic change in lumen diameter is 10%, although this number may be altered with advancing age or coronary disease.⁵⁵ The change in lumen configuration may produce deformation and bending of the atherosclerotic plaque, especially in the shoulder region.⁶⁰ Over time, these cyclic changes may weaken the plaque and lead to disruption. Sudden changes in vascular tone may also produce a bending of plaques that may cause rupture.

Longitudinal Flexion

With the beating of the heart, the coronary arteries tethered to the surface of the myocardium are subjected to longitudinal deformation. Similar to circumferential bending, this stretching of the arterial wall may weaken plaques or, with acute changes in the contractility of the heart, lead to plaque rupture.³¹

Hemodynamic Factors

Hemodynamic stress tends to be less than the mechanical forces produced by blood and pulse pressure. Hemodynamic factors such as shear stress can cause endothelial cell injury, however. Increased shear stress through stenotic lesions can theoretically

lead to plaque disruption, although this concept has not been shown in angiographic studies.⁶¹

Thrombosis

Thrombus formation is central to the development of acute coronary syndromes. Intrinsic and extrinsic factors may combine to cause rupture of the fibrous cap with exposure of the plaque's central components to the circulating blood and subsequent thrombosis.

Platelet Biology

Aggregation and activation of platelets play an essential role in normal hemostasis and acute coronary syndromes. After injury to the vessel wall, such as in plaque rupture, platelets are involved in the body's initial response (primary hemostasis). Effective primary hemostasis requires three critical events to occur: (1) platelet adherence, (2) platelet activation with granule release, and (3) platelet aggregation.

Platelet Adherence

Damage to the vessel wall exposes the highly thrombogenic sub-endothelial substrate and atheromatous core (specifically collagen and tissue factor) to circulating blood. Platelet adherence to the subendothelial collagen occurs almost immediately through interaction with platelet glycoprotein VI. Adhesion of platelets depends on many platelet receptors and adhesive membrane glycoproteins (Fig. 8-10).⁶² Glycoprotein Ib in the platelet membrane is important in the initial contact of platelets with von Willebrand factor in the subendothelium. von Willebrand factor forms a link between receptors on platelets and subendothelial collagen fibrils allowing platelets to remain attached to the vessel wall despite high shear forces. The membrane receptor complex, glycoprotein IIb/IIIa, binds many relevant proteins, including von Willebrand factor, fibrinogen, and fibronectin.⁶³ This complex plays a crucial role in initial platelet adhesion and platelet aggregation. Through this series of complex receptor-substrate interactions, the platelets form a firmly adherent monolayer and provide a foundation for further clot formation. This collagen-initiated pathway for platelet activation is independent of thrombin.

Figure 8-10. Schematic of platelet activation and receptor sites. 1a, 1b, 1c, and IIb/IIIa, glycoprotein receptor sites; 5HT, serotonin; ADP, adenosine diphosphate; Arach acid, arachidonic acid; BTG, β -thromboglobulin; PDGF, platelet-derived growth factor; PF4, platelet factor 4; TxA₂, thromboxane A₂; Va, activated factor V; vWF, von Willebrand factor; Xa, activated factor X. Other abbreviations correspond with those in Figure 8-10. (From Myler RK, Frink RJ, Shaw RE, et al: *The unstable plaque: pathophysiology and therapeutic implications. J Invasive Cardiol* 1990;2:117-128.)

Platelet Activation and Aggregation

Platelet adhesion leads to the release of certain intracellular products that result in further platelet activity. Platelet activation and secretion are regulated by several factors, including a change in the level of cyclic nucleotides, the influx of calcium, the hydrolysis of membrane phospholipids, and the phosphorylation of crucial intracellular proteins. Binding of agonists such as epinephrine, collagen, and thrombin to platelet receptors activates phospholipase C and phospholipase A_2 , membrane enzymes that catalyze the release of arachidonic acid. Through a series of complex reactions (Fig. 8-11), the released arachidonic acid is eventually converted to thromboxane A_2 and prostacyclin. These two products have opposite effects on platelet activation and vessel wall tone. Thromboxane A_2 is a powerful stimulus for platelet activation and aggregation and produces vasoconstriction, whereas prostacyclin acts to inhibit platelet activation and is a vasodilator. By selective production (or inhibition) of these two substances, changes in the level of platelet activation and vessel wall tone may be achieved.⁶⁴

Other active products secreted by platelets include endoglycosidases and heparin-cleaving enzymes from lysosomes, calcium, serotonin, adenosine diphosphate (ADP) from dense granules, von Willebrand factor, fibronectin, thrombospondin, and PDGF from α granules. These products have many important roles, including modification of coronary vascular tone, cellular proliferation and migration, and interaction with the coagulation system. It has been shown that PDGF is important in the proliferation and migration of smooth muscle cells after vessel damage.¹⁰ Released ADP binds to specific receptors that change the conformation of the glycoprotein IIb/IIIa complex so that it binds von Willebrand factor, fibrinogen, and fibronectin, linking adjacent platelets into a hemostatic plug.

Coagulation Cascade

The coagulation cascade system also plays a key role in normal hemostasis (secondary hemostasis) and acute coronary syndromes. The coagulation system comprises several plasma proteins involved in a series of reactions that culminate in the production of thrombin, which converts fibrinogen to fibrin. The fibrin produced via this system is important in strengthening the primary hemostatic plug formed by platelets.

Figure 8-12. Intrinsic and extrinsic systems of the coagulation cascade. Note interaction between clotting factors (XII, XIIa, XI, XIa, IX, IXa, VII, VIII, X, Xa, and XIIa) and the platelet membrane. (Modified from Fuster V, Stein B, Ambrose JA, et al: *Atherosclerotic plaque rupture and thrombosis: evolving concepts*. *Circulation* 1990;82[Suppl 1]:II-47-II-59.)

The coagulation cascade can be divided into the intrinsic and the extrinsic pathways (Fig. 8-12). Both involve a series of reactions that require the formation of surface-bound complexes and the conversion of inactive precursor proteins into active proteases. The intrinsic pathway (factors XII, XIIa, XI, and XIa) is activated by exposure of blood components to the negatively charged, damaged subendothelium and medial surfaces of the vessel. The extrinsic pathway is activated by interaction of tissue factor released from the damaged vessel wall and factor VII.

Ultimately, these two pathways produce complexes that activate factor X. Activated factor X interacts with factor V, calcium, and phospholipid to form a complex that catalyzes the conversion of prothrombin to thrombin. This reaction is accelerated 1000-fold on the surface of activated platelets.

Thrombin has multiple functions in hemostasis, of which the primary function is the conversion of plasma fibrinogen to fibrin. After conversion to fibrin, the modified molecule polymerizes into an insoluble gel. The fibrin polymer is stabilized by cross-linking with other fibrin strands through the action of factor XIIIa, which results in an adherent thrombus. In addition, thrombin activates factors V, VIII, and XIII, and stimulates platelet secretion and aggregation.

Fibrinolysis

Balancing the prothrombotic events after vessel wall injury are several hemostatic mechanisms that favor fibrinolysis, decrease platelet aggregation, and cause vasodilation. Tissue plasminogen activator is the main physiologic activator of the fibrinolytic system with Hageman factor fragments and urokinase playing a minor role. Tissue plasminogen activator converts plasminogen adsorbed to the fibrin clot to plasmin. The plasmin acts to degrade the fibrin polymer into fragments resulting in clot lysis. Circulating thrombin stimulates several mechanisms designed to limit clot formation. The thrombin itself is inactivated by plasma protease inhibitors,⁶⁵ especially antithrombin III, which also inhibits activated factors VII, IX, and X. The thrombin also stimulates endothelial cells to release tissue plasminogen activator and produce prostacyclin and nitrous oxide, which act in concert to inhibit platelet aggregation and cause vasodilation.

Intact endothelial cells have several other important functions after vessel wall injury. These cells produce protein C, protein S, and heparin-like glycosaminoglycans that act to neutralize thrombin and activated factors V and VIII. In addition, stimulation of adenylyl cyclase and accumulation of cyclic adenosine monophosphate within these cells lead to inhibition of phospholipase A₂ and decreased production of thromboxane A₂ that causes increased vasodilation.

The diverse actions of the intrinsic fibrinolytic system act to offset the thrombogenic stimulus of vessel wall injury. In the usual situation, a delicate balance is maintained that results in the formation of enough thrombus to provide hemostasis at the site of vascular injury without producing significant flow disturbance within the vessel. After a significantly strong thrombogenic stimulus (i.e., deep vessel injury), however, massive platelet activation with subsequent fibrin deposition may overwhelm the intrinsic fibrinolytic system and cause thrombus formation, thrombus growth, and vessel vasospasm that leads to a significant reduction in blood flow.

Factors That Influence Thrombus Formation

Several local and systemic factors present at the time of plaque rupture may influence the degree and duration of thrombus deposition after vessel wall injury. Interaction of these factors may account for the different pathologic and clinical manifestations of acute coronary syndromes.

Local Factors

Degree of Vessel Wall Injury

The degree of vessel wall injury plays an important role in the biochemical response to plaque rupture. With mild amounts of vascular injury (superficial type III vascular damage), platelet

adherence reaches a maximum within 5 to 10 minutes, and results in a thrombus that can be dislodged by flowing blood. In contrast, deep vessel injury (deep type III injury) with exposure of fibrillar collagen results in markedly enhanced platelet deposition and thrombus formation that cannot be dislodged even at increased shear rates.⁶⁶ Tissue factor exposed by deeper injury likely contributes to the increased thrombogenicity by activating the extrinsic coagulation system.

Degree of Stenosis

The amount of platelet adherence is also determined by their transport into the injured area.⁶³ Transport of platelets is determined by the shear rate, which is the difference in blood velocity between the center of the vessel and along the vessel wall. Shear rates increase with decreasing vessel diameter (i.e., increased stenosis) and with increasing flow. In vitro studies mimicking mild vascular injury with exposure of de-endothelialized vessels to low shear rates show the adherence of only a single layer of platelets. With the same amount of injury, but at higher shear rates, the initial platelet deposition rate and maximal extent of deposition are significantly increased.⁶⁷

The degree of stenosis may influence the severity of thrombus formation by other mechanisms. That platelet deposition is greater with increasing amounts of stenosis suggests that platelet activation may be induced by shear forces generated by the sudden change in vessel geometry.⁶⁸ In addition, the flow characteristics of blood through the atherosclerotic lesion are partly determined by the extent of diameter stenosis. Flow is accelerated as blood passes through a stenosis and decelerates distal to the lesion. The sudden deceleration induces flow separation and recirculation vortices. The high shear rate area (the stenosis) favors platelet deposition, whereas the low shear rate area (the poststenotic recirculation zone) favors the deposition of fibrin. The combination of higher shear rates with large changes in flow dynamics seen in the more severely stenotic vessels results in a thrombus that is richer in platelets at the apex and contains larger amounts of fibrin distally.⁶³ These platelet-rich regions may be less amenable to fibrinolysis.⁶⁹

Residual Thrombosis

The presence of residual thrombus predisposes to recurrent thrombotic vessel occlusion by two mechanisms. The residual thrombus may encroach into the vessel lumen and cause a more stenotic lesion with increased shear rates, which may lead to further platelet activation and deposition.⁶⁶ Residual thrombus is a powerful thrombogenic stimulus. The degree of platelet deposition is increased twofold to fourfold on the surface of residual thrombi compared with on the surface of deeply injured arterial walls,⁷⁰ and the thrombi continue to grow despite heparin treatment.⁷¹ Residual thrombi may offset the effects of the natural fibrinolytic system and add to the extent of thrombosis after plaque rupture.

Systemic Factors

Experimental and clinical studies suggest that primary hypercoagulability can enhance thrombus formation. In this model, after plaque disruption, individuals with one or two "thrombogenic risk factors" may form a small amount of thrombus that is clinically silent. In other individuals with more prothrombotic risk factors, a larger thrombus may be formed after the same degree of vessel injury resulting in a more occlusive lesion that may produce unstable angina or acute MI.⁷²

The level of circulating catecholamines at the time of plaque disruption may have important consequences. Platelet aggregation and thrombin generation can be promoted by catecholamines.⁶⁸ Such diverse factors as cigarette smoking, emotional state, and time of day have a direct effect on catecholamine levels and may provide a link between these clinically recognized risk factors and acute coronary syndromes.

Metabolic abnormalities such as the metabolic syndrome or any of its components, including diabetes, hypertension, and obesity, may increase thrombogenicity mediated through the inflammation they induce. Patients with hypercholesterolemia show increased platelet reactivity at sites of vascular damage⁷³ and hypercoagulability.⁷⁴ There is evidence that platelet reactivity and coagulation are increased in diabetics, suggesting a direct mechanism for a prothrombotic state that may be responsible for the increased incidence of MI in these patients.⁶⁸

Finally, defective naturally occurring fibrinolysis may contribute to enhanced thrombus formation. High levels of naturally occurring inhibitors, such as plasminogen-activator inhibitor,⁷⁵ may predispose to an increased risk of acute coronary syndromes. High levels of lipoprotein(a) may also be important in ischemic heart disease. Apolipoprotein(a) is a glycoprotein present in lipoprotein(a) that has close structural homology with plasminogen.⁷⁶ This close homology may enable apolipoprotein(a) to act as a competitive inhibitor of plasminogen and cause a prothrombotic state. In addition, increased levels of other hemostatic proteins, such as fibrinogen and factor VII, have been identified in patients with ischemic heart disease.⁶⁸ Fibrinogen and factor VII activity are increased with advancing age, obesity, hyperlipidemia, diabetes, smoking, and emotional stress, all factors associated with an increased risk of MI.

Integrated Pathogenesis of Acute Coronary Syndromes

The acute coronary syndromes, unstable angina, non-ST elevation MI, ST elevation MI, and sudden cardiac death, all result from acute reductions in coronary blood flow. In these disease processes, atherosclerotic plaque rupture occurs and initiates a cascade of events that culminates in the formation of a thrombus overlying the damaged area. After plaque rupture and thrombus formation, there are different clinical outcomes influenced by location of the plaque rupture, existence of collaterals, the extent of the vessel injury, the degree of stenosis, and the thrombotic-thrombolytic equilibrium at the time of rupture (Fig. 8-13).

Conclusion

Coronary atherosclerosis is the most common cause of ischemic heart disease. Atherosclerosis without thrombosis is generally a benign disease, however. Disrupted atheromatous plaques are commonly associated with the formation of mural or occlusive thrombi, usually adherent to the area of damage. Certain types of plaques—those rich in lipids and surrounded by a thin fibrous cap—are the most prone to rupture. Numerous factors, intrinsic and extrinsic to the plaque itself, interact to cause the formation of a vulnerable lesion and, ultimately, plaque disruption. Fissuring or rupturing of plaques plays a fundamental role in the onset of acute coronary syndromes. In addition, repetitive damage to

Figure 8-13. Schematic representation of the proposed outcome of atherosclerotic plaque fissuring. *Left panel*, Initial plaque fissure. *Upper right panel*, Fissure is sealed, and the incorporated thrombus undergoes fibrotic organization, contributing to the progression of coronary artery disease. *Middle right panel*, Fissure leads to intrainimal and intraluminal thrombosis resulting in partial or transient reduction of coronary flow as seen in unstable angina. *Lower right panel*, Fissure results in occlusive thrombosis, which, if persistent, can lead to myocardial infarction or sudden ischemic death, particularly in the absence of collateral flow. (From Davies M, Thomas A: *Plaque fissuring—the cause of acute myocardial infarction, sudden death, and crescendo angina*. *Br Heart J* 1985;53:363-373.)

the plaque with thrombosis and fibrotic organization is important in the insidious progression of coronary artery disease.

Over the past several years, much has been learned concerning the specific mechanisms involved in the pathophysiology of acute coronary syndromes. As discussed in subsequent chapters, this improved understanding has led to the development of treatments directed at specific steps in the pathogenesis of unstable angina, MI, and sudden cardiac death. Through these and future advances, physicians and scientists may hope to make a significant impact on the number one cause of death in industrialized society.

Regulatory Mechanisms to Control Coagulation

Clinical Laboratory Testing

What Can Go Wrong with Hemostasis

Overview and Definitions

COAGULATION is the clotting of blood or plasma. Hemostasis is the process by which bleeding is stopped, and is the first component of the host response to injury. Its product is a hemostatic plug or hemostatic clot. Thrombosis is inappropriate clot formation within an intact vascular structure. Its product is a thrombus. Blood coagulation can occur at a site of injury (hemostasis), within an intact vessel (thrombosis), or in a test tube, but hemostasis is a physiologic process that can occur only in a living, bleeding organism.

Hemostasis consists of primary hemostasis, in which platelets adhere and are activated at a site of injury, and secondary hemostasis, in which the initial platelet plug is consolidated in a meshwork of fibrin. The hemostatic process represents a delicate, tightly regulated balance between effective activation of local hemostatic mechanisms in response to injury and control by regulatory mechanisms that prevent inappropriate activation or extension of coagulation reactions. The interactions of the protein components of coagulation can be studied in cell-free plasma and have been described as a “cascade” of proteolytic reactions. By contrast, the process of hemostasis occurs on cell surfaces in a tissue environment and is subject to regulation by various biochemical and cellular mechanisms.

The adequacy of procoagulant levels can be assessed in the routine plasma clotting assays: the prothrombin time (PT) and activated partial thromboplastin time (aPTT). Platelet number and function can be assessed in the clinical laboratory. Levels of individual plasma coagulation inhibitors and other regulatory proteins can also be assayed. There is no laboratory test, however, that can provide a global assessment of the adequacy of hemostasis or the risk of thrombosis. Each laboratory test gives only a part of the picture, and the assessment of hemostatic function always requires that laboratory results be interpreted in the context of the clinical picture.

Hemostasis

Because hemostasis involves more than simply getting blood to clot—it must clot at the right time and place and only to the extent needed to stop bleeding—our understanding of hemostasis must include a consideration not only of the proteins, but

also the cellular and tissue components that are needed to regulate the coagulation process adequately in vivo.

Necessary Components

Vascular Bed

It is very important that blood not clot within the vascular system. In the baseline state, vascular endothelial cells provide a nonthrombogenic interface with the circulating blood. Endothelial cells do not normally express molecules that support platelet adhesion or promote activation and activity of the coagulation proteins. In addition, the antithrombotic features of the endothelial surface go beyond simply being “inert” with respect to coagulation. The endothelium also expresses molecules that actively downregulate the coagulation reactions on its surface: principally thrombomodulin to localize activated protein C to the endothelial surface, and heparan sulfates to localize antithrombin (AT) to the endothelial surface. A further discussion of these mechanisms is presented in the section on thrombosis. These properties are crucial in preventing coagulation from being initiated at inappropriate sites within the vasculature and preventing appropriately initiated hemostatic reactions from spreading within the vascular tree.

Extravascular Tissues

When an injury disrupts a blood vessel, it allows blood to contact extravascular cells and matrix. Extracellular matrix proteins, such as collagen, fibronectin, thrombospondin, and laminin, interact with adhesive receptors on blood platelets and support formation of the initial platelet plug at the site of injury. Perivascular tissues also express significant levels of tissue factor (TF).^{1,2} Exposure of TF to blood initiates the process of thrombin generation on the surfaces of adherent platelets and ultimately leads to stabilization of the initial platelet plug in a fibrin clot (i.e., secondary hemostasis). Different tissues express different complements of matrix components and procoagulants. The tissue environment plays a role in determining the intensity of the procoagulant response to an injury.

Platelets

Membrane receptors for collagen and other subendothelial and extravascular matrix proteins are present on the platelet membrane and mediate binding of unactivated platelets at sites of

injury.³⁻⁵ Platelet binding is also mediated by von Willebrand factor (vWF) bridging between collagen and the platelet receptor glycoprotein (GP) Ib. These receptor binding events also transmit an activation signal to the platelets. Full platelet activation also requires stimulation by thrombin, however, which is produced as the coagulation reactions are initiated. The platelet surface receptor for fibrinogen, GPIIb/IIIa, rapidly changes conformation from an inactive to an active form on platelet activation.⁶ This change in conformation allows platelet aggregates to be stabilized by binding to fibrinogen even before conversion to fibrin begins. Platelet activation also initiates the synthesis of prostaglandins and thromboxanes—compounds that modulate platelet activation and promote vasoconstriction.⁷

Platelet adhesion and activation at a site of injury, in concert with local vasoconstriction, provides initial hemostasis for small caliber vessels. When hemostasis is achieved by these mechanisms, the subsequent stabilization of the platelet plug in a fibrin meshwork can proceed more effectively than if bleeding continues. Initial hemostasis may be established even if a deficiency of plasma coagulation proteins is present. The platelet plug is insufficient, however, to provide long-term hemostasis, and delayed rebleeding occurs if it is not reinforced by a stable fibrin clot during secondary hemostasis.

Coagulation Proteins

Adequate levels and function of each of a series of procoagulant proteins are required for hemostasis. The coagulation proteins can be organized into several groups based on their structural features.

The vitamin K–dependent factors include factors II (prothrombin), VII, IX, and X. These factors each have a structural domain in which several glutamic acid residues are post-translationally modified to γ -carboxyglutamic acid (Gla) residues by a vitamin K–dependent carboxylase.⁸ The vitamin K cofactor is oxidized from a quinone to an epoxide in the process. A vitamin K epoxide reductase cycles the vitamin K back to the quinone form to allow carboxylation of additional glutamic acid residues. The negatively charged Gla residues bind calcium ions. These binding interactions hold the Gla-containing proteins in their active conformation. The calcium-bound form of the Gla-domain is responsible for mediating binding of the coagulation factors to phospholipid membranes. Lipids with negatively charged head groups, particularly phosphatidylserine, are required for binding and activity of the Gla-containing factors.

The carboxylation process is inhibited by the anticoagulant warfarin, which competes with vitamin K for binding to the reductase.⁹ Inhibition by warfarin results in the production of undercarboxylated forms of the vitamin K–dependent proteins, which are nonfunctional.

The vitamin K–dependent procoagulants are zymogens (inactive precursors) of serine proteases. Each is activated by cleavage of at least one peptide bond. The activated form is indicated by the letter “a.” Factors VIIa, IXa, and Xa each require calcium ions, a suitable cell (phospholipid) membrane surface, and a protein cofactor for their activity in hemostasis.

Factor IIa (thrombin) is a little different from the activated forms of the other vitamin K–dependent factors. Its Gla domain is released from the protease domain during activation. It no longer binds directly to phospholipid membranes. It also does not require a cofactor to cleave fibrinogen and initiate fibrin assembly, or to activate platelet receptors. Factor IIa that escapes

the vicinity of a hemostatic plug can bind, however, to a cofactor on endothelial cell surfaces, thrombomodulin.¹⁰ After binding to thrombomodulin, factor IIa can no longer activate platelets or cleave fibrinogen. Instead, it triggers an antithrombotic pathway by activating protein C on the endothelial surface.

Proteins C and S are also vitamin K–dependent factors. They do not act as procoagulants, but rather as antithrombotics on endothelial surfaces.¹¹ Protein C is the zymogen of a protease, whereas protein S has no enzymatic activity, but serves as a cofactor for activated protein C. The activated protein C/protein S complex cleaves and inactivates factor Va and factor VIIIa, preventing propagation of thrombin generation on normal healthy endothelium.

Factors V and VIII are large structurally related glycoproteins that act as cofactors. They have no enzymatic activity of their own, but when activated by proteolytic cleavage, they dramatically enhance the proteolytic activity of factors Xa and IXa.

Factor VIII circulates in a noncovalent complex with vWF, which prolongs its half-life in the circulation. The vWF/factor VIII complex binds to the platelet surface via GPIb as vWF mediates adhesion of platelets to collagen under high shear conditions. Cleavage and activation of factor VIII releases it from vWF so that it can assemble into a complex with factor IXa on the platelet surface, where it activates factor X.

Factor V circulates in the plasma, and it is packaged in the alpha granules of platelets. It is released on platelet activation in a partially activated form. Plasma and platelet-derived factor V can be fully activated by cleavage by factor Xa or IIa. Factor Va then assembles into a complex with factor Xa on the platelet surface, where it activates prothrombin to factor IIa.

TF is also a cofactor, but is structurally unrelated to any of the other coagulation factors. Instead, it is related to one class of cytokine receptors.¹² This lineage emphasizes the close evolutionary and physiologic links between the coagulation system and the other components of the host response to injury. Rather than circulating in the plasma as do the other coagulation factors, TF is a transmembrane protein.¹³ TF serves as the cellular receptor and cofactor for factor VIIa. It is primarily expressed on cells outside the vascular space under normal conditions, although monocytes and endothelial cells can express TF in response to inflammatory cytokines. The factor VIIa/TF complex can activate factor IX and factor X, and is the major initiator of hemostatic coagulation.¹³

Another group of related proteins are the *contact factors*—factors XI and XII, prekallikrein, and high-molecular-weight kininogen. These proteins share the feature of binding to charged surfaces. The only one of this group that is needed for normal hemostasis is factor XI.¹⁴ The other contact factors may play a role, however, in thrombosis in some settings. Factor XI is a zymogen that can be activated to a protease by factor XIIa, but is likely activated primarily by thrombin during the hemostatic process. Factor XIa activates factor IX.

Fibrinogen provides the key structural component of the hemostatic clot. Two small peptides, fibrinopeptides A and B, are cleaved from fibrinogen by thrombin, and the resulting fibrin monomer polymerizes into a network of fibers. The fibrin polymer is stabilized further when it is cross-linked by activated factor XIII. Factor XIIIa is a transglutaminase that is activated by thrombin coincident with fibrin formation.¹⁵

Thrombin plays a key role in activating procoagulant and anticoagulant factors and triggering formation of fibrin. In addition,

thrombin has cytokine-like activities that bridge the transition between hemostasis, inflammatory/immune responses, and wound healing. Thrombin is truly a multifunctional molecule that affects the host response to injury at many levels.

Even before the structure and function of the various factors had been defined, their interactions had been studied during plasma clotting. In the 1960s, two groups proposed a “waterfall” or “cascade” model of the interactions of the coagulation factors leading to thrombin generation. These schemes were composed of a sequential series of steps in which activation of one clotting factor led to the activation of another, finally leading to a burst of thrombin generation.^{16,17} At that time, each clotting factor was thought to exist as a proenzyme that was activated by proteolysis. The existence of cofactors without enzymatic activity was not recognized until later. The original models were subsequently modified as information about the coagulation factors accumulated and eventually evolved into the Y-shaped scheme shown in Figure 9-1. The “cascade” model shows distinct intrinsic and extrinsic pathways that are initiated by factor XIIa and the factor VIIa/TF complex. The pathways converge on a “common” pathway at the level of the factor Xa/factor Va (prothrombinase) complex.

This scheme was not proposed as a literal model of the hemostatic process *in vivo*; rather, it was derived from studies of plasma clotting in a test tube and was intended to represent the biochemical interactions of the procoagulant factors. The coagulation “cascade” does reflect well the process of plasma clotting,

as in the PT and aPTT tests. The lack of any other clear and predictive concept of hemostasis has meant, however, that until more recently most physicians have also viewed the “cascade” as a model of physiology, and the PT and aPTT as reflecting the risk of clinical bleeding.

The limitations of the coagulation cascade as a model of the hemostatic process *in vivo* are highlighted by certain clinical observations. Patients deficient in the initial components of the intrinsic pathway—factor XII, high-molecular-weight kininogen, or prekallikrein—have a greatly prolonged aPTT, but no bleeding tendency. Patients deficient in factor XI also have a prolonged aPTT, but usually have a mild to moderate bleeding tendency. Other components of the intrinsic pathway have a crucial role in hemostasis because patients deficient in factor VIII or factor IX have a serious bleeding tendency even though the extrinsic pathway is intact. Similarly, patients deficient in factor VII also have a serious bleeding tendency even though the intrinsic pathway is intact. Although the cascade model accurately reflects the protein interactions that lead to plasma clotting, and is an essential guide to interpretation of PT and aPTT results, it is not an adequate model of hemostasis *in vivo*.

The numbering of the coagulation factors does not follow their order in the cascade. The coagulation factors were numbered roughly in the order in which they were discovered. Because many workers had described the same molecules under different names, designating them with roman numerals seemed the fairest way to reconcile the nomenclature confusion.¹⁸

Figure 9-1. The extrinsic and intrinsic pathways in the modern cascade model of coagulation. These two pathways are conceived as each leading to formation of the factor Xa/Va complex, which generates thrombin (IIa). *Lipid/Ca* indicates that the reaction requires a phospholipid surface and calcium ions. These pathways are assayed clinically using the prothrombin time (PT) and activated partial thromboplastin time (aPTT). HK, high-molecular-weight kininogen; PK, prekallikrein.

Process of Hemostasis

Having all the right ingredients is not enough to ensure an effective hemostatic process. Cellular interactions are crucial to directing and controlling hemostasis. Normal hemostasis is impossible in the absence of platelets. In addition, TF is an integral membrane protein, and its activity is normally associated with cells, but platelets have little TF activity. Interactions between at least these two types of cells are necessary. Because different cells express different levels of procoagulants and anticoagulants and have different complements of receptors, it is logical that simply representing the cells involved in coagulation as phospholipid vesicles overlooks the active role of cells in directing hemostasis. Hemostasis *in vivo* can be conceptualized as occurring in a stepwise process, regulated by cellular components,¹⁹ as described subsequently.

Step 1: Initiation of Coagulation on Tissue Factor–Bearing Cells

The process of thrombin generation is initiated when TF-bearing cells are exposed to blood at a site of injury. TF is a transmembrane protein that acts as a receptor and cofactor for factor VII. When bound to TF, zymogen factor VII is rapidly converted to factor VIIa through mechanisms not yet completely understood, but that may involve factor Xa or noncoagulation proteases. The resulting factor VIIa/TF complex catalyzes activation of factor X and activation of factor IX. The factors Xa and IXa formed on TF-bearing cells have very distinct and separate functions in initiating blood coagulation.²⁰ The factor Xa formed on TF-bearing cells interacts with its cofactor, factor Va, to form prothrombinase complexes and generate small amounts of thrombin on the TF cells (Fig. 9-2). The small amounts of factor Va required for prothrombinase assembly on TF-bearing cells are activated by

Figure 9-2. The initiation step in a cell-based model of hemostasis. Initiation occurs on the tissue factor (TF)-bearing cell as activated factor X combines with its cofactor, factor Va, to activate small amounts of thrombin.

factor Xa,²¹ activated by noncoagulation proteases produced by the cells,²² or released from platelets that adhere nearby. The activity of the factor Xa formed by the factor VIIa/TF complex is largely restricted to the TF-bearing cell because factor Xa that dissociates from the cell surface is rapidly inhibited by tissue factor pathway inhibitor (TFPI) or AT in the fluid phase.

In contrast to factor Xa, the factor IXa activated by factor VIIa/TF does not act on the TF-bearing cell and does not play a significant role in the initiation phase of coagulation. Factor IXa can diffuse to adjacent platelet surfaces because it is not inhibited by TFPI and is inhibited much more slowly by AT than factor Xa. Factor IXa can bind to a specific platelet surface receptor²³; interact with its cofactor, factor VIIIa; and begin to activate factor X directly on the platelet surface.

The small amount of thrombin produced on the TF-bearing cells is insufficient to clot fibrinogen, but it is sufficient to initiate events that amplify the initial procoagulant signal and “prime” the clotting system for a subsequent burst of platelet surface thrombin generation. This thrombin is responsible for^{24,25} (1) activating platelets, (2) activating factor V, (3) activating factor VIII and dissociating factor VIII from vWF, and (4) activating factor XI.

It is likely that most (extravascular) TF is bound to factor VIIa even in the absence of an injury, and that low levels of factor IXa, factor Xa, and thrombin are produced on TF-bearing cells at all times. This process is kept separated from key components of hemostasis, however, by an intact vessel wall. The very large components of the coagulation process are platelets and factor VIII bound to multimeric vWF. These components normally come into contact with the extravascular compartment only when an injury disrupts the vessel wall. Platelets and factor VIII/vWF leave the vascular space and adhere to collagen and other matrix components at the site of injury.

Step 2: Amplification of the Procoagulant Signal by Thrombin Generated on the Tissue Factor–Bearing Cell

Binding of platelets to collagen or via vWF during primary hemostasis leads to partial platelet activation. The coagulation process is most effectively initiated, however, when enough thrombin is generated on or near the TF-bearing cells to trigger full activation of platelets. Thrombin diffuses through the fluid phase and binds to its receptor GPIb²⁶ and cleaves its proteolytically activated receptors.²⁷ These two receptor types synergize in mediating platelet activation. The small amounts of thrombin generated during the initiation step are also responsible for activation of coagulation factors XI and VIII on the platelet surface in the amplification step, as illustrated in [Figure 9-3](#).

Platelets not only plug the vascular defect at a site of injury, but also provide the specialized membrane surface on which activation of many of the coagulation proteins occurs. Unactivated platelets express a very low level of phosphatidylserine, the primary procoagulant phospholipid, on their surfaces. On activation, phosphatidylserine is rapidly translocated from the inner to the outer leaflet of the platelet plasma membrane. It is then available to support binding and activity of the coagulation complexes.²⁸

Platelet secretion of granule contents occurs more slowly after activation than membrane surface changes. Dense and alpha granules within the platelet cytoplasm contain numerous components that play a role in the coagulation process, such as partially activated factor V, factor VIII/vWF, factor XIII, fibrinogen, protease inhibitors, and platelet agonists (adenosine diphosphate [ADP], epinephrine, and serotonin). Secretion of these platelet agonists enhances platelet activation further. When platelets are activated, the cofactors Va and VIIIa are rapidly localized on the platelet surface.²⁹ Factor IXa formed by the factor VIIa/TF complex can diffuse through the fluid phase, bind to the surface of activated platelets, and assemble into a complex with factor VIIIa. Factor XI activated by thrombin on the platelet surface^{25,30} can activate more factor IX from the plasma to factor IXa. At the end of the amplification phase, the platelets accumulated at the injury site are activated and have bound activated coagulation factors on their surfaces.

Step 3: Propagation of Thrombin Generation on the Platelet Surface

The multiple positive feedback mechanisms of the amplification phase rapidly lead to a burst of thrombin generation in the propagation phase, as illustrated in [Figure 9-4](#). The “tenase” (factor IXa/factor VIIIa) complexes progressively activate factor X from the plasma to factor Xa on the platelet surface. Factor Xa then associates with factor Va to support a burst of thrombin generation of sufficient magnitude to produce a stable fibrin clot.

The large amount of thrombin generated on the platelet surface is responsible for stabilizing the hemostatic clot in more ways than just promoting fibrin polymerization. Most of the thrombin generated during the hemostatic process is produced after the initial fibrin clot is formed. The platelet-produced thrombin also stabilizes the clot by (1) activating factor XIII,³¹ (2) activating the thrombin-activated fibrinolysis inhibitor,³² (3) cleaving the platelet PAR-4 receptor,³³ and (4) being incorporated into the structure of the clot. Activated factor XIII covalently cross-links the fibrin strands and increases resistance to plasmin degradation. Thrombin-activated fibrinolysis inhibitor also increases resistance to fibrinolysis by cleaving off lysines

Figure 9-3. Amplification step in a cell-based model of hemostasis. The small amount of thrombin generated on tissue factor (TF)-bearing cells amplifies the procoagulant response by diffusing to the platelet surface, where it activates platelets via the protease activated receptor-1 (PAR-1), activates factor XI, and activates factor VIII and releases it from its carrier molecule von Willebrand factor (vWF).

Figure 9-4. Propagation step in a cell-based model of hemostasis. The activated coagulation factors bound to the platelet surface during the amplification phase progressively activate factor X and factor II from the plasma, resulting in a large burst of thrombin production.

from the fibrin strands that serve as sites for fibrinolytic enzyme binding. Activation of platelet PAR-4 receptors promotes clot contraction, which pulls together the edges of a wound and makes the hemostatic plug more dense and impermeable. "Excess" thrombin produced during the hemostatic process can remain bound within the fibrin polymer and retains its proteolytic activity. It can rapidly activate more platelets and clot more fibrinogen if the hemostatic plug is disrupted and bleeding resumes.

The role of factor XI in hemostasis has been controversial because even severe factor XI deficiency does not result in a hemorrhagic tendency as severe as that in severe factor VIII or factor IX deficiency. This situation can be explained if factor XI is viewed as a "booster" of thrombin generation. Factor XI is not essential for platelet-surface thrombin generation, as are factor IX and factor VIII. Rather, factor XIa activates additional factor IXa on the platelet surface to supplement factor

IXa/factor VIIIa complex formation and enhance platelet surface factor Xa and thrombin generation. Its deficiency does not compromise hemostasis to as great an extent as factor IX or factor VIII deficiency.

Our knowledge of the platelet contribution to thrombin generation continues to evolve. There is evidence that there are multiple types of activated platelets. Platelets with the highest procoagulant activity are produced when they are stimulated with thrombin and collagen; these have been referred to as COAT (*collagen and thrombin stimulated*) platelets.³⁴ These platelets have enhanced thrombin-generating ability because of enhanced binding of tenase and prothrombinase components.^{35,36} The in vivo relevance of the COAT platelet phenomenon is unclear, but it may be that the greatest procoagulant activity is generated on platelets that have bound to collagen matrix and been exposed to thrombin. When the exposed collagen is covered by a platelet/fibrin layer, additional platelets that

accumulate are not activated to the COAT state—tending to damp down the procoagulant signal when the area of the wound has been walled off by a hemostatic clot.

Even though each phase of the cell-based model of hemostasis has been depicted as a discrete step, the phases should be viewed as an overlapping continuum of events. Thrombin produced on the platelet surface early in the propagation phase may initially cleave substrates on the platelet surface and continue to amplify the procoagulant response, in addition to leaving the platelet and promoting fibrin assembly.

The cell-based model of hemostasis shows us that the extrinsic and intrinsic pathways are not redundant. We can consider the extrinsic pathway to consist of the factor VIIa/TF complex working with the factor Xa/Va complex, and the intrinsic pathway to consist of factor XIa working with the complexes of factors VIIIa/IXa and factors Xa/Va. The extrinsic pathway operates on the TF-bearing cell to produce small amounts of thrombin that initiate the coagulation process and amplify the initial procoagulant signal. By contrast, the intrinsic pathway operates on activated platelet surfaces to produce the large burst of thrombin that leads to formation and stabilization of the fibrin clot.

Regulatory Mechanisms to Control Coagulation

Although the inability to provide effective hemostasis is a serious problem, the inability to limit coagulation to sites of hemostasis is at least as great a problem. Multiple biochemical and cellular regulatory mechanisms have evolved to limit and localize the coagulation reactions. The coagulation reactions do not “cascade” unimpeded into a torrent of thrombin production, but must instead overcome a series of regulatory barriers.

Plasma Protease Inhibitors

Several circulating protease inhibitors can inactivate one or more of the coagulation proteases. The coagulation proteases are relatively protected from inhibition while bound to a membrane surface. Proteases that escape into the fluid phase are subject to inhibition, however. The presence of inhibitors does not prevent activation and activity of coagulation, but tends to confine the coagulation proteases to act on the cell surfaces on which they were activated.

AT (formerly called antithrombin III) plays a particularly important role in regulating hemostasis. AT is a serine protease inhibitor (serpin) that can inhibit most of the procoagulant factors, including factors IIa, VIIa, IXa, Xa, and XIa. The effectiveness of AT is increased by binding to heparinoids on the endothelial surfaces and by exogenous heparins. Hereditary and acquired deficiencies of AT lead to a significant thrombotic tendency.³⁷

TFPI is also an important control mechanism. This molecule is a multifunctional Kunitz-type inhibitor.³⁸ One of its Kunitz domains inhibits factor Xa. When it has bound factor Xa, another Kunitz domain can bind factor VIIa in the factor VIIa/TF complex. TFPI can assist in localizing factor Xa to the cell surface on which it was activated and limiting the activity of the TF pathway.

Not only are the plasma protease inhibitors key players in confining a clot to the proper location, but they also impose a threshold effect on activation of coagulation.³⁹ In the presence

of inhibitors, coagulation does not proceed unless procoagulant factors are generated in sufficient amounts to overcome the effects of inhibitors. If the triggering event is not sufficiently strong, the system returns to baseline rather than continuing through the coagulation process. Under pathologic conditions, the trigger for clotting may be so strong as to overwhelm the control mechanisms and lead to disseminated intravascular coagulation or thrombosis.

Endothelial Antithrombotic Mechanisms

When a fibrin/platelet clot is formed over an area of injury, the clotting process must be terminated to avoid thrombotic occlusion in adjacent normal areas of the vasculature. If the coagulation mechanism were not controlled, clotting could extend throughout the vascular tree after even a modest procoagulant stimulus.

Endothelial cells play a major role in confining the coagulation reactions to a site of injury. Conversely, endothelial damage or dysfunction can play a major role in promoting thrombosis. Endothelial cells have several types of anticoagulant/antithrombotic activities (Fig. 9-5). The protein C/protein S/thrombomodulin system is activated in response to thrombin generation.⁴⁰ Some of the thrombin formed during hemostasis can diffuse away or be swept downstream from a site of injury. When thrombin reaches an intact endothelial cell, it binds to thrombomodulin on its surface. The thrombin/thrombomodulin complex activates protein C, which is localized to the endothelial surface by binding to the endothelial protein C receptor (EPCR). The activated protein C can move into a complex with its cofactor, protein S, and inactivate any factor Va or factor VIIIa that has found its way to the endothelial cell membrane; this prevents the generation of additional thrombin in the intact vasculature.

Endothelial cells also localize anticoagulant protease inhibitors to their surfaces. AT binds to the glycosaminoglycan heparan sulfate on the endothelial surface, which enhances inactivation of proteases near the endothelium.⁴¹ TFPI can also be bound to heparan sulfate or linked to the endothelial surface via a glycosyl phosphatidylinositol (GPI) anchor. Endothelial

Figure 9-5. Antithrombotic mechanisms of the endothelial cell surface. Endothelial cells express glycosaminoglycan (GAG) molecules containing heparan sulfate to which thrombin and antithrombin can bind. They also express thrombomodulin (TM) and the endothelial protein C receptor (EPCR), which localize components of the protein C/protein S system to the endothelial surface.

cells also inhibit platelet activation by releasing the inhibitors prostacyclin and nitric oxide, and degrading ADP by their membrane ecto-ADPase, CD39.⁴²

Fibrinolysis

Even as the fibrin clot is being formed in the body, the fibrinolytic system is being initiated to disrupt it. The final effector of the fibrinolytic system is plasmin, which cleaves fibrin into soluble degradation products. Plasmin is produced from the inactive precursor plasminogen by the action of two plasminogen activators: urokinase-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA). The plasminogen activators are regulated by plasminogen activator inhibitors. Plasminogen is found at a much higher plasma concentration than the plasminogen activators. The availability of the two plasminogen activators in the plasma generally determines the extent of plasmin formation. tPA release from endothelial cells is provoked by thrombin and venous occlusion.⁴³ tPA and plasminogen bind to the evolving fibrin polymer. When plasminogen is activated to plasmin, it cleaves fibrin at specific lysine and arginine residues, resulting in dissolution of the fibrin clot. The fibrinolytic system is crucial to removing an appropriate hemostatic clot as wound healing occurs. It is also essential to removing intravascular thrombi before significant tissue injury can occur. The pulmonary vasculature can release large amounts of fibrinolytic enzymes to remove small thromboemboli that become lodged there.

Intravascular deposition of fibrin is also associated with the development of atherosclerosis. An effective fibrinolytic system tends to protect against the chronic process of atherosclerotic vascular disease and the acute process of thrombosis. Conversely, defects of fibrinolysis increase the risk of atherothrombotic disease. Elevated levels of plasminogen activator inhibitor-1, an inhibitor of fibrinolysis, are associated with an increased risk of atherosclerosis and thrombosis,⁴⁴ as are decreased levels of plasminogen.⁴⁵ The effectiveness of hemostasis *in vivo* depends not only on the procoagulant reactions, but also on the fibrinolytic process.

Clinical Laboratory Testing

The commonly used clinical coagulation tests do not reflect the complexity of hemostasis *in vivo*; this does not mean that the PT and aPTT are useless. Clinicians need to understand what these tests can and cannot tell us. These “screening” coagulation tests are abnormal when there is a deficiency of one or more of the soluble coagulation factors. They do not predict what the risk of clinical bleeding will be. Two patients with identical aPTT values can have drastically different risks of hemorrhage. All of the common coagulation tests, including the PT, aPTT, thrombin clotting time, fibrinogen levels, and coagulation factor levels, tell us something about the plasma level of soluble factors required for hemostasis. Their clinical implications must be evaluated by the ordering physician. Just because the PT and aPTT are within the normal range, it does not follow that the patient is at no risk for bleeding. Conversely, a mild elevation in these clotting times does not mean that the patient is at risk for bleeding after an invasive procedure.

Many whole-blood coagulation tests are being presented as a means of evaluating overall hemostatic status in selected clinical settings. Although whole-blood tests have the advantage

that they may reflect the contributions of platelets to the hemostatic process, they still do not reflect the contributions of the TF-bearing cells and local tissue conditions. Any laboratory test requires skilled interpretation and clinical correlation in evaluating the true risk of bleeding.

What Can Go Wrong with Hemostasis

Hemorrhage

Many patients who develop hemorrhage do not have a pre-existing bleeding tendency. Bleeding after surgical or accidental trauma or during a medical illness is often associated with the development of an acquired coagulopathy. The hallmark of coagulopathy is microvascular bleeding, which is oozing from cut surfaces and minor sites of trauma, such as needle-sticks. Microvascular bleeding can lead to massive blood loss. Causes of coagulopathic bleeding include consumption of coagulation factors and platelets, excessive fibrinolysis, hypothermia, and acidosis.

Consumption of Coagulation Components

Disseminated intravascular coagulation (DIC) normally comes to mind in relation to consumption. Clotting factors and platelets can also be consumed, however, during appropriate physiologic attempts at hemostasis. In this case, it is appropriate to replace the depleted factors with transfusion therapy.

DIC can be much more complicated to manage.⁴⁶ The mainstay of treatment is to treat the underlying disorder, such as sepsis. In early or mild/compensated DIC, administration of low-dose heparin may be considered to control the procoagulant response to inflammation, infection, or malignancy. In more severe or advanced DIC, replacement therapy may be necessary to attempt to manage the bleeding tendency associated with depletion of coagulation factors and platelets.

Excessive Fibrinolysis

The process of fibrinolysis is initiated as the fibrin clot assembles. Fibrin serves as the framework to which plasminogen binds and is activated to plasmin by tPA and uPA. Even when formation of a fibrin clot does not succeed at establishing hemostasis, a significant amount of fibrinolytic activity may still be generated and thwart subsequent efforts at hemostasis. Fibrinolytic inhibitors have proven to be useful in some circumstances.

Hypothermia

Many patients become hypothermic during medical illness or after surgical or accidental trauma.⁴⁷ Hypothermia can directly interfere with the hemostatic process by slowing the activity of the coagulation enzymes. Less well recognized is the finding that platelet adhesion and aggregation is impaired even in mild hypothermia.⁴⁸ In hypothermic coagulopathic patients, increasing the core temperature can have a beneficial effect on bleeding by improving platelet function and coagulation enzyme activity.

Acidosis

Acidosis can have an even more profound effect on the coagulation process than hypothermia, and the two metabolic abnormalities often coexist. A decrease in the pH from 7.4 to 7.2 reduces the activity of each of the coagulation proteases by more than half.⁴⁹ Acidosis should be considered as a possible contributor to coagulopathic bleeding in medical and surgical patients.

Thrombosis

Disruption of the normal regulatory functions of any of the components of hemostasis can result in thrombosis. Generally, thrombosis is a multifactorial problem—congenital and acquired abnormalities in the antithrombotic activities of the vascular endothelium can synergize with enhanced platelet reactivity and alterations in procoagulant or anticoagulant levels ultimately to produce thrombosis. The risk of thrombosis in any given individual at and any given time is a product of the individual's accumulated genetic, environmental, and lifestyle risk factors.

Inflammation can trigger numerous responses that predispose further to thrombosis.⁵⁰ The coagulation and inflammatory responses interface at the levels of the tissue factor pathway, the protein C/protein S system, and the fibrinolytic system. Proinflammatory cytokines can affect all of these coagulation mechanisms, and coagulation proteases, anticoagulants, and fibrinolytic enzymes can modulate inflammation by specific cell receptors. Inflammatory cytokines can promote an increase in tissue factor and a decrease in thrombomodulin by the endothelium.⁵¹ Activation of coagulation is closely linked with the progression of atherosclerotic vascular lesions. Progressively impaired vascular function further predisposes to thrombosis. Ultimately, rupture of an unstable atherosclerotic plaque can expose procoagulant activity and provoke an acute thrombotic event.⁵² Management of cardiovascular disease often involves preventing and managing thrombosis and its consequences. Venous and arterial thrombosis tend to have different mechanisms and risk factors, and are best managed by different strategies.

Venous Thrombosis

The major mechanism of venous thrombosis is related to inappropriate activation of the coagulation reactions—often on inflamed endothelium. Stasis can play an exacerbating role when activated factors are not rapidly diluted in flowing blood. Abnormalities of coagulation factors and increased levels of coagulation factors that potentially increase thrombin generation are linked to venous thrombosis.^{53,54} The inherited hemostatic abnormalities most often associated with venous thromboembolism are factor V Leiden and factor II G20210A mutations, and deficiencies in AT, protein C, and protein S. Acquired abnormalities also play a major role. Major clinical risk factors for venous thromboembolism include malignancy, myeloproliferative disorders, trauma, surgery (especially orthopedic surgery), immobilization or paralysis, and prior venous thromboembolism. Minor risk factors include advanced age, obesity, bed rest, use of hormone replacement therapy or oral contraceptives, pregnancy and postpartum period, and inflammatory bowel disease.

Venous thrombosis is extremely common in hospitalized patients. Although it is often asymptomatic, it is a significant cause of morbidity and of mortality from pulmonary embolism. Incidence of venous thrombosis can be reduced dramatically by the appropriate use of thromboprophylaxis with anticoagulants such as heparin and low-molecular-weight heparins.⁵⁵⁻⁵⁷

Arterial Thrombosis

Arterial thrombosis is primarily related to formation of platelet aggregates at sites of high shear and turbulent flow. As atherosclerotic plaques develop, they not only alter the

nonthrombogenic nature of the endothelium, but also disrupt normal laminar blood flow and produce increased turbulence. Although increased platelet reactivity can contribute to arterial thrombosis, the vascular alterations play a key role in promoting platelet adhesion and activation.⁵⁸ There is also considerable evidence that TF-mediated activation of the coagulation system and thrombin generation can be important contributors to arterial thrombosis.⁵⁹ Thrombin generation at a site of plaque rupture can be the trigger for platelet activation and adhesion.⁶⁰

The risk factors most closely linked to arterial thrombosis are smoking, hypertension, dyslipidemia, and diabetes. Inherited thrombophilia plays much less of a role in arterial than venous thrombosis.⁶¹ Lifestyle changes can have a significant impact on the risk of arterial thrombosis. The most effective management is by therapies targeting platelet activation and adhesion. The results of more recent studies indicate that in addition to the efficacy of aspirin in reducing cardiac events in patients with acute coronary syndromes, more potent antiplatelet and anticoagulant therapies are valuable in high-risk patients.

What Happens after the Bleeding Stops

When hemostasis is completed, the process of wound healing can begin. Many of the activities involved in wound healing are influenced by thrombin. Thrombin plays a major role in platelet activation and degranulation. Several key cytokines modulating wound healing are released from activated platelets, including transforming growth factor- β and platelet-derived growth factor. The amount and rate of thrombin generated during hemostasis influences the initial structure of the fibrin clot—the framework on which cell migration occurs. In addition, thrombin has chemotactic and mitogenic activities for macrophages, fibroblasts, smooth muscle cells, and endothelial cells. Generation of the “right” amount of thrombin during the coagulation process not only may be essential for effective hemostasis, but also may set the stage for effective wound healing. Conversely, thrombin generation at sites of vascular injury plays a role in the development of local inflammatory changes and progression of atherosclerotic lesions.

Conclusion

MYOCARDIAL INFARCTION (MI) describes the process of myocardial cell death caused by ischemia, or the perfusion imbalance between supply and demand within the coronary arteries resulting from an acute thrombotic process. In the United States in 2006, approximately 16.8 million (7.6%) people had coronary heart disease, and an estimated 935,000 people experienced an acute MI that year, of which more than 150,000 resulted in death.¹ In 2009, it was estimated that approximately every 25 seconds an American would have a coronary event, and about every minute an individual would die from one.¹ The early recognition and diagnosis of acute MI is vital for the institution of therapy to limit myocardial damage and preserve cardiac function.

Acute coronary syndrome (ACS) refers to the constellation of clinical symptoms caused by active myocardial ischemia. Patients with ACS can be grouped into two major categories of acute MI: (1) patients with new ST segment elevation on the electrocardiogram (ECG) that is diagnostic of acute ST segment elevation myocardial infarction (STEMI), and (2) patients with non-ST segment elevation myocardial infarction (NSTEMI) who have positive cardiac biomarkers in an appropriate clinical setting, with or without ECG ST segment depression or T wave inversion.²

International registry data found that of patients who presented with an ACS, 25% experienced NSTEMI, whereas 30% had STEMI.³ Clinical trials have established the benefit of early reperfusion therapy in patients with STEMI and an early invasive strategy in patients with NSTEMI, and so a rapid and accurate assessment of patients with suspected acute MI is essential for optimal management.^{2,4} This chapter describes the diagnostic modalities for the evaluation of patients with suspected acute MI.

History

There have been considerable advances in the detection of myocardial injury and necrosis in the last several decades. As a result, the definition of MI has evolved over time. Beginning in the 1950s, the World Health Organization used epidemiologic data to define acute MI as the presence of at least two of the following three criteria: (1) clinical symptoms suggestive of myocardial ischemia, (2) ECG abnormalities, or (3) elevation in serum markers indicative of myocardial necrosis.⁵ The development of more sensitive and specific biomarkers of myocardial necrosis and precise imaging techniques for ischemic myocardial

Table 10-1. Classification of Myocardial Infarction (MI)

Type	
1	Spontaneous MI resulting from a primary coronary event, such as coronary artery plaque erosion, or rupture, fissure, or dissection
2	MI associated with ischemia secondary to either increased oxygen demand or decreased supply, such as in coronary artery spasm, coronary embolism, anemia, arrhythmia, hypertension, or hypotension
3	Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by new ST segment elevation, new left bundle branch block, or evidence of fresh thrombus in a coronary artery by angiography or at autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood
4a	MI associated with percutaneous coronary intervention
4b	MI associated with stent thrombosis as documented by angiography or autopsy
5	MI associated with coronary artery bypass graft surgery

Modified and adapted from Thygesen K, Alpert JS, White HD: Universal definition of myocardial infarction. *J Am Coll Cardiol* 2007;50:2173-2195.

dysfunction has led to further refinement of the diagnosis of MI. In 2007, a Global Task Force assembled from the European Society of Cardiology, the American College of Cardiology, the American Heart Association, and the World Heart Federation published a consensus statement that sought to standardize cardiac biomarker detection, incorporate cardiac imaging into the evaluation of a patient with MI, and classify the different types of MIs, furthering the evolution of the definition of acute MI.⁶

Definition of Myocardial Infarction

MI is defined by the presence of myocardial necrosis combined with the clinical presentation of myocardial ischemia. The diagnosis of acute MI requires the increase or decrease (or both) of cardiac biomarkers (preferably troponin) with at least one value greater than the 99th percentile of the upper reference limit and at least one of the following: symptoms of ischemia, ECG changes indicative of active ischemia (new ST segment–T wave changes or new left bundle branch block [LBBB]), or imaging evidence of new regional wall motion abnormality or loss of viable myocardium.⁶ The type of MI can be classified further depending on the etiology of the infarct (Table 10-1).

Biochemical Markers of Acute Myocardial Infarction

The ideal biochemical marker should be present in high concentration in the myocardium, absent in noncardiac tissue, released rapidly in a linear fashion after myocardial necrosis, and present in the serum long enough to be easily detectable by an

inexpensive and widely available assay. Table 10-2 summarizes serum cardiac markers. Cardiac biomarkers are an essential component of the criteria used to establish the diagnosis of acute MI. Troponins have become the preferred biomarkers for the detection of myocardial necrosis and are a class I indication in the diagnosis of MI.⁶⁻⁸ The improved sensitivity and tissue specificity of cardiac troponins compared with creatine kinase MB (CK-MB) and other conventional cardiac biochemical markers of acute MI have been well established.^{8,9} Troponins are not only useful for diagnostic implications, but also impart prognostic information and can assist in the risk stratification of patients presenting with suspected ACS.

In addition to the established biomarkers of myocardial necrosis, B-type natriuretic peptide (BNP) and C-reactive protein (CRP) are pathologically diverse biomarkers that could potentially enhance risk stratification in ACS further. Finally, several novel markers of myocardial ischemia and their usefulness during acute MI are currently being evaluated in clinical studies. To date, measurement of more than one specific biomarker of myocardial necrosis is unnecessary for establishing the diagnosis of MI and is not currently recommended.¹⁰ Certain biomarkers should no longer be used in the evaluation of acute MI because of their poor specificity secondary to their wide tissue distribution, including aspartate aminotransferase, total lactate dehydrogenase, and lactate dehydrogenase isoenzymes.¹¹

Detectable increases in cardiac biomarkers are indicative of myocardial injury. Biomarker elevations are not synonymous with acute MI, however. Many disease states, such as sepsis, hypovolemia, atrial fibrillation, congestive heart failure, pulmonary embolism, myocarditis, intracranial hemorrhage, stroke, and renal failure, can be associated with an increase in cardiac biomarkers. These elevations arise from mechanisms other than thrombotic coronary artery occlusion and require treatment of the underlying cause, rather than the administration of anti-thrombotic and antiplatelet agents.^{12,13}

Serum markers of myocardial necrosis have a vital role in the diagnosis and prognosis of acute MI, but the diagnosis of acute MI is not predicated exclusively on the presence of increased biomarkers. Acute MI should be diagnosed when biomarkers are detected, and the clinical setting is consistent with myocardial ischemia.

Troponin

Cardiac troponins are regulatory proteins that control the calcium-mediated interaction of actin and myosin, which results in contraction and relaxation in striated muscle. The troponin complex comprises three subunits: troponin C, which binds calcium; troponin I, which inhibits actin-myosin interactions; and troponin T, which attaches the troponin complex by binding to tropomyosin and facilitates contraction. Troponin C is expressed by cells in cardiac and skeletal muscle; in contrast, the amino acid sequences of troponins I and T are unique to cardiac muscle. This difference has allowed for the development of rapid, quantitative assays to detect elevations of cardiac troponins in the serum. Troponin is the preferred biomarker for use in the diagnosis of acute MI because of superior tissue specificity and sensitivity for MI and its usefulness as a prognostic indicator.

Diagnosis

Troponin is released early in the course of acute MI. An increased concentration of cardiac troponin is defined as exceeding the 99th percentile of a reference control group. Troponin

Table 10-2. Biochemical Markers of Myocardial Necrosis

Marker	Initial Appearance (hr)	Mean Time to Peak	Return to Basal	Sampling Schedule
Myoglobin	1-4	6-7 hr	24 hr	Frequent; every 1-2 hr after CP
Cardiac troponin I	3-12	24 hr	5-10 days	Initially and 6-9 hr after CP
Cardiac troponin T	3-12	12 hr–2 days	5-14 days	Initially and 6-9 hr after CP
Creatine kinase (CK)	3-12	24 hr	Unknown	Every 8 hr
CK-MB (tissue isoform)	2-6	18 hr	48-72 hr	Initially and 3-4 hr after CP
Lactate dehydrogenase (LDH)	10	24-48 hr	10-14 days	Once at least 24 hr after CP

CK-MB, MB isoenzyme of creatine kinase (CK); CP, chest pain.

Modified and adapted from Adams J, Abendschein DR, Jaffe AS: Biochemical markers of myocardial injury: is MB creatine kinase the choice for the 1990's? *Circulation* 1993;88:750-763.

Figure 10-1. Time course of elevation of biochemical markers of acute myocardial infarction. The relative timing and extent of the increase above normal values of the commonly used serum markers after acute myocardial infarction are shown. CK, creatine kinase; CK-MB, creatine kinase MB isoenzyme; LDH, lactate dehydrogenase.

exceeding this limit on at least one occasion in the setting of clinical ischemia is indicative of myocardial necrosis.⁶ Elevated troponin can be detected within 2 to 4 hours after the onset of myocardial injury.¹³ Serum levels can remain increased for 4 to 7 days for troponin I and 10 to 14 days for troponin T (Fig. 10-1).¹⁴

The initial release of troponin is from the cellular cytosol, whereas the persistent elevation is a result of the slower dispersion of troponin from degrading cardiac myofilaments.¹⁵ As a result of these kinetics, the sensitivity of troponin increases with time. At 60 minutes after the onset of acute MI, the sensitivity is approximately 90%, but maximal sensitivity of troponin (approximately 99%) is not achieved until 6 or more hours after the initiation of myocardial necrosis.¹³ Blood samples for the measurement of troponin levels are recommended to be drawn at presentation and 6 to 9 hours later to optimize the clinical sensitivity for ruling in acute MI and the specificity for ruling out acute MI.⁸

The specificity of troponin I is approximately 85% to 95% with serial testing.¹⁶ As a result of this high tissue specificity, cardiac troponin is associated with fewer false-positive results in the setting of concomitant skeletal muscle injury than CK-MB.

This inherent characteristic of troponin has been used in the diagnosis and assessment of myocardial injury in patients with chronic muscle diseases, in marathon runners, in patients after electrical cardioversion, in patients with cardiac contusions, and in patients with perioperative MIs.¹⁶⁻¹⁹ The tissue specificity of cardiac troponin is distinct from the specificity for the mechanism of myocardial injury; if elevated troponins are found in the absence of myocardial ischemia, an evaluation for alternative etiologies of myocardial injury should be pursued.

Despite the ongoing development of increasingly sensitive troponin assays, troponin kinetics do not reliably permit the very early (initial 1 to 3 hours) detection of myocardial necrosis.⁸ In patients presenting within 6 hours of symptom onset, the clinical scenario, ECG findings, and adjunctive imaging techniques are necessary for the rapid and accurate diagnosis of acute MI. In the case of STEMI, reperfusion therapy should not be delayed waiting for confirmatory biomarkers of myocardial injury.

Elevated troponins not only are vital to the diagnosis of NSTEMI, but also serve to direct treatment by identifying patients who would benefit from an early invasive management strategy.²⁰ In the TACTICS-TIMI 18 study, patients with any increase in troponin who underwent early angiography (within 4 to 48 hours) and revascularization (if appropriate) achieved an approximately 55% reduction in the odds of death or MI compared with patients undergoing conservative management.²¹

Prognosis

In addition to the diagnostic value of troponin, cardiac troponins yield prognostic information. Prognosis is related partly to the extent of the increase in troponin in patients with an ischemic mechanism for myocardial injury.²²⁻²⁴ Increased concentrations of troponin are associated with angiographic findings of greater lesion complexity, impaired blood flow in the culprit artery, and decreased coronary microvascular perfusion.²¹

Cardiac troponin has also been proven to be a potent independent indicator of recurrent ischemic events and the risk of death among patients presenting with ACS.²⁵ The TIMI-IIIB trial showed that in patients presenting with ACS, mortality was consistently higher among patients with elevated troponin I (>0.4 ng/mL) at the time of admission. There were statistically significant increases in mortality with increasing levels of troponin I. Even after adjustment for baseline variables, age older than 65, and ST segment depression on ECG, an elevated troponin I had the strongest impact on mortality.²⁶ Additionally, the GUSTO IIa trial

found that elevated troponin T (>0.1 ng/mL) was significantly predictive of 30-day mortality in patients with acute myocardial ischemia even after analysis was adjusted for ECG category and CK-MB level.²⁷ In patients with STEMI, increased troponin is also associated with a significantly higher mortality at 30 days, which persisted even after adjustment for age, heart rate, systolic blood pressure, location of infarction, and Killip class.²⁸

Risk Stratification

Cardiac troponin is a class I indication for risk stratification in patients with ACS.⁸ Patients presenting with clinical evidence of ischemia and positive troponins, even at low levels, have worse outcomes than patients without evidence of elevated troponin.²⁹ The MISSION! trial showed that peak troponin T levels are a good estimate of infarct size and an independent predictor for left ventricular function at 3 months and major adverse cardiac events at 1 year.²³

Creatine Kinase MB

CK is a cytosolic carrier protein for high-energy phosphates.¹³ CK-MB is an isoenzyme of CK that is most abundant in the heart; however, CK-MB also constitutes 1% to 3% of the CK in skeletal muscle, and is present in a small fraction in other organs, such as the small bowel, uterus, prostate, and diaphragm.³⁰ The specificity of CK-MB may be impaired in the setting of major injury to these organs, especially skeletal muscle.

Although cardiac troponin is the preferred marker of myocardial necrosis, CK-MB by mass assay is an acceptable alternative when cardiac troponin is unavailable.⁸ The diagnostic limit for CK-MB is defined as the 99th percentile in a sex-specific reference control group.⁶ All assays for CK-MB show a significant twofold to threefold higher 99th percentile limit for men compared with women. In addition, CK-MB can have twofold to threefold higher concentrations in African Americans than whites. These discrepancies have been attributed to physiologic differences in muscle mass.¹¹ It is recommended that two consecutive measurements of CK-MB above the diagnostic limit be required for sufficient evidence of myocardial necrosis because of the inherent lower tissue specificity of CK-MB compared with troponin.⁸

The temporal increase of CK-MB is similar to that of troponin in that it occurs within 3 to 4 hours after the onset of myocardial injury, but in contrast to troponin, CK-MB decreases to the normal range by 48 to 72 hours (see Fig. 10-1). The rapid decline of CK-MB to the reference interval by 48 to 72 hours allows for the discrimination of early reinfarction when symptoms recur between 72 hours and 2 weeks after the index acute MI, when troponin may still be elevated.⁸ More recent data suggest, however, that serial troponin I values provide similar information.³¹ Similar to troponin, the amount of CK-MB released is useful for estimation of infarct size, which correlates with ejection fraction, incidence of ventricular arrhythmias, and prognosis.¹⁴

Myoglobin

Myoglobin is a ubiquitous, heme-related, low-molecular-weight protein present in cardiac and skeletal muscle. In the setting of myocardial necrosis, myoglobin levels increase rapidly and are detectable within the first 2 to 4 hours. Elevations persist for 12 to 24 hours before being excreted by the kidneys. Myoglobin has a high sensitivity and a high negative predictive value for myocardial death, making it an attractive tool for the early exclusion of acute MI.⁸ Myoglobin is not specific for myocardial necrosis,

however, especially in the presence of skeletal muscle injury and renal insufficiency.¹⁴

A prospective study assessing the use of myoglobin in the early evaluation of acute chest pain revealed that myoglobin level was 100% sensitive for diagnosis of acute MI at 2 hours; the negative predictive value was also 100% with serial testing, but the specificity was low, limiting the clinical usefulness of myoglobin in the evaluation of acute MI.³² When myoglobin was directly compared with troponin in the early detection of coronary ischemia, using the 99th percentile of troponin I as a cutoff (0.07 μ g/L), the cumulative sensitivity of troponin was higher.³³ A multimarker strategy including troponin and myoglobin has not been shown to yield a superior overall diagnostic performance compared with troponin alone.³³

Adjunctive Biomarkers

Two emerging biomarkers that may be useful adjuncts in the diagnosis and prognosis of acute MI are the natriuretic peptides and inflammatory markers. BNP, a counter-regulatory peptide, and its propeptide, NT-proBNP, are released from cardiac myocytes in response to cardiac stretch. After transmural infarction, the plasma concentrations of BNP increase rapidly and peak at approximately 24 hours.⁸ The peak value of BNP has been found to be proportional to the size of the infarction.³⁴ In patients presenting with acute MI, elevated BNP and NT-proBNP levels have been shown to predict a higher risk of death and heart failure, independent of other prognostic variables.¹³

Increased concentrations of inflammatory biomarkers are detectable in a substantial proportion of patients presenting with acute MI; however, the precise basis for this relationship has not been conclusively established. Studies have implicated inflammation as a contributor to plaque compromise in ACS.³⁵ CRP, an acute-phase reactant protein made in the liver, has been the focus of much clinical investigation. In a cohort study of patients with STEMI, the patients with increased CRP were more likely to have complications of acute MI.³⁶ Similarly, several studies have revealed high-sensitivity CRP to be an independent predictor of short-term and long-term outcomes in patients with ACS.⁸ At this time, there are no therapeutic strategies specific to CRP or BNP and NT-proBNP; however, these biomarkers, in conjunction with troponin, may be useful for risk assessment in patients with acute MI.

Novel Cardiac Markers

Several novel markers of myocardial ischemia, such as ischemia-modified albumin, soluble CD-40 ligand, fatty acid binding protein, myeloperoxidase, choline, and cystatin C, are currently being investigated in the setting of acute MI.¹³ Ischemia-modified albumin is among the most thoroughly investigated of these markers.³⁷ It has been observed that the affinity of the N-terminus of human albumin for cobalt is reduced in the setting of acute myocardial ischemia with detectable changes in binding occurring within minutes.³⁸ The sensitivity (83%) of ischemia-modified albumin in the very early period (1 to 3 hours) of myocardial ischemia and its high negative predictive value (96%) make it a promising marker for the immediate detection of ischemia before myocardial necrosis.³⁹ The pursuit of new markers is rapidly progressing; which markers will become clinically useful depends on several factors, including clinical efficacy, assay availability, and cost-effectiveness.

Clinical Evaluation

The evaluation of a patient presenting with acute MI should start with a targeted history that ascertains the following: (1) characterization and duration of chest discomfort and any associated symptoms; (2) prior episodes of myocardial ischemia or MI, percutaneous coronary intervention, or coronary bypass surgery; (3) history of hypertension, diabetes mellitus, tobacco use, and cerebrovascular disease; and (4) assessment of bleeding risk.⁴⁰

The classic description of acute MI consists of crushing, substernal chest pain or viselike tightness with or without radiation to the left arm, neck, jaw, interscapular area, or epigastrium. This presentation is associated with an estimated 24% probability of acute MI; the probability decreases to about 1% if the pain is positional or pleuritic in a patient without a prior history of coronary artery disease (Table 10-3).⁴¹ Alternatively, the chest pain may be described as sharp, burning, or stabbing, which is associated with a 23% probability of acute MI.⁴¹ Patients commonly may deny pain, but describe a sensation of chest discomfort.⁴⁰ The duration of the discomfort is usually prolonged, lasting more than 30 minutes, but may wax and wane, or even remit. There may be associated vagal symptoms of nausea, vomiting, lightheadedness, and diaphoresis.

Elderly patients and women more commonly have atypical presentations that mimic abdominal pathology or a neurologic event (Table 10-4).⁴² One third of all MIs are unrecognized, especially in patients without prior history of MI, and about half of these unrecognized MIs are associated with atypical presentations.^{43,44} Silent myocardial ischemia is defined as objective

documentation of myocardial ischemia in the absence of angina or anginal equivalents.⁴⁵ Diabetes and hypertension are known to be associated with silent ischemia and infarction. The prognosis of acute MI patients, whether symptomatic or asymptomatic, is similar.⁴³

Response of chest pain to antacids, nitroglycerin, or analgesics can be misleading and should not be relied on. Nitroglycerin can relieve esophageal spasm, and, conversely, pain from acute MI may not always respond well to nitroglycerin because the pain is due to infarction rather than ischemia. Studies suggest that esophageal stimulation can cause angina and reduce coronary blood flow in patients with coronary artery disease; however, this response is absent in patients with heart transplant, supporting the notion of a cardioesophageal reflex, which can complicate further the use of response to treatment as a diagnostic tool.⁴⁶

Physical Examination

An uncomplicated acute MI has no pathognomonic physical signs, but the physical examination is crucial in the early assessment of the complications of acute MI and in establishing a differential diagnosis for the chest pain. The general assessment can reveal a restless and anguished patient with or without confusion owing to poor cerebral perfusion. A clenched fist across the chest, known as Levine sign, may be observed. The patient can appear ashen, pale, or diaphoretic and be cool and clammy to the touch. Tachycardia and hypertension indicate high sympathetic tone and are usually consistent with anterior MI. Bradycardia and hypotension signify high vagal tone and may be seen with inferior-posterior MI with or without right ventricular involvement. Hypotension could also be secondary to the development of cardiogenic shock or a result of medication, especially nitroglycerin, morphine sulfate, or β blockade. Visualization of elevated jugular venous pressure is seen as a consequence of significant left or right ventricular dysfunction.

Auscultation for additional heart sounds, cardiac murmurs, and friction rubs is mandatory. A soft S_1 is heard with decreased left ventricular contractility, and an S_4 gallop indicates decreased left ventricular compliance.⁴⁰ Killip and Kimball proposed a

Table 10-3. Value of Clinical Characteristics in Predicting Acute Myocardial Infarction (AMI) in Patients with Chest Pain

Characteristics of Pain	Probability of AMI (%)
Description of pain	
Pressure, tightness, crushing	24
Burning, indigestion	23
Aching	13
Sharp, stabbing	5
Fully positional	4
Definitely pleuritic	0
Radiation of pain	
Radiation to jaw, neck, left arm, or left shoulder	19
Reproducibility	
Pain partially reproducible by chest wall palpation	6
Combination of variables	
Sharp or stabbing pain; no prior angina or MI; pleuritic, positional, or reproducible by palpation	1

Modified and adapted from Lee TH, Cook EF, Weisberg M: Acute chest pain in the emergency room: identification and examination of low-risk patients. *Arch Intern Med* 1985;145:65-69.

Table 10-4. Atypical Symptoms of Myocardial Infarction in Elderly Patients

Symptom	Percentage of Patients with Symptoms		
	65-74 years old	75-84 years old	≥85 years old
Chest pain	77	60	37
Shortness of breath	40	43	43
Sweating	34	23	14
Syncope	3	18	18
Acute confusion	3	8	19
Stroke	2	7	7

Table 10-5. Relationship between Electrocardiogram (ECG) Changes and Diagnosis of Myocardial Infarction (MI)

ECG Finding	Patients Who Had MI (Positive Predictive Value) (%)	MI Patients (Sensitivity) (%)
≥1 mm ST elevation or Q waves in ≥2 leads (not old)	76	45
New ischemia or strain with ≥1 mm ST depression in ≥2 leads (not old)	38	20
Other ST or T wave changes of ischemia or strain (not known to be old)	21	14
Old infarction, ischemia, or strain	8	5
Other new or old abnormality	5	5
Nonspecific ST-T changes	5	7
Normal	2	3

Modified and adapted from Rouan GW, Lee TH, Cook EF, et al: Clinical characteristics and outcome of acute myocardial infarction in patients with initially normal or non-specific electrocardiograms (a report from the multicenter chest pain study). *Am J Cardiol* 1989;64:1087-1092.

prognostic classification in 1967 that is still useful today for the evaluation of patients with acute MI.⁴⁷ The classification scheme is based on the presence of a third heart sound (S_3) and rales on physical examination. Class I patients are without S_3 or rales, class II patients have rales over less than 50% of the lung fields with or without S_3 , class III patients have pulmonary edema with rales covering greater than 50% of the lung fields, and class IV patients are in cardiogenic shock. Evidence of heart failure on physical examination correlates with greater than 25% of myocardial involvement.⁴⁰ A systolic murmur should prompt an evaluation for complications of MI, such as mitral regurgitation from papillary muscle rupture or the formation of a ventricular septal defect, which may also be accompanied by a palpable precordial thrill. All peripheral pulses should be evaluated and documented. The finding of asymmetric or absent pulses, especially in the presence of tearing chest pain with radiation to the back, may indicate the presence of aortic dissection as an alternative diagnosis.

Other causes of cardiac and noncardiac chest pain that may be differentiated by physical examination include pericarditis, pulmonary embolism, costochondritis, pneumothorax, peptic ulcer disease, and acute cholecystitis. The initial clinical evaluation and physical examination should be directed toward expeditiously identifying the most likely etiology of each patient's presentation. The rapid triage of patients with ACS is crucial for the institution of the most appropriate early reperfusion therapy.

Electrocardiogram

The ECG is crucial in the initial assessment of patients with ACS. On arrival to the emergency department, the recommended “door-to-evaluation” time, which includes performing and interpreting the ECG, is 10 minutes.⁴⁰ The 12-lead ECG in the emergency department is the center of the decision pathway. The ECG aids in the diagnosis of acute MI and suggests the distribution of the infarct-related artery and estimates the amount of myocardium at risk.⁶ The presence of ST segment elevation in two contiguous leads or a new LBBB identifies patients who benefit from early reperfusion therapy, either fibrinolytic therapy or primary percutaneous coronary intervention.

Early fibrinolytic therapy should be instituted within 30 minutes of arrival, whereas patients arriving at a facility with primary percutaneous coronary intervention should have a “door-to-balloon” time of 90 minutes or less.⁴⁸ New LBBB or anterior infarction are important predictors of mortality.⁴⁰ In patients with ischemic chest pain, ST segment elevation has a specificity of 91% and a sensitivity of 46% for diagnosing acute MI. Conversely, the probability of acute MI in patients with chest pain and an initially normal ECG is low—approximately 3% (Table 10-5).^{49,50} Comparison with a previous ECG (if available) is indispensable and may help to avoid unnecessary treatment in patients with an abnormal baseline ECG.⁵¹ If the initial ECG is not diagnostic of STEMI, but the patient remains symptomatic, serial ECGs at 5- to 10-minute intervals should be performed to detect acute or evolving changes.⁴⁰

The classic evolution of acute MI on ECG begins with an abnormal T wave that is often prolonged, peaked, or depressed. Most commonly, increased, hyperacute, symmetric T waves are seen in at least two contiguous leads during the early stages of ischemia.⁶ This is followed by ST segment elevation in the leads facing the area of injury with ST segment depression in the reciprocal leads. Increased R wave amplitude and width in conjunction with S wave diminution are often seen in leads exhibiting ST segment elevation.⁶ This evolution may conclude with the formation of Q waves. The time course of development of these changes varies, but usually occurs in minutes to several hours. A more recent study revealed that among patients presenting within 6 hours of symptom onset of STEMI, the patients who exhibited Q waves on their baseline ECG had more advanced disease with worse clinical outcomes.⁵² This study underscores the need for early recognition of acute MI, not only by medical personnel, but also in the community.

In patients with inferior STEMI, right-sided ECG leads should be obtained to screen for ST segment elevation suggestive of right ventricle infarction (class I indication).⁴⁰ Infarction of the right ventricle associated with inferior acute MI has important therapeutic and prognostic implications.⁵³ Right ventricle infarction is likely when the ST segment is elevated 1 mm or more in the right precordial leads from RV_4 to RV_6 . This finding has a sensitivity of about 90% and a specificity of 100% for proximal right coronary artery occlusion.⁵⁴ Other changes

Table 10-6. Sensitivity and Specificity of Electrocardiogram (ECG) Changes in Left Bundle Branch Block for Diagnosis of Acute Myocardial Infarction

ECG Changes	Sensitivity (%)	Specificity (%)
ST segment elevation ≥ 1 mm concordant with QRS polarity	73	92
ST segment depression ≥ 1 mm in leads V_1, V_2, V_3	25	96
ST segment elevation ≥ 5 mm discordant with QRS polarity	31	92
Positive T waves in leads V_5 and V_6	26	92

Modified and adapted from Sgarbossa EB: Recent advances in the electrocardiographic diagnosis of myocardial infarction: left bundle branch block and pacing. *Pacing Clin Electrophysiol* 1996;19:1370-1379.

reported to be associated with right ventricle infarction are (1) ST segment elevation isolated to lead V_1 , (2) elevated ST segments in leads V_1 - V_4 , and (3) T wave inversion isolated to lead V_2 .⁵⁴ The ECG changes of right ventricle infarction are usually transient, persist for hours, and then resolve within a day.

A normal ECG can be seen in 10% of cases of acute MI.⁵⁵ One explanation for this apparent discrepancy is that the infarction is occurring in an electrocardiographically silent area, such as the posterior or lateral wall in the distribution of the left circumflex artery.⁵⁶ Acute posterior injury is suggested by marked ST segment depression in leads V_1 and V_2 in combination with prominent R waves (at least 0.04 second) or an R/S ratio greater than 1 in the anterior precordial leads. These ECG findings are neither sensitive nor specific for posterior infarction, however, and frequently are not evident on the initial ECG.⁵⁷ In the case of patients who present with clinical evidence of acute MI, but have a nondiagnostic ECG, the latest American College of Cardiology/American Heart Association guidelines state that it is reasonable to obtain supplemental posterior ECG leads, V_7 and V_9 , to assess for left circumflex infarction (class IIa indication).² Several studies have shown that ST segment elevation in leads V_7 and V_9 assists in the early identification and treatment of patients with acute posterior wall infarction, who are having ischemic chest pain, but do not display ST segment elevation on the standard 12-lead ECG.^{53,56,57}

Several conditions can potentially confound the ECG diagnosis of acute MI or cause a pseudoinfarct pattern with Q/QS complexes in the absence of MI. These include pre-excitation, obstructive or dilated cardiomyopathy, bundle branch block, left and right ventricular hypertrophy, myocarditis, cor pulmonale, and hyperkalemia.⁶

Bundle Branch Block Patterns and Acute Myocardial Infarction

The presence of LBBB or ventricular pacing can mask the ECG changes of acute MI. In the GUSTO-1 trial, LBBB was seen in about 0.5% and ventricular pacing in about 0.1% of patients with acute MIs.⁵⁸ Based on this finding, Sgarbossa⁵⁹ developed criteria to evaluate for MI in the presence of left ventricular conduction abnormalities (Table 10-6). These changes in the ST segment or T waves, although very specific, are not seen in a significant proportion of patients, and other modalities such as biomarkers and adjunctive imaging may be required for diagnosis.

The same criteria used to assess for acute MI in the presence of LBBB are also applicable to patients with endocardial ventricular pacemakers except for the T wave criteria. The most indicative finding of acute MI in the presence of ventricular pacing was ST segment elevation 5 mm or greater in the leads with predominantly negative QRS complexes.⁵⁹ In right bundle branch

block, the initial pattern of ventricular activation is normal, and the classic pattern of acute MI on ECG is usually not altered.

Imaging Techniques

Noninvasive imaging can assist in the diagnosis and characterization of acute MI. Commonly used imaging techniques in acute and chronic MI are echocardiography, radionuclide ventriculography, myocardial perfusion scintigraphy, and magnetic resonance imaging (MRI).⁶ Imaging techniques are useful in the diagnosis of MI by virtue of their ability to detect myocardial viability, either directly with radionuclide techniques or indirectly with echocardiography or MRI. In the appropriate clinical setting and in the absence of nonischemic causes, demonstration of a new loss of myocardial viability meets the criteria for MI.⁶

Reinfarction

Reinfarction is suspected when there are recurrent clinical signs of myocardial ischemia lasting 20 minutes or longer after an initial MI. The incidence of reinfarction is reported to be less than 20%.³¹ In patients who show evidence of recurrent MI, an immediate measurement of a cardiac biomarker is recommended, followed by a second sample 3 to 6 hours later. Reinfarction is diagnosed if there is an increase of greater than 20% in the second sample.⁶ Traditionally, CK-MB has been used to assess for reinfarction; however, there is increasing evidence that troponin values yield similar information.³¹ The ECG diagnosis of reinfarction should be considered when ST segment elevation of 0.1 mV or more occurs in a patient previously having a lesser degree of ST segment elevation, or if there is the development of new pathognomonic Q waves, in at least two contiguous leads.⁶ The re-elevation of the ST segments can also be seen in life-threatening myocardial rupture, and should prompt an expeditious evaluation for the complications of acute MI.

Conclusion

The rapid recognition and diagnosis of acute MI is crucial for the institution of therapy to restore perfusion, minimize myocardial damage, and preserve cardiac function. The cardiac biomarkers, particularly troponin, have become the hallmark of acute MI, but must always be interpreted in the context of the clinical scenario, ECG, and applicable imaging technique. Advances in the efficiency and sensitivity of diagnostic modalities will improve cardiovascular care in the future, and maintain the decline in the morbidity and mortality associated with acute MI that has marked the last 30 years.⁴⁸

Inferior Myocardial Infarction
Right Ventricle Myocardial Infarction
Anterior Myocardial Infarction

Left Main Occlusion
Diagnosis in Bundle Branch Block

Inferior Myocardial Infarction

In 80% of cases, the culprit vessel in inferior myocardial infarction (MI) is the right coronary artery. The circumflex artery is the culprit vessel in all other cases, with the rare exception of a distally extending inferoapical “wraparound” left anterior descending artery, which is suggested when there is concomitant ST segment elevation in the precordial leads.¹ ST segment elevation in lead III that exceeds the magnitude of elevation in lead II with reciprocating ST segment depressions in I and aVL of greater than 1 mm strongly suggests the right coronary artery as the culprit over the circumflex artery. The ST segment vector is directed toward the right when the right coronary artery is involved, which accounts for the elevation in lead III greater than lead II (Fig. 11-1). The added findings of electrocardiogram

(ECG) evidence of right ventricle MI increases the specificity for the right coronary artery, and localizes the occlusion to a proximal location.²

Conversely, the circumflex artery is suggested when ST segment elevation in lead III is not greater than lead II, and by the absence of ST segment depression in leads I and aVL.³⁻⁵ An isoelectric or depressed ST segment with a negative T wave in lead V_{4R} is very specific, but insensitive for proximal circumflex artery occlusion.^{6,7} ST segment depression in leads V₁ and V₂ has been reported to be specific for the circumflex artery, although a dominant right coronary artery can produce similar findings. The presence of ST depression in leads V₁ and V₂ with a prominent R wave in lead V₂ can be nonspecific and can suggest involvement of the left ventricular posterior wall or

Figure 11-1. Inferior ST elevation myocardial infarction. Elevation in lead III is greater than II and ST depressions in leads I and aVL indicate the right coronary artery as the culprit vessel. Note the posterior injury current and the presence of complete heart block. Elevation in aVR suggests concomitant right ventricular infarction due to occlusion proximal to the RV marginal branches.

concomitant disease in the left anterior descending artery. Performing an ECG with posterior leads (V₇-V₉) can show a primary posterior wall injury pattern with ST segment elevation. A localization schema for inferior MI is summarized in Table 11-1.

Right Ventricle Myocardial Infarction

In the setting of inferior MI, right-sided precordial lead recordings are strongly indicated. The presence of right ventricular involvement portends a worse prognosis and enables the clinician to identify a subgroup of inferior MI with a propensity toward hemodynamic instability and shock leading to increased in-hospital mortality.⁸ Right ventricle MI is always associated with a proximal occlusion of the right coronary artery, before the takeoff of the right ventricular marginal branches. The most sensitive sign is 1 mm of ST segment elevation in lead V_{4R}.⁹ This sign is not fully specific for right ventricle MI, however, because this can be seen in acute pulmonary embolus, anteroseptal MI, and pericarditis. ST segment elevation in lead V₁ in association with elevation in leads II, III, and aV_F is highly correlated with the presence of right ventricular infarction.^{2,10} Isolated right ventricle infarction, although rare, can be easily confused with anterior wall infarction, owing to the anterior location of the right ventricle, with ST segment elevation manifest only in the early precordial leads (V₁-V₃).¹¹

Table 11-1. Inferior Myocardial Infarction: ST Segment Elevation II, III, aV_F

Right Coronary Artery	Circumflex Artery
ST segment elevation III > II	ST segment elevation II ≥ III
ST segment depression >1 mm I, aV _L	ST segment elevation I, aV _L , V ₅ -V ₆
ST segment elevation V _{4R} Or V ₁	ST segment depression V _{4R}

Anterior Myocardial Infarction

In acute anterior MI, ST segment elevation is present in the precordial leads. The challenge in anterior wall MIs lies in identifying the site of occlusion within the vessel in relation to the septal and diagonal branches. In very proximal left anterior descending artery occlusion, before the first septal and diagonal branches, the ST segment is elevated in leads V₁-V₃ and aV_L, with ST segment depression in aV_F.^{12,13} The ST segment deviation vector points toward the base of the heart, and ST segment elevation can be seen in aV_R and aV_L. ST segment elevation exceeding 2.5 mm in V₁ is also highly correlated with occlusion proximal to the first septal branch.¹⁴ Acquired right bundle branch block with a Q wave is an insensitive, but extremely specific marker of proximal occlusion of the left anterior descending artery because the septal perforators supply blood to the right bundle (Fig. 11-2). ST segment elevation in leads V₁-V₃ with elevation in the inferior leads suggests occlusion distal to the origin of the first diagonal branch.¹³ In addition, if aV_L is elevated, it suggests an occlusion distal to the septal branch, but proximal to the diagonal branch. If aV_L is depressed, it suggests an occlusion distal to the diagonal branch, but proximal to the septal branch.¹⁵ In distal left anterior descending artery occlusions, ST segment elevation is seen in leads V₃-V₆ and in the inferior leads. A localization schema for anterior MI is summarized in Table 11-2.

Left Main Occlusion

When the left main coronary artery is occluded, ischemia occurs in the left anterior descending artery and circumflex artery. This ischemia results in an ST segment deviation vector that points toward aV_R. ST segment elevation in aV_R and lead V₁ is frequently present, and there is higher specificity for left main occlusion when aV_R elevation is greater than V₁.¹⁶ With the exception of aV_R and V₁, there is marked precordial and

Figure 11-2. Anterior ST elevation myocardial infarction. Occlusion of the proximal left anterior descending artery is indicated by the presence of diffuse precordial ST elevations and right bundle branch block pattern. There is elevation in the II, III, and aV_F because the distal portion of the vessel wraps around the apex to supply the inferior wall.

Table 11-2. Anterior Myocardial Infarction: ST Segment Elevation V ₁ -V ₃		
Left Main Artery	Proximal Left Anterior Descending Artery	Distal Left Anterior Descending Artery
ST segment elevation aVR > V ₁	ST segment elevation V ₁ (>2.5 mm)	ST segment elevation II, III, aVF
Global ST segment depressions	New right bundle branch block	ST segment depression II, III, aVF

Figure 11-3. Left main coronary artery occlusion. Elevation in aVR and V1 with global ST depressions.

inferior ST segment depression, reflecting posterior and basal wall ischemia (Fig. 11-3).

Diagnosis in Bundle Branch Block

Bundle branch block is present on the initial ECG in approximately 7% of patients presenting with acute MI.¹⁷ Ischemia can be difficult to interpret in right and left bundle branch block because of the delayed depolarization and abnormal repolarization of the corresponding ventricle, and its attendant secondary ST segment changes. In the setting of STEMI, primary ST segment elevations in the precordium and new Q waves are fairly specific in the presence of right bundle branch block.

More challenging is the interpretation of acute MI in the setting of left bundle branch block, which also causes secondary ST segment repolarization changes. Because there is delay in the left ventricular activation in native left bundle branch block or iatrogenic right ventricular pacing, Q waves cannot be used to diagnose infarction. Prominent notching greater than 50 ms in the QRS can indicate prior infarction, however. Two signs are extremely insensitive but have specificity approaching 85% for prior MI in the setting of left bundle branch block. Cabrera sign refers to prominent notching in the ascending limb of the S wave in leads V₃-V₅. A similar finding with prominent notching of the ascending limb of the R wave in lead I, aVL, or V₆ is called Chapman sign.^{18,19}

Based on the GUSTO-1 trial, the Sgarbossa criteria²⁰ were proposed to improve specificity for diagnosis of acute MI in the setting of left bundle branch block. Primary ST segment elevation, 1 mm concordant with the major QRS vector, was given a score of 5, and discordant 5-mm ST segment elevations were assigned a score of 2. ST segment depressions greater than 1 mm in leads V₁-V₃ were given a score of 3. A score of at least 3 was 90% specific for the diagnosis of MI. Discordant 5-mm ST segment elevations were the most specific in pace-induced left bundle branch block.²¹

Conclusion

Historical Perspective

Thrombosis was implicated as the cause of acute myocardial infarction (MI) almost a century ago.¹ The pathophysiology remained obscure, however, and as recently as 35 years ago most investigators believed that thrombosis was a secondary event.² Clarity followed demonstrations by Chazov and colleagues³ and later Rentrop and coworkers,⁴ who showed angiographically that recanalization was achievable pharmacologically with favorable electrocardiographic (ECG) and clinical consequences. It then became progressively clear that ischemic injury could be attenuated by restoration of myocardial perfusion.⁵

Underlying this rapid paradigm shift was a hypothesis formulated by Braunwald that MI evolves dynamically, that the magnitude of irreversible injury sustained is related to the duration of ischemia, and that the clinical consequences of infarction are largely a reflection of the extent of irreversible injury sustained.⁶ It was postulated that reduction of myocardial oxygen requirements, enhancement of myocardial perfusion, or both when implemented within the first few hours after the onset of myocardial ischemia would mitigate the magnitude of irreversible injury sustained by the myocardium and would improve prognosis. Against this backdrop, the value of induction of reperfusion with pharmacologic agents, percutaneous coronary intervention (PCI), or both ultimately became established and resulted in marked improvements in prognosis. Before this paradigm shift had occurred, early (30-day) mortality from acute ST segment elevation myocardial infarction (STEMI) was greater than 30%. Presently, 30-day mortality is 7%, largely as a

result of reliance on early reperfusion as the linchpin of therapy. This chapter addresses the developments responsible for this profound improvement in survival.

Coronary Occlusion and Reperfusion of Myocardium: Fibrinolysis and the Development of Fundamental Concepts Underlying Treatment

MI remains the leading cause of death in much of the Western world.⁷ Benefit attributable to reduction in myocardial oxygen requirements is modest. Early administration of intravenous β blockers elicited variable and limited reduction in mortality,⁸⁻¹¹ perhaps, although inconsistently, attributable to reduction in infarct size.¹²⁻¹⁴ These observations are consistent with subsequent observations made in the COMMIT Trial,¹⁵ which showed reductions in the incidences of reinfarction and ventricular arrhythmia, but an increased incidence of cardiogenic shock. Beneficial effects of intravenous nitrates were seen with meta-analyses,¹⁶ but often not in individual trials. Before reperfusion became a mainstay of treatment, hospital mortality after acute MI was almost fourfold greater than it is today.^{17,18}

The duration of coronary occlusion was shown to be a determinant of the extent of myocardial damage in laboratory animals in 1941.¹⁹ In the 1970s, it became clear that infarct size was a major determinant of prognosis.^{20,21} This discovery and the subsequent proof that coronary artery thrombosis was often the

Figure 12-1. Frequency of total coronary occlusion in patients with acute transmural myocardial infarction undergoing angiography at discrete time intervals after the onset of symptoms. There is a significant decrease in the incidence of total coronary occlusion over time: 0 to 4 hours compared with 6 to 12 hours ($P < .05$) and with 12 to 24 hours ($P < .01$). (From DeWood MA, Spores J, Notske R, et al: Prevalence of total coronary occlusion during the early hours of transmural myocardial infarction. *N Engl J Med* 1980;303:899.)

precipitating cause of infarction led to a focus on restoration of blood flow through the infarct-related artery with plasminogen activators.

Coronary Thrombosis and the Pathogenesis of Acute Myocardial Infarction

Although plaque rupture followed by coronary thrombosis is known to precipitate acute MI,^{22,23} its role has been debated extensively. Early autopsy studies of patients who died suddenly failed to show a high incidence of coronary thrombotic occlusion, perhaps because of antemortem or postmortem fibrinolysis. Although Herrick¹ attributed fatal acute MI to a thrombotically occluded coronary artery in 1912, and plaque fissuring was implicated as causal in 1966,²⁴ autopsy studies in the late 1970s did not show preponderant coronary thrombosis in patients who had died of acute MI.^{2,25} These studies led to the speculation that coronary thrombosis was a consequence, rather than the underlying cause, of acute MI.²⁵

In 1980, DeWood and colleagues²⁶ reported the results of coronary angiography performed early after the onset of acute transmural MI. This pivotal study showed a high prevalence of total and subtotal coronary occlusion, particularly within the first 4 hours after the onset of symptoms. The study also showed a high incidence of spontaneous recanalization over time. Within 4 hours of symptom onset, 87% of infarct-obstructed arteries were completely occluded. The prevalence of coronary occlusion was only 65%, however, 12 to 24 hours after onset (Fig. 12-1). When patients with subtotal occlusion of the obstructed artery were included, the prevalence of angiographically demonstrable coronary thrombosis in the first 4 hours was 98%. Angiographic data from a smaller number of patients confirmed that thrombi are almost universally prevalent at the time of occurrence of acute STEMI.²⁷

Efforts to reduce mortality soon focused on rapid restoration of blood flow in thrombotically occluded coronary arteries. It became clear that dissolution of clots postmortem²⁸ explained the failure of earlier autopsy studies to detect the high prevalence of thrombi in victims of sudden cardiac death after acute MI. It is now known that the use of plasminogen activators can reduce early hospital mortality of patients with acute MI to 2% to 6% when early administration and optimal dosing of clot-selective agents are employed.²⁹⁻³¹

Coronary Thrombolytic Agents: Proving the Value of Reperfusion

The maintenance of fluidity of blood depends on a complex balance between thrombosis, thrombolysis, and counter-regulation by inhibition of both processes. In vessels supplying regions of the heart undergoing acute MI, the rupture or fissuring of an underlying atherosclerotic plaque leads to thrombosis with exposure of the blood to the procoagulant effects of exposed type I collagen, von Willebrand factor, and tissue factor in the vessel wall. Activation of platelets accompanying the vascular injury accelerates ongoing thrombosis.^{32,33} Thrombin and fibrin generated by the coagulation cascade may undergo concomitant or subsequent lysis resulting from activation of the fibrinolytic system and conversion of the zymogen plasminogen to the active serine protease, plasmin, by the circulating plasminogen activators, tissue plasminogen activator (t-PA) or urokinase plasminogen activator (UK). These key components of the fibrinolytic system had been identified by 1950,^{28,34} well before acceptance of coronary thrombosis as the crucial step leading to transmural MI.

Circulating plasminogen is activated endogenously by t-PA and UK, resulting in the generation of plasmin that leads to degradation of fibrin to form soluble fibrin degradation products. Such products, activation peptides, and enzyme inhibitor complexes can be measured quantitatively as markers of fibrinolysis. Examples include fibrinopeptide A, prothrombin 1.2 and other prothrombin fragments, a fragment of the fibrinogen β chain (β 1-42), and complexes of thrombin-antithrombin.³⁵⁻³⁸ A specific degradation product of cross-linked fibrin, a fragment known as D-D dimer, reflects degradation of fibrin associated with fibrinogenolysis accompanying a systemic lytic state seen whenever plasminemia is present.^{39,40} Fibrinolysis is inhibited by circulating α_2 -antiplasmin, an inhibitor of plasmin, and by inhibitors of plasminogen activators in blood, primarily plasminogen activator inhibitor 1 (PAI-1).⁴¹ The fibrinolytic system is shown schematically in Figure 12-2.

Simultaneous thrombosis and thrombolysis influences the dynamic impact of thrombotic coronary occlusion. Any strategy designed to reduce myocardial damage must enhance the rapidity and extent of recanalization and promote sustained patency. Exogenously administered plasminogen activators require “conjunctive” measures to ensure that clot lysis is prompt and not retarded or reversed by thrombosis.

Plasminogen activators can paradoxically promote thrombosis. First-generation plasminogen activators, agents that are not fibrin-selective or clot-selective, such as streptokinase (SK), UK, and anisoylated plasminogen activator complex (APSAC), convert circulating and clot-bound plasminogen indiscriminantly

Figure 12-2. Regulation of the plasma fibrinolytic system.
(From Collen D: *Towards improved thrombolytic therapy*. *Lancet* 1993;342:34.)

to plasmin. Rapid depletion of plasma α_2 -antiplasmin occurs with plasminemia, which may generate thrombin from precursors and activation of the coagulation cascade.^{42,43} Procoagulant effects of plasminemia reflect activation of the so-called extrinsic and intrinsic coagulation pathways.⁴⁴⁻⁴⁶ The thrombin activity induced may activate platelets and lead to reocclusion after initially successful clot lysis.⁴⁷ Plasminemia also can lead to a phenomenon we have called plasminogen steal, in which conversion of circulating plasminogen to plasmin induces a leaching of fibrin-associated plasminogen into blood through mass action.⁴⁸ The consequent reduction in clot-associated plasminogen diminishes the intensity of fibrinolysis and reduces the efficacy of plasminogen activators.

Thrombolytic Agents

The available thrombolytic agents are plasminogen activators. These agents function as proteases that directly or indirectly hydrolyze a single peptide bond (Arg⁵⁶¹Val⁵⁶²) on the inactive substrate molecule, plasminogen, to form the active serine protease enzyme, plasmin. Plasmin is responsible for the degradation of fibrin and diverse other proteins, with consequent dissolution of intravascular thrombi. So-called first-generation agents (non-fibrin-selective) include SK, UK, and APSAC. Second-generation and later generation (fibrin-selective) agents include t-PA, single-chain urokinase-type plasminogen activator (scu-PA), staphylokinase, and others, including molecular variants of t-PA such as TNK t-PA (tenecteplase). Agents that are relatively fibrin-specific, such as t-PA, produce less depletion of fibrinogen, less plasminemia, and less depletion of α_2 -antiplasmin than that seen with non-fibrin-specific agents such as SK. Fibrin-bound plasmin generated by clot-selective agents is not susceptible to rapid inhibition by α_2 -antiplasmin in the blood, in contrast to the circulating free plasmin that is neutralized promptly until α_2 -antiplasmin is depleted.²⁸ Table 12-1 summarizes the nomenclature, classification, and mechanism of action of several agents.

Non-Fibrin-Selective Agents

Streptokinase

SK is a protein present in numerous strains of hemolytic streptococci. It is a single-chain polypeptide that lacks the serine residue required for enzymatic activity, but it can activate plasminogen indirectly through an intricate, three-step process.^{49,50} Initially, SK forms an equimolar complex with plasminogen, resulting in exposure of the active site on the plasminogen molecule, which leads to the enzymatic conversion of plasminogen to plasmin by the exposed active site. The plasminogen-SK complex is converted to various, differentially cleaved plasmin-SK complexes,⁵¹ some of which are less active or more rapidly cleared than the SK-plasminogen complex, but can still convert plasminogen to plasmin.⁵²

Because SK is not fibrin-selective, extensive conversion of circulating plasminogen to plasmin occurs with subsequent depletion of fibrinogen, plasminogen, and factors V and VIII from the bloodstream. The accumulation of by-products of fibrinogen breakdown products, depletion of circulating α_2 -antiplasmin, and hyperplasminemia that occur constitute a systemic lytic state. A systemic lytic state occurs with all therapeutically effective doses of non-fibrin-selective plasminogen activators given intravenously. It is less intense with low-dose intracoronary administration.⁵³

The circulating half-life of SK is approximately 18 to 25 minutes. Depletion of fibrinogen to less than 50% of baseline values persists for approximately 24 hours, however. Because of the foreign nature of the protein and the near-universal human exposure to the bacterial sources of the agent (beta-hemolytic streptococci), administration of SK is complicated by inhibition of the administered drug by circulating IgG antibodies and problems of immunogenicity and attendant allergic reactions. In most humans, approximately 350,000 U of SK is necessary to neutralize circulating antibodies, but the range varies widely.⁵⁰⁻⁵⁴ With the conventional clinical dose of 1.5 million U, pretreatment circulating antibody levels do not correlate with subsequent patency rates or clinical outcome.⁵⁵

After administration of SK, anti-SK titers rise quickly and are virtually universally elevated within 5 days, remaining above baseline for 30 months.^{56,57} Consequently, repeated administration of SK is impractical and is not recommended.

The unfavorable profile of adverse reactions associated with SK (presumably attributable to plasmin-mediated activation of kininogen) limits clinical use of this agent to some extent. The overall incidence of hypotension ranges from 10% to 40%.^{50,58} It is highest with rapid infusion.⁵⁹ Severe hypotension requiring pressor agents or fluids occurs in 5% to 10% of patients. Other allergic reactions reported include fever, chills, urticaria, rash, flushing, and muscle pain. In the large-scale ISIS-2 and GUSTO-I trials, the incidence of minor allergic reactions was 4% to 6%.^{30,60} The incidence of anaphylactic shock is low, occurring in 0.7% of patients in GUSTO-I.³⁰

The conventional dose of SK is 1.5 million U administered over 1 hour by intravenous infusion. This regimen was described in 1983,⁶¹ and was used successfully in the GISSI-1 trial in 1986.⁶² More rapid administration can lead to a high incidence of hypotension and should be avoided.

Anisoylated Plasminogen Streptokinase Activator Complex

APSAC is a first-generation plasminogen activator that is a complex of human Lys-plasminogen and SK, with acylation of the plasminogen designed to block the active site until deacylation

Table 12-1. Classification and Characteristics of Plasminogen Activators

Agent	Other Names	Approximate Half-life	Intravenous Dose	Advantages and Disadvantages
First Generation				
Streptokinase	SK	18-25 min	1.5 million U over 1 hr	Not clot selective; immunogenic; reduced patency rates; inexpensive
Urokinase	UK, two-chain urokinase-type plasminogen activator (tCU-PA)	15 min	1.5 million U bolus, then 1.5 million U over 90 min	Not clot selective; nonimmunogenic; patency similar to SK; expensive
Anisoylated plasminogen streptokinase activator complex	APSAC, Anistreplase, Eminase	100 min	30 U bolus	Easy bolus administration; weak clot selectivity; expensive
Second Generation				
Tissue-type plasminogen activator		5 min	15 mg bolus, then 50 mg in first 30 min, then 35 mg in next 60 min	Clot selective; nonimmunogenic; superior patency rates; expensive
One chain	rt-PA, Alteplase, Activase, Actilyse			
Two chain	t-PA, Duteplase			
Single-chain urokinase-type plasminogen activator	SCU-PA, Prourokinase, Saruplase	5 min	20 mg bolus, then 60 mg over 1 hr	Relative clot selectivity
Staphylokinase	STA (bacterial origin)	1-2 min	10 mg over 30 min	Clot selective; may be immunogenic
	STAR (recombinant)			No large clinical trials
Third Generation*				
Vampire bat–plasminogen activator (Bat-PA)				
Mutants: domain deletion or substitution (rt-PA-TNK, r-PA)				
Chimeric plasminogen activators				
Antibody-targeted plasminogen activators				

*Further characteristics not provided because of limited experience in humans.

occurs slowly in vivo.⁵⁰ It is administered by intravenous bolus injection.⁶³ Deacylation occurs in the circulation, but the complex manifests no fibrin specificity.⁶⁴ Its half-life in the circulation is approximately 100 minutes. Because SK is the major component of APSAC, the drug is immunogenic and has a side-effect profile similar to that for SK. Similar induction of anti-SK antibodies⁵⁶ occurs, precluding repeated administration. Its fibrinolytic properties are virtually identical to the fibrinolytic properties of SK. The recommended dose in patients with acute MI is 30 U, given as an intravenous bolus. The nadir in plasma fibrinogen and α_2 -antiplasmin is comparable to that seen with 1.5 million U of SK.⁵⁰

Urokinase

UK, an endogenous trypsin-like enzyme, is a direct plasminogen activator. It is present in urine and occurs in two forms in blood and tissue: a high-molecular-weight form and a

low-molecular-weight form.⁶⁵ Its precursor is scu-PA, which is enzymatically inactive. Cleavage of scu-PA by plasmin yields high-molecular-weight UK, a two-chain, disulfide-linked molecule that lacks fibrin specificity and indiscriminantly activates circulating and fibrin-bound plasminogen, with associated depletion of α_2 -antiplasmin. It degrades fibrinogen and other plasma proteins and induces a systemic lytic state comparable to that seen with SK.

UK has a plasma half-life of approximately 15 minutes. Primary clearance is in the liver, with a small fraction (3% to 5%) cleared by the kidney.⁵⁴ UK has been used commonly in patients undergoing interventional procedures for coronary or peripheral vascular disease and in patients with pulmonary embolism. It is nonimmunogenic and can be administered as an intravenous bolus⁶⁶ or by infusion. The recommended dose for acute MI is a bolus of 1.5 million U followed by 1.5 million U given over 90 minutes.

Relatively Fibrin-Selective Agents

Tissue Plasminogen Activator

t-PA is an endogenous serine protease synthesized and secreted by human vascular endothelium and numerous other types of cells. When t-PA was isolated from a human (Bowes) melanoma cell line,⁶⁷ definitive evaluation of its biochemical and pharmaceutical features became possible. It was first given to patients with acute MI in 1984.⁶⁸ The cloning and expression of the human t-PA gene in *Escherichia coli* in 1983 by Pennica and colleagues⁶⁹ and the development of recombinant t-PA led to administration of t-PA to patients.⁷⁰

The plasma half-life of t-PA is only 5 minutes. Fibrinolytic activity persists on and within clots for 7 hours, however.⁷¹ t-PA is metabolized by the liver. It is inhibited in plasma by PAI-1 and other inhibitors. PAI-1, the “fast-acting inhibitor,” was characterized in the early 1980s.⁷²⁻⁷⁴ Infused t-PA rapidly saturates circulating PAI-1, and subsequently, circulating free t-PA complexes more slowly with inhibitors such as C-1 esterase inhibitor and α_2 -antiplasmin.^{74,75}

An important advantage of t-PA compared with SK is its affinity for fibrin-bound plasminogen through sites in the NH₂-terminal (heavy) chain.⁵⁰ In the absence of fibrin, t-PA is a weak activator of plasminogen. When fibrin is present, however, activation of plasminogen associated with it is rapid and intense. Clinically, conventional doses of t-PA induce some degradation of circulating fibrinogen (to approximately 50% of baseline) and some elevation of concentrations of fibrinogen degradation products. The relative fibrin specificity of t-PA accounts for the more rapid clot lysis seen with t-PA compared with SK.⁷⁶ Because the specificity for fibrin is not absolute, however, doses used clinically elicit degradation of circulating fibrinogen, albeit less than that seen with SK.⁷⁷

In contrast to SK, t-PA is not associated with immunogenicity. Its modest effects on circulating plasminogen do not lead to the degree of hyperplasminemia seen with non-fibrin-specific agents such as SK, and the overall risk of hemorrhage is less.

t-PA is available commercially as alteplase, which is primarily single-chain t-PA. Duteplase, a primarily double-chain t-PA with a different primary structure and different properties, was used in the ISIS-3 study, but is not commercially available. The two agents differ considerably with respect to risk of toxicity and probably differ in therapeutic efficacy.^{50,78-80}

In early clinical trials, the intravenous dose of t-PA was 60 mg in the first hour, with an initial 6-mg bolus, followed by 20 mg/hr for the next 2 hours. The total dose, 100 mg, was selected in part because higher doses had been associated with intracerebral hemorrhage (1.9% incidence with 150 mg administered over 3 hours).⁸¹ Neuhaus and coworkers⁸² introduced “front-loaded” dosing (i.e., 15-mg bolus with 50 mg given by infusion over the first 30 minutes, followed by 35 mg over the next 60 minutes). This regimen was associated with a 91% patency rate at 90 minutes, and it has now been approved by the U.S. Food and Drug Administration.

Third-Generation Fibrinolytic Agents

Numerous agents, sometimes referred to as third-generation agents, are designed to modify pharmacokinetics. Modifications are designed to prolong the half-life, increase fibrinolytic activity, increase fibrin selectivity, or exhibit other potentially advantageous properties. Deletion and substitution

mutants of naturally occurring plasminogen activators, chimeric activators (i.e., with components of UK and t-PA), and molecules containing homing antibodies to fibrin or platelet domains and receptors are being explored. Some examples follow.

Staphylokinase

The profibrinolytic properties of staphylokinase, a protein elaborated by strains of *Staphylococcus aureus*, have been recognized for more than 40 years.⁸³ Results in early studies in animals were not promising,^{84,85} and enthusiasm for this agent soon waned. A recombinant DNA-synthesized variety (STAR) has been developed. Compared with SK, it is more powerful and fibrin selective.⁸⁶ STAR, similar to SK, is not an enzyme. It forms an active proteolytic complex in 1:1 stoichiometry with plasminogen. Although immunogenic, it is a remarkably fibrin-selective fibrinolytic agent.⁸⁷ Its thrombolytic potency with platelet-rich arterial thrombi is impressive.⁸⁸ Compared with SK, STAR induces more frequent and more persistent arterial recanalization. In a pilot study, Collen and Van de Werf⁸⁹ showed successful coronary recanalization in four of five patients with evolving acute MI with 10 mg of intravenous recombinant staphylokinase. Plasma fibrinogen and α_2 -antiplasmin were not significantly decreased, and allergic reactions did not occur. Neutralizing antibodies to STAR were detected in plasma consistently within 14 to 35 days, however. Variants with less immunogenicity are being pursued (2004 D Collen, personal communication).

Tissue Plasminogen Activator Mutants

Hundreds of deletion, insertion, substitution, and combination mutants of wild-type t-PA have been synthesized. One, reteplase, initially called r-PA (also known as BM 06.022), has been studied in clinical trials and marketed as Retavase. Reteplase lacks the kringle 1 domain, resulting in a prolonged half-life and facilitating bolus administration.⁹⁰ It induces coronary recanalization rapidly in dogs,⁹¹ and has elicited early vessel patency in initial clinical studies. Early reocclusion has been encountered, however, implying the potential need for a double-bolus dosing regimen.^{92,93} It is not as fibrin-selective as wild-type t-PA.

Mutants of t-PA with prolonged half-lives have often exhibited reduced thrombolytic efficacy.⁹⁴ Generally, they have not seemed to be superior to wild-type t-PA.⁹⁵ One exception is a so-called triple mutant of t-PA, referred to as TNK t-PA (tenecteplase).⁹⁵ The acronym refers to the three amino acid substitutions that differentiate TNK t-PA from wild-type t-PA. They result in reduced inhibition of the plasminogen activator by PAI-1, prolongation of half life as a result of decreased uptake by the reticuloendothelial system mediated by mannose receptors, and consequent efficacy after bolus injection. TNK t-PA seems to induce reperfusion more rapidly than t-PA in patients treated within 3 hours after onset of symptoms.⁹⁶

Mortality Benefit of Pharmacologic Reperfusion: Clinical Trials of Coronary Thrombolysis

Early Observations

Recanalization trials performed in the late 1970s and early 1980s provided vital information by angiographically documenting relief of thrombotic coronary occlusion induced by

Figure 12-3. Recanalization rates from the TIMI phase I trial. At 90 minutes, recanalization with recombinant tissue plasminogen activator (rt-PA) is twice that seen with streptokinase (SK). (From Chesebro JH, Knatterud G, Roberts R, et al: *Thrombolysis In Myocardial Infarction (TIMI) trial, phase I: a comparison between intravenous tissue plasminogen activator and intravenous streptokinase*. *Circulation* 1987;76:143.)

plasminogen activators. Initially, coronary thrombolysis was performed with intracoronary administration of plasminogen activators. This approach showed the feasibility of clot lysis and induction of recanalization.^{3,4} Rentrop and colleagues,^{97,98} using intracoronary SK, showed improved cardiac function and alleviation of chest pain accompanying recanalization compared with intracoronary nitroglycerin alone or conventional therapy. The Western Washington randomized trial⁹⁹ substantiated the efficacy of intracoronary SK in lysing coronary thrombi, with favorable effects on mortality. High rates of recanalization with intravenously administered t-PA were observed soon thereafter.^{68,100,101}

Intracoronary administration of SK seemed to be more capable of inducing prompt recanalization than SK administered intravenously.¹⁰² Logistic constraints on the availability of immediate cardiac catheterization, time delays, increased costs, and increased risk limited enthusiasm, however, for intracoronary administration of plasminogen activators as primary therapy for patients with acute MI. The appeal of the intravenous route was considerable. Nevertheless, observations in a study in which intracoronary SK was administered after PCI and stenting with apparently increased myocardial perfusion compared with the perfusion seen in the absence of SK may rekindle interest in the intracoronary administration of fibrinolytic drugs.¹⁰³

The TIMI phase I trial compared intravenous t-PA (80 mg over 3 hours) with intravenous SK (1.5 million U over 1 hour).¹⁰⁴ After 90 minutes, twice as many occluded arteries had been opened by t-PA (62%) as by SK (31%) (Fig. 12-3). The superiority of t-PA was evident, regardless of the interval between symptom onset and treatment. t-PA induced more rapid and more frequent clot lysis in the infarct-affected artery.

Patency Trials

Patency trials delineate angiographically defined patency at specified intervals after treatment. Prompt treatment seemed to maximize benefit in the multicenter GISSI-1 mortality trial in 1986.⁶² Patency trials are characterized by an unavoidable lack

of certainty, however, regarding the actual incidence of thrombotic occlusion before therapy, and the inclusion of patients with spontaneous thrombolysis. Nevertheless, such trials were helpful in comparing diverse agents with respect to overall patency. Angiography was required because noninvasive criteria of reperfusion, including relief of chest pain, ECG changes, early washout of enzymes, and arrhythmias, did not reflect actual incidences of recanalization.¹⁰⁵

It soon became clear that the extent and persistence of restoration of flow required to salvage ischemic myocardium were pivotal. Angiographic classifications based on the transit of contrast media through an infarct-related occluded vessel after treatment with plasminogen activators provided useful indices. One set of criteria employed frequently was established in the TIMI phase I trial in 1985 (Table 12-2).¹⁰⁶ It classified coronary flow from TIMI grade 0 (no flow) to TIMI grade 3 (brisk flow of contrast material). TIMI grade 1 (minimal flow of contrast material) and TIMI grade 2 (delayed flow of contrast material) were seen in patients with residual stenosis, coronary vasospasm, ongoing thrombosis, and the no-reflow phenomenon, in which forward flow is restricted, despite a patent vessel, by microvascular stasis downstream as a result of leukocyte and platelet plugging, vasoconstriction, or tissue and cellular edema.

Myocardial contrast echocardiography has been used also to assess the adequacy of restored perfusion. In 39 patients with acute anterior MI in whom recanalization was induced by percutaneous transluminal coronary angioplasty (PTCA) or thrombolysis, subsequent delivery of microbubbles into the coronary circulation followed by two-dimensional surface echocardiography identified nine patients in whom microcirculatory reflow was absent despite coronary patency.¹⁰⁷ Compared with the remainder of the study group, these patients exhibited significantly reduced segmental and global left ventricular function indicative of suboptimal myocardial salvage.

Most early patency trials employed angiographic end points to delineate patency 90 minutes after the administration of a thrombolytic agent. Patients with TIMI grade 2 or TIMI grade 3 were considered together in delineating overall patency incidence. Even when no thrombolytic agent is given, patency rates range from 9% to 29% in the 0- to 90-minute interval.^{100,104,108-112} Considerable “catch up” occurs (i.e., patency attributable to endogenous fibrinolysis), as judged from results of arteriography performed later. Patency rates range from 36%¹¹³ to 78%¹¹⁴ 3 to 21 days after MI in patients not treated with plasminogen activators.^{115,116}

Despite the higher patency rates seen with t-PA compared with SK, results of early megatrials (GISSI-1, ISIS-2)^{60,62} comparing the two agents did not show differences in mortality. The apparent lack of coupling between patency and mortality in these early trials fueled speculation that benefits did not depend on early opening of an infarct-occluded artery, regardless of how quickly coronary recanalization was achieved. Although an infarct-related occluded artery rendered patent late may confer some benefits unrelated to salvage of jeopardized myocardium, such as altered ventricular remodeling and improved electrical stability,^{117,118} the reduction of mortality of patients treated with thrombolytic agents depends primarily on the rapidity and persistence of recanalization. A striking 50% reduction in mortality rates occurred for patients treated within 1 hour of symptom onset in the GISSI-1⁶⁰ and ISIS-2⁶² trials, with the benefit less striking but still evident in patients treated within 3 to

Table 12-2. Angiographic Definitions of Perfusion from the TIMI Phase I Trial

Grade 0 (no perfusion)	There is no antegrade flow beyond the point of occlusion
Grade 1 (penetration without perfusion)	Contrast material passes beyond area of obstruction, but “hangs up” and fails to opacify the entire coronary bed distal to the obstruction for the duration of the cineangiographic filming sequence
Grade 2 (partial perfusion)	Contrast material passes across the obstruction and opacifies the coronary bed distal to the obstruction. Rate of entry of contrast material into the vessel distal to the obstruction, its rate of clearance from the distal bed, or both are perceptibly slower than entry into or clearance from comparable areas not perfused by the previously occluded vessel, such as the opposite coronary artery or the coronary bed proximal to the obstruction
Grade 3 (complete perfusion)	Antegrade flow into the bed distal to obstruction occurs as promptly as antegrade flow into the bed proximal to the obstruction, and clearance of contrast material from the involved bed occurs as rapidly as clearance from an uninvolved bed in the same vessel or the opposite artery

From Chesebro JH, Knatterud G, Roberts R, et al: Thrombolysis and Myocardial Infarction (TIMI) trial, phase I: a comparison between intravenous tissue plasminogen activator and intravenous streptokinase. *Circulation* 1987; 76:143.

4 hours. A 1% mortality rate was seen in the MITI project³¹ for patients with documented MI treated with t-PA within 70 minutes of the onset of symptoms. In many patients, no late scintigraphic evidence of irreversible injury was observed, consistent with extensive and perhaps complete myocardial salvage. The failure to recognize the dependence of mortality reduction on early patency in the megatrials previously mentioned probably reflects the late time to treatment (and obviation of benefit) for many patients, and the failure to employ the adequate conjunctive anticoagulation needed to sustain initially induced patency.

The magnitude of restoration of flow seems to be a major determinant of benefit. *Patency* may be an inadequate term to describe the full impact of any given reperfusion therapy: TIMI grade 2 and TIMI grade 3 flow have different implications. Patients with delayed transit of contrast material in the infarct-affected artery (TIMI grade 2 flow) may not be exhibiting optimal or adequate recanalization. The TEAM-2 study analyzed data with respect to flow in patients treated with intravenous APSAC or SK.¹¹⁹ When TIMI flow grades were considered with respect to enzymatic and ECG markers of infarct size, no statistically significant difference was seen for TIMI flow grades 0, 1, or 2. Better outcomes were seen, however, with TIMI grade 3 flow.

In a retrospective analysis of four multicenter German studies (907 patients), TIMI grade 2 flow was associated with a mortality similar to that of patients with persistently infarct-occluded vessels.¹²⁰ The in-hospital mortality rate of patients with TIMI grades 0 and 1 was 7.1%. With TIMI grade 2, it was similar (6.6%). With TIMI grade 3, the mortality rate was significantly lower (2.7%). The GUSTO-I angiographic study provided another comparison. Lack of patency (TIMI grade 0 or 1) was associated with the highest mortality rate (8.9%). Traditionally defined patency (TIMI grades 2 and 3) was associated with a lower mortality rate (5.7%; $P = .004$).¹²¹ The mortality for patients with TIMI grade 2 flow was 7.4%, and even lower (4.4%) for patients with TIMI grade 3 flow ($P = .08$).

Front-loaded regimens of t-PA seem to be superior in terms of induction of TIMI grade 3 flow compared with other agents. The GUSTO-I angiographic trial directly compared SK, t-PA, and the combination of t-PA and SK (Table 12-3).¹²¹ Front-loaded t-PA was associated with complete reperfusion at 90 minutes (TIMI grade 3) in 54% of patients. With SK alone, complete reperfusion occurred in less than 32% of patients (29% with subcutaneous

heparin and 32% with intravenous heparin). In patients given t-PA and SK, reperfusion occurred in 38%. Similar rates of complete reperfusion at 60 minutes had been seen in earlier trials, with patency and TIMI grade 3 flow ranging from 54% to 62%^{29,82,122} with front-loaded t-PA compared with 40% with intravenous APSAC²⁹ and 40% with the standard dose of t-PA.¹²²

Patency trials have consistently shown more rapid and more complete reperfusion of infarct-occluded coronary arteries with the clot-selective agent t-PA than with other agents alone or agents in combination. Enhanced reperfusion coupled with conjunctive anticoagulation and other strategies designed to sustain reperfusion are the pivotal determinants of the efficacy of coronary recanalization in improving survival of patients treated with plasminogen activators.

One straightforward intervention would undoubtedly decrease mortality and increase the efficacy of coronary thrombolysis markedly. Fresh clots lyse much more rapidly than older ones in which fibrin cross-linking has proceeded.¹²³ Intervention within 30 to 60 minutes is likely to be particularly beneficial because more myocardium would remain viable and amenable to salvage, and because clot lysis would be much more rapid and complete. The rapidity with which patients are treated should be maximized. Current American College of Cardiology (ACC)/American Heart Association (AHA) guidelines recommend the “earliest possible application of therapy,” and refer to therapy with fibrinolytic agents in the setting of STEMI with symptoms within 12 hours and ECG changes of 0.1 mV in two contiguous leads or new left bundle branch block as a class 1a recommendation.

Left Ventricular Function and Pharmacologic Induction of Reperfusion

Left ventricular contractile function as an end point in trials of coronary thrombolysis requires exceptionally careful analysis. Early placebo-controlled trials of coronary thrombolysis in which left ventricular ejection fraction was a primary end point showed variable but generally consistent group improvement in left ventricular function and indices of infarct size (e.g., enzymatic, scintigraphic) in patients treated with thrombolytic agents.^{99,114,124-130} Similar results were seen with global and regional measures of ventricular function.^{124,129} Improvement in ejection fraction has generally been greatest in groups of patients with anterior infarction, consistent

Table 12-3. Results of the GUSTO-1 Angiographic Study: Patency and Reocclusion of the Infarct-Occluded Artery According to Treatment Group

Variable	Patients with Feature/Patients Examined (%)			
	Streptokinase + Subcutaneous Heparin	Streptokinase + Intravenous Heparin	Accelerated t-PA	t-PA + Streptokinase
Patency

Reocclusion				
From TIMI grade 2 at 90 min to grade 0 or 1 at follow-up	3/56 (5.4)	6/58 (10.3)	2/64 (3.1)	4/72 (5.6)
From TIMI grade 3 at 90 min to grade 0 or 1 at follow-up	4/54 (7.4)	1/69 (1.4)	9/121 (7.4)	4/92 (4.3)
Overall reocclusion [¶]	7/110 (6.4)	7/127 (5.5)	11/185 (5.9)	8/164 (4.9)

^{*}*P* = .032 for the comparison of this group with the group given t-PA with streptokinase.

[†]*P* < .001 for the comparison of this group with the groups given streptokinase with subcutaneous or intravenous heparin.

[‡]*P* < .001 for the comparison of this group with the group given streptokinase with subcutaneous heparin.

[§]*P* = .032 for the comparison of this group with the group given streptokinase with subcutaneous heparin.

^{**}*P* < .001 for the comparison of this group with the group given t-PA with streptokinase.

[¶]Overall patency rates (TIMI 2 and 3 flow) at 90 minutes and complete reperfusion rates (TIMI 3 flow only) at 90 minutes are superior with the regimen of accelerated t-PA and intravenous heparin, with similar reocclusion rates in all four groups.

t-PA, tissue plasminogen activator.

From GUSTO Angiographic Investigators: The effects of tissue plasminogen activator, streptokinase, or both on coronary artery patency, ventricular function, and survival after acute myocardial infarction. *N Engl J Med* 1993; 329:1618.

with the large amount of left ventricular muscle supplied by the left anterior descending coronary artery. Patients with inferior infarction have shown improved regional and global left ventricular function as well.^{127,131} Analysis of results in the ISAM study indicated that the patency of an infarct-occluded artery at 1 month was associated with good left ventricular function regardless of treatment (active or placebo) and the vessel involved.¹³²

A key observation was made by Van de Werf,¹³³ who recognized that effective thrombolysis enhances survival of patients with severely reduced left ventricular function who would have otherwise died. Lower ejection fractions are observed in the entire group of treated patients. In essence, the low ejection fractions in survivors with severe insults account for the apparent paradox that becomes prominent when large reductions in early mortality are achieved. This paradox has been called the *ventricular function–mortality paradox*. When it is considered along with methodologic limitations, it becomes clear that, contrary to speculation by some authors,¹³⁴ assessment of ventricular

function in groups is an ambiguous end point for comparing different agents or delineating the efficacy of specific conjunctive and adjunctive regimens. Conversely, sequential measurement of regional ventricular function in individual patients provides a more valid measure of benefit conferred by early and sustained recanalization.

Despite such limitations, correlations between patency and improved function have been striking. In more than 1200 patients enrolled in the five phases of the TAMI trials, TIMI grade 2 flow was associated with a higher incidence of recurrent ischemia and congestive heart failure, and with reduced improvement in global and regional left ventricular function compared with TIMI grade 3 flow.¹³⁵ When patients were evaluated according to TIMI flow grades regardless of the treatment used, patients with TIMI grade 3 had more preservation of regional wall motion, lower end-systolic volume indices, and higher left ventricular ejection fraction values than patients with TIMI flow grades 0, 1, and 2 (Table 12-4) as judged from 90-minute and 5- to 7-day angiography. The results are consistent

Table 12-4. Association between Patency Grade and Measures of Left Ventricular Function from the GUSTO Trial

Variable*	TIMI 0	TIMI 1	TIMI 2	TIMI 3
At 90 min	<i>n</i> = 233	<i>n</i> = 84	<i>n</i> = 275	<i>n</i> = 370

^{**}*P* = .034 for the comparison of this group with the groups with TIMI grades 0 and 1.

^{†¶}*P* = .007 for the comparison of this group with the group with TIMI grade 2.

ESVI, end-systolic volume index; RWM, regional wall motion.

From GUSTO Angiographic Investigators: The effects of tissue plasminogen activator, streptokinase, or both on coronary artery patency, ventricular function, and survival after acute myocardial infarction. *N Engl J Med* 1993; 329:1618.

with the fact that myocardial necrosis is virtually complete in 4 to 6 hours.¹¹⁷ The investigators underscore the critical importance of the rapidity and completeness of recanalization.

The TAMI-6 trial evaluated effects of late myocardial reperfusion (6 to 24 hours) induced by thrombolysis with intravenous t-PA (standard dose with a weight-adjusted regimen) or PTCA in patients with acute MI.¹³⁶ Compared with placebo-treated patients, patients subjected to late intervention exhibited no difference in ejection fraction or infarct zone regional wall motion at 1 or 6 months. Compared with t-PA, placebo was associated with a significantly greater end-diastolic volume at 6-month follow-up (*P* = .006). Late thrombolysis or angioplasty exerted no benefit in terms of systolic function despite some prevention of cavity dilation in patients treated with thrombolytic agents. The observations are consistent with the view that early and complete recanalization salvages myocardium, improves systolic function, and reduces mortality.

Pivotal Placebo-Controlled Trials

Results of early, placebo-controlled trials showed consistent reduction of mortality despite differences among them with respect to entry criteria, thrombolytic agents, "conventional care," and adjunctive therapy. In 1986, the landmark GISSI-1⁶² trial showed a reduction in the overall 21-day mortality rate from 13% to 10.7% for 11,806 patients treated with intravenous SK rather than the usual treatment at that time. The trial documented a 47% reduction in mortality rates for patients treated

with SK within 1 hour of symptom onset. Later studies of t-PA (ASSET, ECSG-5) showed analogous mortality reductions compared with placebo.^{114,137} Beneficial effects on survival with APSAC were seen in the AIMS trial,¹³⁸ with a 47% reduction in the 30-day mortality rate for the treatment group leading to early termination of this placebo-controlled trial.

The largest of all the early placebo-controlled trials was ISIS-2.⁶⁰ This trial randomly assigned 17,187 patients with acute MI to treatment with intravenous SK, oral aspirin, both, or neither. The 2 × 2 factorial design substantiated a reduction of mortality for patients treated with SK. The effects of aspirin alone were comparable. In retrospect, it seems clear that aspirin was reducing mortality in a subset of patients with unstable angina lumped with MI patients in this study, which failed to include a qualifying ECG as an entry criterion. The enrollment window from the onset of symptoms was 24 hours. As in GISSI-1, maximal benefit was seen in patients treated early (<4 hours from symptom onset). The smaller reduction in the 5-week mortality for patients treated in the 5- to 24-hour interval (*P* = .004) may have reflected prevention of MI in some patients with unstable angina or misidentification of the time of onset of MI in view of the omission of a qualifying ECG. Mortality reduction for patients treated in the interval 12 to 24 hours after symptom onset was not significant.

Time to treatment has been evaluated in the LATE study, in which 5711 patients presenting with acute MI that occurred 6 to 24 hours earlier were randomly assigned to intravenous t-PA

or placebo.¹³⁹ Treatment within 12 hours of symptom onset was associated with a 26% reduction of mortality for patients given t-PA. In patients treated from 12 to 24 hours, no benefit was evident. The EMERAS¹⁴⁰ study compared intravenous SK with placebo in 4534 patients treated within 6 to 24 hours of symptom onset. In the 12- to 24-hour group, no benefit was shown, but some benefit (not significant) was implicated in the 6- to 12-hour group. This result may have reflected some misclassification of the actual time of onset of infarction or consequences of interruption of stuttering infarcts.

The apparently greater benefit seen with t-PA compared with SK in the LATE and EMERAS trials may reflect more effective lysis by t-PA of aged thrombi. Alternatively, more rapid lysis by t-PA than with SK may be responsible. A meta-analysis of more than 50,000 patients suggested that mortality can be reduced in patients treated within, but not beyond, 12 hours.¹⁴¹ The most compelling evidence indicates that the benefits of fibrinolytic induction of recanalization are minimal if it is not accomplished early, optimally within a few hours after onset of symptoms.

Mortality in Direct Comparison Trials

In 1992, the GISSI-2¹⁴² trial reported no difference in the mortality rates of 12,490 patients treated with intravenous SK compared with standard-dose t-PA (alteplase, single-chain t-PA). In contrast to most smaller trials in the United States, patients were not given protocol-mandated intravenous heparin; patients in the heparin arm were given 12,500 U subcutaneously beginning 12 hours after the onset of infusion of the fibrinolytic drug. The overall mortality of 8.8%, although lower than that seen earlier in GISSI-1, was considerably higher than the mortality rate in the pooled data (5.6%) from numerous trials with t-PA. Neither SK nor t-PA seemed to have been tested under conditions in which benefit could be optimal. The lack of intravenous heparin and the late time to treatment seem to contribute to this phenomenon. ISIS-3¹⁴³ compared SK with t-PA (duteplase, double-chain t-PA) and APSAC in 41,299 patients. As in GISSI-2, ISIS-3 employed subcutaneous heparin (in 50% of the patients) at a dose of 12,500 U begun 4 hours after enrollment. No difference in mortality could be ascribed to any of the strategies. Combined results in the GISSI-2 trial for the overall 35-day mortality rate showed identical, high (10%) values for patients treated with SK and patients treated with t-PA.¹⁴³

Viewed superficially, the results of these megatrials seem to conflict with the results of mechanistic trials that had clearly linked coronary recanalization with improved survival. The lack of adequate anticoagulation seems to be one major factor that contributed to high mortality rates and a lack of difference between t-PA and SK. The subcutaneous heparin regimen used does not lead to adequate anticoagulation in virtually any patient in the first 24 hours because of binding of heparin to endothelial cell binding sites and slow absorption.¹⁴⁴

The need for administration of heparin with t-PA has been underscored by results in HART.¹⁴⁵ The investigators randomly assigned 205 patients with acute MI to treatment with t-PA, aspirin, and intravenous heparin or t-PA and aspirin alone. Although 90-minute patency is the same (79%) with t-PA with and without heparin, as shown in the TAMI-3 trial,¹⁴⁶ the patency rates between 7 hours and 24 hours in HART were 82% in the heparin group and only 52% in the aspirin group ($P < .0001$). A high incidence of reocclusion occurred when heparin was omitted. Analysis of the level of anticoagulation showed that patients

Figure 12-4. Correlation between the level of anticoagulation and patency in the HART trial. Dramatically improved patency rates are seen when recombinant tissue plasminogen activator is combined with sufficient heparin to prolong the activated partial thromboplastin time (aPTT) to greater than 60 seconds. (Hsia J, Kleiman N, Aguirre F, et al; HART Investigators: Heparin-induced prolongation of partial thromboplastin time after thrombolysis: relation to coronary artery patency. *J Am Coll Cardiol* 1992;20:31-35.)

Figure 12-5. Patency trials comparing intravenous recombinant tissue plasminogen activator with and without intravenous heparin. All three trials show improved patency rates with conjunctive heparin. (Data from references 145, 149, and 150.)

with activated partial thromboplastin times (aPTTs) longer than 60 seconds had patency rates of 95%, in contrast to the dramatically lower late patency rate of 45% for patients with aPTTs less than 45 seconds (Fig. 12-4).¹⁴⁷

Analogous results were obtained by the European Cooperative Study Group.¹⁴⁸ The patency rate was higher for patients treated with t-PA and heparin and highest for patients with optimal anticoagulation. The same result was seen by Bleich and colleagues¹⁴⁹ and in the ECSG-6 study.¹⁵⁰ A consistent increase in persistence of coronary patency (from 7 to 120 hours after treatment) in patients undergoing coronary thrombolysis with t-PA accompanied coadministration of heparin, as shown in Figure 12-5. In view of the inadequate rapidity and magnitude of anticoagulation induced by the subcutaneous heparin dosage used in GISSI-2/International trial^{142,151} and ISIS-3,¹⁴³ the high

Table 12-5. Major Clinical Outcomes from the GUSTO-1 Trial

Outcome	Streptokinase + Subcutaneous Heparin (n = 9796)	Streptokinase + Intravenous Heparin (n = 10,377)	Accelerated t-PA + Intravenous Heparin (n = 10,344)*	Both Thrombolytic Agents + Intravenous Heparin (n = 10,323)	P Value, Accelerated t-PA ver- sus Both Streptokinase Groups
Mortality, 24-hr	2.8 [†]	2.9	2.3	2.8	.005
Mortality, 30-day	7.2	7.4	6.3	7.0	.001
Or nonfatal stroke	7.9	8.2	7.2	7.9	.006
Or nonfatal hemor- rhagic stroke	7.4	7.6	6.6	7.4	.004
Or nonfatal dis- abling stroke	7.7	7.9	6.9	7.6	.006

*There are significant reductions in mortality and the combined end point of mortality plus stroke (including intracranial bleeding) seen in the accelerated t-PA group. The outcomes are similar for the other three treatment groups.

mortality rate and lack of fibrinolytic drug-dependent differences in ISIS-3¹⁴³ and the GISSI-2/International trials^{142,151} are probably attributable to a design that led to substandard rates and rapidity of coronary recanalization and to a failure to maintain patency (particularly in the t-PA group), rather than to a lack of dependence of benefit and survival on early recanalization.

Because of allegations regarding the efficacy of combinations of fibrinolytic agents,¹⁵²⁻¹⁵⁴ and the need to delineate the relative merits of conjunctive anticoagulation, the GUSTO-I trial was implemented to compare four different regimens in 41,021 patients: SK with subcutaneous heparin, SK with intravenous heparin, front-loaded (also called accelerated) t-PA with intravenous heparin, and a combination of SK and t-PA with intravenous heparin.³⁰ The 30-day mortality was lowest with front-loaded t-PA and intravenous heparin (6.3%) and significantly less than that with combination therapy (7%), SK and subcutaneous heparin (7.2%), and SK and intravenous heparin (7.4%) (Table 12-5). Reduction of mortality directly depended on the rapidity and adequacy of recanalization.¹²¹ Front-loaded t-PA was associated with fewer allergic reactions, less hypotension, less overall bleeding, and a lower incidence of recurrent ischemia, reinfarction, and diverse cardiac complications than the other regimens.³⁰ The incidence of reocclusion was no higher than that with the other regimens.¹²¹ Overall, front-loaded t-PA led to more rapid and complete recanalization and an increase in the combined end point of survival without a stroke, equivalent to 10 lives saved per 1000 patients treated compared with either SK regimen.

Fibrinolysis, Reperfusion, and the Importance of Early Treatment

The fundamental principle that benefits of coronary thrombolysis directly depend on rapid and sustained induction of infarct-related artery patency implies several considerations for optimizing results.¹⁵⁵ Among these considerations are optimal dosage regimens with highly fibrin-selective agents, novel agents resistant to inhibitors targeted to clots, optimal

antiplatelet and anticoagulant agents and regimens, and coupling later mechanical interventions to thrombolysis in patients with inadequate infarct-occluded artery luminal dimensions. No approach is more important, more powerful, more readily achieved, or more underused than the reduction of the time to treatment after onset of symptoms in patients with early, evolving acute MI. Advantages of this approach include the enhanced myocardial salvage that can be anticipated when recanalization is induced before the bulk of jeopardized ischemic myocardium is blighted,¹⁵⁶ and the increased rapidity and extent of lysis that can be anticipated with fresh clots compared with more mature thrombi already undergoing cross-linking of fibrin¹²³ and consequent occupancy of lysine-binding sites that otherwise serve to bind plasminogen to fibrin.

The MITI phase I pilot study¹⁵⁷ documented an average 73-minute delay from recognition of acute MI (documented by transmission of ECG data by cellular telephone) to in-hospital treatment with coronary thrombolysis, even with highly skilled paramedical personnel. Subsequently, randomized trials were performed to identify the potential benefits of reducing this delay by implementation of prehospital coronary thrombolysis compared with in-hospital treatment.^{31,158,159}

The importance of early treatment with fibrinolytic drugs has led to a European practice of prehospital fibrinolysis. Despite the theoretical appeal of this approach and favorable results with low mortality in several small studies, results of more recent studies of prehospital fibrinolysis without subsequent mandatory PCI compared with primary PCI are not compelling in support of this practice. Examples include the results of the Leipzig study,¹⁶⁰ which showed superiority of primary PCI compared with administration of 50% of conventional doses of TNK combined with abciximab reflected by resolution of ST segment elevation within 90 minutes; results in the SWEDES reperfusion trial,¹⁶¹ in which prehospital administration of lytic agents without mandatory subsequent PCI was shown to be inferior to primary PCI despite a briefer interval between the onset of symptoms and initiation of treatment as reflected by resolution

of ST segment elevation and TIMI flow grade at angiography 5 to 7 days later; and analogous results in a more recent registry study,¹⁶² in which lower 30-day and 1-year mortality was evident in patients treated with primary PCI compared with prehospital lysis without PCI regardless of whether symptoms persisted for less than or more than 2 hours before the onset of treatment, and despite the fact that prehospital lysis led to more favorable results than in-hospital lysis.

The CAPTIM study¹⁶³ did not detect differences in benefit with prehospital lysis compared with primary PCI, but subsequent analysis suggested that prehospital lysis was more favorable, although not significantly ($P = .058$), when performed within 2 hours after onset of symptoms compared with primary PCI. The ASSENT 3-plus study,¹⁶⁴ in which TNK was studied with unfractionated heparin compared with enoxaparin as prehospital regimens, showed better safety with unfractionated heparin with very low overall rates of the primary end points in both groups. Taken together, available data indicate that a pivotal component of favorable outcomes is the rapidity of treatment and restoration of patency of the infarct-related artery. Despite the theoretical advantage of prehospital thrombolysis consistent with this determinant, objective information in aggregate is consistent with the superiority of primary PCI to a strategy of prehospital thrombolysis in most instances. Although European practice frequently entails prehospital thrombolysis, conventional care in the United States relies more completely on PCI.

Conjunctive Therapy

The activation of circulating platelets and the blood coagulation system in patients with acute MI is a result of complex phenomena.⁴⁶ Administration of plasminogen activators paradoxically contributes to these reactions. All available thrombolytic agents exhibit at least some nonspecificity, resulting in plasminemia with consequent activation of the coagulation cascade because of proteolytic cleavage of factors XII, X, and V and activation of factor X to Xa.^{44,45,165} Thrombin is generated in vivo, reflected by elevated concentrations in plasma of fibrinopeptide A, a cleavage product from fibrinogen elaborated by thrombin. Thrombin also activates platelets.

Suppression of coagulation and activation of platelets is necessary as conjunctive therapy to accelerate coronary recanalization, optimize its extent, and prevent reocclusion.¹⁶⁵ We have used the term *adjunctive therapy* in a restricted sense to refer to measures designed to reduce myocardial injury through mechanisms independent of the mode of recanalization and without directly influencing recanalization. Examples include methods used to reduce myocardial oxygen requirements or attenuate cellular injury.

Platelet-Targeted Conjunctive Therapy

Platelets can promote thrombosis by providing surfaces favoring the assembly of prothrombinase, activation of factor XII, and cross-linking of fibrin mediated by factor XIII. Platelets also can inhibit thrombolysis by the release of PAI-1 and α_2 -antiplasmin. Inhibition of platelet activation should potentiate clot lysis. At least five pathways exist through which activation of platelets can occur.

Aspirin improved survival when used in conjunction with SK in the large ISIS-2 trial.⁶⁰ It is an established conjunctive agent that is usually given at an initial dose of 162 mg (chewable

aspirin) as soon as possible when thrombolysis is planned, followed by daily doses of 162 to 325 mg.

Platelet activation is inhibited by aspirin through the blockade of cyclooxygenase and synthesis of thromboxane. Inhibition is incomplete, and other mechanisms can still activate platelets. A more complete inhibition can be induced by blocking the glycoprotein (GP) IIb/IIIa receptor on the platelet surface; the receptor provides the fibrinogen binding site that is required for platelet aggregation. Monoclonal antibodies directed at this receptor offer a promising approach to the blockade of platelet aggregation, which is implicated in the early thrombotic reocclusion associated with platelet-rich thrombi relatively resistant to lysis with plasminogen activators.^{47,166-168}

Monoclonal antibodies to GP IIb/IIIa enhance lysis of platelet-rich thrombi¹⁶⁸⁻¹⁷⁰ and reduce reocclusion^{168,171} when administered in combination with t-PA to laboratory animals. In clinical studies, a humanized murine monoclonal antibody 7E3 Fab (abciximab) has proven promising. In the TAMI-8 pilot study,¹⁷² 7E3 Fab was administered 3 hours after t-PA, heparin, and aspirin. Fewer episodes of recurrent ischemia and higher patency rates resulted. Analogous, favorable results have been obtained after PTCA.^{173,174} GP IIb/IIIa blockade has emerged as a valuable conjunctive measure for patients treated with PCI, but its value in association with thrombolytic agents is compromised by excess bleeding and its clearly deleterious consequences.⁴⁶ In the CLARITY TIMI-28 trial,¹⁷⁵ in which a 300-mg loading dose of clopidogrel was compared with placebo in patients treated with fibrinolytic drugs followed by mandatory angiography within 2 to 8 days and "open-label" clopidogrel subsequently, results with clopidogrel were more favorable. Significantly more patients exhibited occlusion of the infarct-related artery at angiography or death ($P = .01$) in the placebo-treated group (21.7%) compared with the clopidogrel group (15%). There was no difference in the incidence of mortality or the incidence of bleeding. Use of antiplatelet drugs in the adenosine diphosphate (ADP) antagonism class may be beneficial in association with administration of fibrinolytic agents.

Thrombin-Targeted Conjunctive Therapy Unfractionated Heparin

Prevention and amelioration of the generation and activation of thrombin are important determinants of the success of coronary recanalization.¹⁷⁶ Intravenous heparin is the most widely used conjunctive agent for this purpose. Heparin acts on thrombin indirectly, however, by complexing with antithrombin III, forming a bulky moiety that is ineffective in inhibiting clot-bound thrombin.^{165,177,178} Nevertheless, its antithrombin effects improve the rate of patency induced by fibrinolytic agents. Conjunctive antithrombin agents are particularly important with second-generation fibrinolytic agents because they elicit more modest elevations of circulating fibrinogen degradation products, moieties with some intrinsic anticoagulant and antiplatelet properties. Even with non-fibrin-selective agents, heparin is beneficial, however.¹²¹

The benefits of intravenous heparin (including low-molecular-weight heparin [LMWH]) in mechanistic trials are evident from the recanalization and patency rates delineated angiographically. Mortality data are also consistent with its beneficial effects.¹⁷⁹ In the GUSTO-I angiographic study, intravenous heparin induced greater early patency than subcutaneous heparin, even with the nonselective agent SK (see Table 12-3).¹²¹

Alternatives to Unfractionated Heparin

Several studies have addressed the potential benefit of agents other than unfractionated heparin in combination with fibrinolytic drugs. In the ASSENT 3 trial,¹⁸⁰ in which TNK plus LMWH was compared with half-dose TNK plus a bivalirudin, a low dose unfractionated heparin and TNK+ weight-adjusted unfractionated heparin LMWH seemed to be the superior conjunctive agent with respect to the combination of efficacy and safety. Although unfractionated heparin plus a bivalirudin exhibited the lowest incidence of the combined end point of 30-day mortality, reinfarction, and refractory ischemia, the regimen was associated with a greater incidence of bleeding, especially in elderly patients. The ASSENT 3-plus trial,¹⁶⁴ in which 1639 patients were studied after treatment with TNK plus enoxaparin compared with unfractionated heparin, showed superiority of enoxaparin ($P = .08$), but no difference in the combined end point of safety plus efficacy. There was a significant increase in intracranial hemorrhage (2.2% versus 1%; $P = .047$) associated with administration of the LMWH, especially in elderly patients.

In the EXTRACT TIMI-25 study,¹⁸¹ in which 20,479 patients were enrolled and treated with either TNK (80% of patients) or SK (20% of patients) combined with unfractionated heparin or enoxaparin, the combined end point of death or MI within 30 days was significantly lower with the LMWH enoxaparin ($P < .001$), with an odds ratio (OR) of 0.83 and a confidence interval (CI) of 0.77 to 0.90. There was an increased incidence of overall episodes of bleeding, but not of intracranial hemorrhage with enoxaparin, and the incidence of urgently required target vessel revascularization was lower with enoxaparin. In this study, enoxaparin dosage was reduced with respect to advanced age and other criteria, perhaps accounting in part for the favorable results.

In the OASIS VI study¹⁸² of fondaparinux, in which 12,092 patients were treated with fibrinolytic drugs or PCI combined with heparin during the procedure compared with unfractionated heparin or placebo in patients treated with SK or r-PA, results with fondaparinux were better (11.2% versus 9.7%) with respect to the incidence of the primary end point of death or MI within 30 days in patients who were not treated with PCI. Less bleeding was encountered in the patients treated with fondaparinux. The reason for administration of heparin during PCI in OASIS VI¹⁸² was that the results in the OASIS V study¹⁸³ showed an unacceptable incidence of thrombus formation on guidewires without the addition of heparin to fondaparinux. Results of OASIS VI¹⁸² suggest that fondaparinux is a reasonable alternative as a conjunctive agent compared with unfractionated heparin for patients treated with thrombolytic drugs.

Hirudin

Intrinsic limitations of heparin as a pharmaceutical, particularly its dependence on antithrombin III for activity, were an impetus to the development of direct-acting antithrombins. Such agents are likely to induce more complete inhibition of thrombin. The most initially studied example is hirudin, a protein isolated originally from the medicinal leech (*Hirudo medicinalis*) and subsequently synthesized through recombinant technology. Hirudin binds directly to thrombin, inhibiting its catalytic and anion binding sites.^{178,179,184-187} In animals, hirudin exerted more favorable synergistic effects with respect to accelerating thrombolysis and sustaining patency in thrombotically occluded

canine coronary arteries compared with aspirin, heparin, and a GP IIb/IIIa receptor antagonist.¹⁸⁸

Results of three clinical trials¹⁸⁹⁻¹⁹¹ employing hirudin in patients with acute MI or unstable angina led to a critical reappraisal of dosage and the optimal approach to balancing safety and efficacy.¹⁹¹ The GUSTO IIA trial¹⁸⁹ compared intravenous heparin titrated to aPTT values of 60 to 90 seconds with intravenous hirudin at a fixed dose (0.6 mg/kg bolus and 0.2 mg/kg/hr infusion) without aPTT adjustment in patients with chest pain and ECG changes consistent with acute MI or unstable angina. This trial was designed to enroll 12,000 patients, but was terminated prematurely after 2564 patients had been studied because of an unacceptably high incidence of intracranial hemorrhage in all treatment groups. The TIMI-9A trial¹⁹⁰ employed the same dose of intravenous hirudin and compared it with aPTT-adjusted (60 to 90 seconds) intravenous heparin combined with front-loaded t-PA or SK (the choice was made at the treating physician's discretion) in patients with acute MI. TIMI-9A also was terminated early because of an unacceptably high incidence of intracranial and other major hemorrhage in the heparin and hirudin groups. The high incidence of complications was particularly profound in the patients treated with SK plus hirudin.

The randomized multicenter German pilot study HIT-III¹⁹¹ compared a different dosage and type of recombinant hirudin with heparin in combination with front-loaded t-PA (alteplase) in patients with acute MI. In all treatment groups, dosage of the antithrombin was adjusted to maintain aPTTs within a range of 2.5 to 3 times baseline values. HIT-III¹⁹¹ had to be terminated early because of an unacceptably high incidence of intracranial bleeding that was confined to the group treated with t-PA plus hirudin (3.4%). No intracranial bleeding occurred in the group treated with t-PA plus heparin.

The increased incidence of catastrophic bleeding encountered in these three studies might have resulted from the prolonged duration of infusion of antithrombin agents (48 to 120 hours); features of the patients studied, including advanced age (in view of the markedly low clearance of hirudin in elderly patients); high doses of the antithrombin agents associated with late bleeding as a result of adjustments based on body weight and aPTT values; and other factors that are discussed later. Regardless of the reason, the lesson to be learned is that therapeutic efficacy and safety depend on optimal dosing, as yet undefined, and its appropriate individualization. The results do not justify denigration of the value of conjunctive therapy.¹⁹² The TIMI-9B trial has been reconfigured to employ a lower dose and duration of infusion of hirudin (bolus of 0.1 mg/kg and infusion of 0.1 mg/kg/hr) and heparin (1000 U/hr without weight adjustment) plus titration of both agents to maintain aPTTs between 55 and 85 seconds.

Other direct-acting antithrombin agents, such as bivalirudin (Hirulog), have been employed in the setting of PCI with promising results.¹⁹³⁻¹⁹⁶ Definitive evaluations of bivalirudin in association with fibrinolytic drugs are unavailable. The HERO-2 study¹⁹⁷ examined the use of bivalirudin or unfractionated heparin in conjunction with intravenous SK on 1-month mortality. There was no significant difference in the primary end point, although the bivalirudin group had a lower rate of reinfarction at 96 hours. Additional direct-acting antithrombins include argatroban, D-phenylalanyl-L-arginyl-chloromethylketone (P-PACK), and other chloromethylketones.¹⁹⁸⁻²⁰¹

Table 12-6. Combined Incidence of Ischemic and Hemorrhagic Strokes in the GISSI/International Trial

Condition	Fibrinolytic Drug		Odds Ratio	Confidence Interval (95%)	P Value (chi-square)
	t-PA	SK			
With heparin	64/5, 170 (1.2%)	53/5, 191 (1%)	1.22	(0.77-1.67)	.3
Without heparin	74/5, 202 (1.4%)*	45/5, 205 (0.9%)	1.65	(1.04-2.26)	.007
Total	138/10, 372 (1.3%)	98/10, 396 (0.9%)	1.40	(1.04-1.76)	.0004

*The stroke rate with t-PA and subcutaneous heparin is similar to the stroke rate with SK. There is a higher incidence of stroke in the t-PA group without subcutaneous heparin.

Intracranial Hemorrhage and Stroke

Hemorrhage, particularly intracranial bleeding, is the major risk associated with the use of thrombolytic agents. Hemorrhage occurs through conversion of ischemic strokes to hemorrhagic ones, and by inducing a modestly higher frequency of de novo hemorrhagic strokes in patients treated with fibrinolytic drugs compared with anticoagulants alone. For patients with infarction who were treated with placebo in the early thrombolytic trials, overall early stroke incidence was approximately 1%.²⁰² With fibrinolytic drugs, stroke incidence is 1.2% to 1.5%, with hemorrhagic stroke accounting for 0.3% to 0.7%. The risk of intracranial bleeding with t-PA is greater than with SK: 0.4% versus 0.3% in the GISSI-2 International trials^{142,151} and 0.7% versus 0.5% in GUSTO-I.³⁰

Patients with infarction are at risk for emboli from carotid plaques, emboli from mural thrombi in the left ventricle, ischemic strokes that can be rendered hemorrhagic by anticoagulants or plasminogen activators, and possibly occult susceptibility to proteolysis of cerebral vessels with unsuspected pathology, such as abnormal cerebrovascular integrity as a result of an aneurysm or β -amyloid deposition (i.e., congophilic angiopathy). Patients may be prone to complications attributable to an endogenous hypercoagulable state or procoagulant effects of plasminogen activators, particularly fibrin-specific agents administered without adequate anticoagulation with intravenous heparin.²⁰² Even before thrombolysis became part of the therapeutic armamentarium, the overall incidence of early stroke of all types accompanying acute MI ranged from 1.7% to 3.2%.²⁰³⁻²⁰⁵ In the GUSTO-I trial,³⁰ the risk of any stroke (including intracranial bleeding) was 1.55% for patients treated with front-loaded t-PA and intravenous heparin and 1.4% for patients treated with SK and intravenous heparin.

As shown by pooling data from numerous early placebo-controlled trials of fibrinolytic agents enrolling tens of thousands of patients, the incidences of stroke were similar with and without plasminogen activators.²⁰⁶ The incidence of stroke overall was higher before thrombolysis was widely used than it is now.²⁰⁷ Coronary thrombolysis exerts only a minimal or no adverse effect on the overall incidence of stroke despite increasing the frequency of intracranial bleeds from the approximately 0.1%²⁰⁷ seen with anticoagulants alone to 0.3% to 0.7%. The increase in intracranial bleeds associated with plasminogen activators seems to be small and more than offset by a reduction

in the incidence of thromboembolic stroke and the decrease in mortality.²⁰⁶

After the GISSI-2/International trials^{142,151} and ISIS-3,¹⁴³ much debate surrounded the incidence of stroke in relation to specific thrombolytic agents (i.e., single-chain t-PA [alteplase], double-chain t-PA [duteplase], and SK). Close examination of the results of the GISSI/International trials showed a significant increase of all-cause stroke in patients given t-PA (alteplase) without subcutaneous heparin compared with patients given subcutaneous heparin (1.4% versus 1.2%).²⁰² The incidence of intracranial hemorrhage was similar when t-PA was compared with SK (0.4% versus 0.3%). The difference in the combined incidence of ischemic and hemorrhagic stroke with t-PA (1.32%) compared with SK (0.9%) seems to be attributable largely to an increase in thromboembolic rather than hemorrhagic events. Because the late use of subcutaneous heparin failed to induce adequate anticoagulation, the increase in ischemic strokes is not surprising in the context of the procoagulant effects and fibrin-selective properties of t-PA. This interpretation is consistent with the lack of difference in the incidence of stroke with SK with or without subcutaneous heparin (1% versus 0.9%),²⁰² as summarized in Table 12-6.

Conversely, the difference in the total incidence of stroke seen with double-chain t-PA (duteplase) and SK in the ISIS-3 trial¹⁴³ was attributable largely to hemorrhagic rather than ischemic stroke (0.7% with duteplase versus 0.2% with SK). The dose of duteplase used in ISIS-3 (0.6 MU/kg) corresponds functionally, with respect to plasmin-generating potential, to a dose of 150 mg of single-chain t-PA (alteplase).^{202,208} It was precisely this dose of alteplase that led to inordinately high intracranial hemorrhage rates (1.5%) in the pilot phase of the TIMI trial.²⁰⁹ The imposition of stricter recruitment criteria and a lower total dose of t-PA (alteplase, 100 mg) in the TIMI trial resulted in a reduction of the hemorrhagic stroke incidence to 0.6%.²⁰⁹

The excess incidence of stroke with t-PA in the GISSI/International trials cannot be lumped with the excess in ISIS-3. In GISSI-2, it reflected primarily a lack of adequate anticoagulation. In ISIS-3, it reflected excessive dosing of the anomalous double-chain t-PA used. A summary of data from these two trials is presented in Table 12-7. Because of the disparate design of these two large studies and the consequent mechanistic differences, meta-analysis²¹⁰ of these trials is inappropriate in delineating the overall risk of patients given t-PA or SK.

Several factors may have contributed to the unexpectedly high incidence of adverse effects in these trials.^{192,211} The

Table 12-7. Overall Incidence of Stroke in the GISSI/International and ISIS-3 Trials

Clinical Event in Hospital	Study	Fibrinolytic Agent Allocated		Odds Ratio	Confidence Interval (95%)
		t-PA	SK		
Total stroke	GISSI/International	136/10,372 (1.32%)	98/10,396 (0.9%)	1.40	(1.04-1.76)
	ISIS-3	188/13,569 (1.4%)	141/13,607 (1%)	1.34	(1.05-1.63)
	Both	324/23,991 (1.4%)	239/24,003 (1%)	1.36	(1.13-1.59)
Cerebral hemorrhage*	GISSI/International	44/10,372 (0.4%)	30/10,396 (0.3%)	1.47	(0.79-2.16)
	ISIS-3	89/13,569 (0.7%)	32/13,607 (0.2%)	2.80	(2.21-3.40)
	Both	133/23,941 (0.6%)	62/24,003 (0.3%)	2.16	(1.51-2.81)
Nonhemorrhagic or undefined stroke	GISSI/International	92/10,372 (0.9%)	63/10,396 (0.7%)	1.36	(0.93-1.79)
	ISIS-3	99/13,569 (0.7%)	109/13,607 (0.8%)	0.91	(0.66-1.16)
	Both	191/23,941 (0.8%)	177/24,003 (0.7%)	1.08	(0.86-1.30)

*The increased incidence of intracranial stroke with alteplase in ISIS-3 results from an inordinate increase in intracranial hemorrhage. In the GISSI/International trial, the increased stroke rate with alteplase reflects higher rates of nonhemorrhagic stroke.

SK, streptokinase; t-PA, tissue plasminogen activator.

From Sobel BE, Collen D: Strokes, statistics and sophistry in trials of thrombolysis for acute myocardial infarction. *Am J Cardiol* 1993; 71:426.

consistency of the results with hirudin suggests that the dosage was probably excessive. The higher rates of intracranial bleeds with t-PA and heparin in GUSTO-IIA than in GUSTO-I may reflect the higher doses and more prolonged administration of heparin (GUSTO-IIA, 70 to 120 hours; GUSTO-I, ≥ 48 hours at the physician's discretion) and the broader interval for enrollment (12 hours compared with 6 hours after symptom onset in GUSTO-I). The duration of heparin infusion may be particularly culpable in view of the late (average 31 hours) occurrence of intracranial bleeds in GUSTO-IIA. The benefits of continuation of heparin beyond 24 hours have not been established.^{192,212} Similar considerations apply to TIMI-9A, in which enrollment was up to 12 hours after symptom onset, and heparin was given at higher doses and for longer than in the GUSTO-I trial. HIT-III limited enrollment to within 6 hours of symptom onset and used a heparin dose similar to that used in GUSTO-I; this may explain the anticipated low overall occurrence of stroke (1.3%) in patients treated with t-PA and heparin and the absence of intracranial bleeds.

These results underscore the need to focus on the treatment of patients with acute MI as early as possible (perhaps only within 6 hours after symptom onset in the absence of extenuating circumstances) and to use heparin in regimens shown to be safe and effective in GUSTO-I. An intravenous bolus of 5000 U should be followed by 1000 U/hr and continued for 24 to 48 hours, unless circumstances dictate otherwise. Target aPTT values of 55 to 85 seconds are appropriate.

Although the relative risk reduction for death conferred by treatment with plasminogen activators is greatest in elderly patients, an age greater than 65 years, weight less than 70 kg, and female gender correlate with an increased risk of intracranial bleeding.^{213,214} Elevated blood pressure is another risk factor,¹⁸⁶ perhaps because prolonged, uncontrolled hypertension induces vasculopathy, rendering cerebral vessels susceptible to the adverse effects of proteolytic agents. The risk of intracranial bleeding increases with systolic blood pressures greater than

150 mm Hg and is particularly high in patients with systolic blood pressures exceeding 175 mm Hg (1.6% intracranial bleeding rate; $P = .001$).¹⁴¹ Older, diminutive, and severely hypertensive patients are at high risk.

Consideration of these factors is needed to select specific treatment modalities prudently for individual patients. Overall, effective regimens for coronary thrombolysis have improved outcomes in aggregate with respect to mortality, nonfatal disabling stroke, and intracranial bleeding, as shown by the GUSTO-I results in Table 12-5, in which front-loaded t-PA with intravenous heparin, SK with intravenous heparin, and combined t-PA and SK with heparin are compared.³⁰

Patient Selection, Complications, and Considerations Pertinent to Specific Groups

Most patients presenting with acute MI are managed initially by primary care physicians, including internists, family practitioners, and emergency physicians.²¹⁵ Sophistication regarding patient selection for treatment options is essential.

The risk of hemorrhage (exclusive of intracranial hemorrhage) was greater in early mechanistic clinical trials in which early and repeated angiography was undertaken more universally than it is today. The incidence of bleeding associated with access sites ranged from 12% to 50% compared with 1% in studies in which angiography was not implemented.²¹⁶ With the availability of refined, small-gauge catheters, modern angiography, avoidance of unnecessary femoral vein puncture, and expertise of experienced angiographers, the risks of early angiography are probably similar to the risks associated with deferred angiography after infarction (TAMI-5)^{152,217} and elective angiography in patients without recent infarction.

Much debate has surrounded the incidence of major "spontaneous" (nonaccess site) bleeding in gastrointestinal,

retroperitoneal, pulmonary, or genitourinary sites relative to the agents used and the use of conjunctive anticoagulation. GUSTO-I³⁰ results show low rates with SK and with front-loaded t-PA (t-PA and intravenous heparin, 0.4%; SK and subcutaneous heparin, 0.3%; SK and intravenous heparin, 0.4%).

Risks associated with immunologically mediated side effects related to some thrombolytic agents include anaphylaxis and other, less serious allergic reactions, such as fever, chills, arthralgias, anaphylactoid reactions, and vasculitis. Such complications occur particularly with SK and agents containing the SK moiety, such as APSAC. Anaphylaxis occurred in 0.6% of patients treated with SK in GUSTO-I.³⁰ It may be under-reported, however, because of the difficulty of diagnosis in the setting of acute MI, when severe hypotension or shock may be attributed erroneously to other causes.

Hypotension occurs commonly with SK, with an average decrease in systolic blood pressure of 35 mm Hg and transient reductions to less than 90 mm Hg in 38% of patients.⁵⁹ It probably reflects activation of the kinin system by plasmin, decreased viscosity of blood secondary to proteolysis, and perhaps negative inotropic effects induced indirectly. Hypotension is much less common in patients treated with fibrin-selective agents. In GUSTO-I, front-loaded t-PA and intravenous heparin was the regimen associated with the lowest mortality and with a significantly lower incidence of mild allergic reactions, anaphylaxis, congestive heart failure, cardiogenic shock, sustained hypotension, atrioventricular block, sustained ventricular tachycardia, ventricular fibrillation, asystole, and atrial fibrillation or flutter.³⁰

Paradoxically, patients who are at the highest risk for complications from coronary thrombolysis may be the patients who can benefit most from treatment. Among all patients presenting with acute MI, approximately 50% are eligible for treatment with thrombolytic agents on the basis of current criteria.²¹⁸ Approximately 20% are treated.²¹⁵ Mortality in patients considered to be ineligible for treatment is fivefold greater than in patients who are treated.²¹⁹ Efforts have been made to determine whether eligibility criteria should be less strict than the criteria employed for other reasons (investigative considerations) in early trials.

Criteria developed by an ACC/AHA Task Force²²⁰ in 1990 are shown in Table 12-8. In contrast to the extensive list of absolute contraindications promulgated, in GUSTO-I,³⁰ the only absolute criteria for exclusion were previous stroke, active bleeding, recent trauma, recent major surgery, and noncompressible vascular puncture sites. Patients with a systolic blood pressure of 180 mm Hg or greater that was unresponsive to therapy were considered to have a relative contraindication. Diabetic patients with hemorrhagic retinopathy were not excluded, and an age limit was not invoked in GUSTO-I. Nevertheless, the rate and profile of complications in this very large trial were acceptable in view of the use of highly effective thrombolytic regimens and conjunctive anticoagulation.

Patients requiring cardiopulmonary resuscitation (CPR) of less than 10 minutes' duration do not seem to be at high risk for additional complications when treated with thrombolytic drugs. Clinical judgment, taking into account the extent of thoracic trauma and neurologic injury sustained, is more helpful than criteria based solely on the duration of CPR.²²¹

Treating physicians must rely on common sense and clinical acumen to anticipate best the risk-benefit ratio for an individual

Table 12-8. Absolute and Relative Contraindications to Coronary Thrombolysis as Proposed by the American College of Cardiology/American Heart Association Task Force

Absolute Contraindications

Active internal bleeding
Suspected aortic dissection
Prolonged or traumatic cardiopulmonary resuscitation
Recent head trauma or known intracranial neoplasm
Diabetic hemorrhagic retinopathy or other hemorrhagic ophthalmic condition
Pregnancy
Previous allergic reaction to thrombolytic agent (streptokinase or APSAC)
Recorded blood pressure >200/120 mm Hg
History of cerebrovascular accident known to be hemorrhagic

Relative Contraindications*

Recent trauma or surgery >2 wk; trauma or surgery more recent than 2 wk, which could be a source of rebleeding, is an absolute contraindication
History of chronic severe hypertension with or without drug therapy
Active peptic ulcer
History of cerebrovascular accident
Known bleeding diathesis or current use of anticoagulants
Significant liver dysfunction
Prior exposure to streptokinase or APSAC; this contraindication is particularly important in the initial 6- to 9-mo period after streptokinase or APSAC administration, and applies to reuse of any streptokinase-containing agent, but does not apply to rt-PA or urokinase

*Risk-benefit analysis in the presence of relative contraindications should be individualized.

APSAC, anisoylated plasminogen streptokinase activator complex; rt-PA, recombinant tissue plasminogen activator.

From ACC/AHA Task Force: Guidelines for the early management of patients with acute myocardial infarction. *Circulation* 1990; 82:683.

patient. An 80-year-old woman with an acute inferior MI of 8 hours' duration and with an admitting blood pressure of 200/120 mm Hg would not likely be a good candidate for thrombolytic drugs. Conversely, a young diabetic patient with a large anterior MI of 90 minutes' duration and with a history of retinopathy that has been well controlled with laser therapy is likely to be a good candidate.

Elderly Patients

Most of the early mechanistic studies of coronary thrombolysis and large trials excluded patients older than 75 years. The incidence of mortality from MI is high for elderly patients, as are risks of bleeding with thrombolytic drugs. Although less than 20% of U.S. citizens are 65 years old or older, 80% of all deaths from acute MI occur in this group.²²² The risk of hemorrhagic

complications with treatment increases with age, as does the risk of all-cause mortality. Nevertheless, subgroup analysis^{218,222,223} shows unequivocally that the relative benefit seen with coronary thrombolysis is greatest for elderly patients. For patients older than 75 years in the ISIS-2/International t-PA/SK trials,^{142,151} mortality reduction was far greater than for younger patients.^{218,223} Generally, and in elderly patients, the enhanced survival benefit of PCI compared with administration of thrombolytic drugs declines as the delay of implementation of PCI compared with the onset of pharmacologic treatment increases.²²⁴

Women

Women have a poor prognosis compared with men after acute MI.^{225,226} Compared with men, rates of induction of coronary patency with thrombolytic drugs are comparable in women, as are the effects of treatment on left ventricular function. Nevertheless, mortality is higher.^{227,228} When adjustments are made for age and comorbidities (e.g., diabetes, hypertension, hypercholesterolemia), the adverse odds ratio (OR) declines (gender alone, 1.7695% CI; adjusted, 1.31 95% CI).²²⁸

The risk of hemorrhagic stroke seems to be higher for women than men with MI treated with plasminogen activators. In GISSI-2, the incidence of hemorrhagic stroke was 0.3% for men and 0.6% for women, with no difference in the incidence of ischemic stroke (0.5% for both).²¹⁴ Similar data are available from the International t-PA/Streptokinase mortality trial,¹⁵¹ with women having a 1% hemorrhagic stroke rate compared with 0.3% for men, a disparity that persists despite adjustments for age and body weight.

Menstruation and pregnancy are potential contraindications to therapeutic thrombolysis. Traditionally, women of childbearing age have been excluded from thrombolytic drug trials. It seems to be safe to treat women of childbearing age who are not pregnant, however, because menstrual bleeding is related more to sloughing of tissue than active bleeding.²²⁷ Pregnancy has been considered by some investigators to be an absolute contraindication to coronary thrombolysis because of the potential risks of fetal or placental hemorrhage and the known incidence of coronary spasm.²²⁷ Apparently massive infarction may warrant treatment if emergency direct angioplasty is not promptly available.

Patients with Congestive Heart Failure or Cardiogenic Shock

In patients presenting with severe congestive heart failure, particularly patients with cardiogenic shock, the risks of coronary thrombolysis are likely to be increased because of biochemical derangements secondary to liver and other organ failure. Improved survival has not been shown. Hospital mortality rates for patients presenting in Killip class IV heart failure in the GISSI-1 trial were no different for SK than for placebo (69.9% and 70.1%). Reduction of mortality may be absent in part because of low rates of adequate recanalization.²²⁹ Results in the SHOCK trial indicate that patients who cannot be treated with PCI immediately should be treated with fibrinolytic drugs and supportive measures such as intra-aortic balloon counterpulsation, and transferred immediately to a facility in which PCI can be performed.

Retrospective analysis suggests that successful reperfusion with PCI contributed to improved survival of patients presenting

with acute MI complicated by cardiogenic shock.²³⁰ If available, direct PCI seems to be the best option. In its absence, thrombolysis should be considered. Efforts to enhance survival by diminishing cytokine-driven expression of nitric oxide have not been shown to be beneficial.²³¹ There is no convincing evidence that any adjunctive pharmacologic measure in addition to restoration of patency of the infarct-related artery enhances survival in patients with cardiogenic shock.

Bundle Branch Block

Patients presenting with symptoms of acute MI may not have diagnostic ECG evidence of acute myocardial injury because of right or left bundle branch block. Nonetheless, these patients often have extensive infarction and may derive benefit from coronary thrombolysis. Current AHA/ACC guidelines underscore the importance of new left bundle branch block with angina as an indication for thrombolysis. Meta-analysis of nine large placebo-controlled trials showed increased survival for more than 2000 patients presenting with bundle branch block with the use of plasminogen activators compared with placebo.¹⁴⁶ The mortality rate for treated patients was 18.7% compared with 23.6% for patients allocated to placebo ($P < .01$).

Treatment of Hemorrhage

In patients treated with thrombolytic drugs, anticoagulants, or both, minor bleeding occurs, frequently at vascular puncture and access sites. Manual compression for 30 minutes or until the bleeding stops is usually effective. In the case of uncontrolled, life-threatening, systemic or intracranial bleeding, stronger measures are needed. Thrombolytic, antiplatelet (e.g., aspirin), and antithrombin (e.g., heparin) agents should be discontinued, and reversal of heparin with protamine (1 mg of protamine per 100 U of heparin) should be considered. Diabetic patients who have been exposed to protamine through injections of NPH insulin are at risk for severe allergic reactions and hypotension if intravenous protamine is given at these doses, and they require special consideration. Packed red blood cells and crystalloid should be administered to maintain the hematocrit greater than 25%.

If the patient has been treated recently with a thrombolytic agent, and the concentration of fibrinogen levels is low or clotting factors are depleted, administration of cryoprecipitate (10 U) or fresh frozen plasma (2 to 4 U) may be required, despite the associated risk of viral hepatitis and human immunodeficiency virus infections. ϵ -aminocaproic acid (Amicar), an antifibrinolytic agent that competes with plasminogen for lysine binding sites on fibrin, should be reserved for patients with refractory bleeding unresponsive to other measures because it can precipitate thrombosis. If used, ϵ -aminocaproic acid should be given in a loading dose of 5 g intravenously, followed by 0.5 to 1 g/hr until bleeding has stopped.²³² A general approach to treatment of hemorrhage after the use of thrombolytic agents^{217,232} has been reviewed elsewhere and is presented in Figure 12-6.²³²

Bleeding in patients given direct-acting antithrombins such as hirudin instead of heparin as the conjunctive agent may present a particular problem.²³³ Fresh frozen plasma may normalize laboratory values, but fail to stop the bleeding. Administration of prothrombin complex concentrate (25 to 30 U/kg) or recombinant coagulation factor VIIa (35 to 120 μ g/kg) may be useful, although risks of thrombosis are substantial.

Figure 12-6. Schematic representation of the strategy for management of serious bleeding in patients treated with plasminogen activators. aPTT, activated partial thromboplastin time; FFP, fresh frozen plasma. Evolution of Coronary Revascularization from Thrombolysis to Percutaneous Coronary Intervention

Much of the progress in coronary thrombolysis and particularly the principles that became established through its use contributed to the foundation for use of PCI for primary treatment of patients with acute coronary syndromes. Although these two modalities have often been contrasted, they are, in reality, simply two approaches that can be used either independently or in a sequential fashion for achieving the desired objective of prompt recanalization of the infarct-related artery, sustained recanalization, and complete recanalization, all of which contribute to the ultimate efficacy of the intervention. PCI has undergone profound evolution since its inception as coronary angioplasty more than 5 decades ago. On the basis of some early studies in which angioplasty was used in association with coronary thrombolysis, it had been thought that PCI was hazardous under these circumstances. Technical progress has largely obviated that concern, however, and the superiority of PCI as an initial intervention in centers that can support it on a 24-hour-a-day basis has become clear.

Surgical Alternative

An alternative way of inducing revascularization for treatment of patients with STEMI is coronary artery bypass graft surgery. Historically, this intervention was preferred, especially in patients with cardiogenic shock before the advent of PTCA and subsequently PCI. In current practice, coronary artery bypass graft surgery is not the favored form of induction of

revascularization through mechanical means because of the high risk entailed with coronary surgery under emergency conditions compared with that associated with elective coronary surgery, and because of time constraints that make it difficult for surgical revascularization to be implemented before completion of the evolving infarct. Based in part on results with emergency coronary artery bypass graft surgery compared with PCI in randomized patient assignment trials and registry data as noted subsequently, the consensus is that primary PCI is the preferred modality for induction of revascularization in the treatment of patients with STEMI.

Feasibility of Early Percutaneous Coronary Intervention for Treatment of ST Segment Elevation Myocardial Infarction

In 1964, Dotter and Judkins²³⁴ conceived of inducing angioplasty of the coronary arteries by sequentially introducing a series of rigid dilation catheters of increasing diameter to compress the stenotic lesion. Ten years later, Gruentzig and Kumpe²³⁵ showed the utility of replacing the rigid catheters with an inflatable dilation balloon in vivo. After meticulous study and refinement, Gruentzig and colleagues²³⁶ performed the first coronary balloon angioplasty in a patient in 1977, providing the foundation for PCI. Despite profound expansion of its indications over time, and treatment of even more complex coronary anatomy and lesions including those responsible for STEMI, success rates now exceed 98%. By 2004, an estimated 664,000 PCI procedures were performed in the United States, constituting a 325% increase in annual implementation compared with that in 1987.²³⁷

Early in the evolution of PCI, its feasibility in addition to fibrinolysis was explored in the setting of acute MI.²³⁸ Partly because of the primitive and unwieldy nature of angioplasty available at

that time, early strategies involving catheter-based techniques focused on the direct infusion of the fibrinolytic agent into the infarct-related artery.^{70,102,239,240} With the advent of superior fibrinolytic agents and the extant logistical difficulties of catheter-based interventions at that time, early attempts with primary PCI languished. First-line therapy for STEMI in the late 1980s was coronary thrombolysis. Nevertheless, limitations of stand-alone fibrinolytic therapy led to a rekindled interest in the combination of clot lysis and subsequent balloon angioplasty.

Experience with fibrinolysis alone showed that in approximately 15% of patients recanalization fails. In almost 50%, restoration of flow in the infarct-related artery is suboptimal. In 10% of patients in whom recanalization is successful, subsequent early infarction occurs.²⁴¹ In influential early studies including the TIMI IIA and TIMI IIB trials, in which strategies of PCI were performed with balloon angioplasty after thrombolysis, no clinical benefit was observed with either immediate or delayed PCI compared with conservative therapy. Immediate PCI led to a much higher incidence of bleeding and emergency coronary artery bypass graft surgery.^{242,243}

Despite the discouraging results of these early trials of combination therapy, several investigators explored the possibility that early balloon angioplasty would be a safe and perhaps more effective alternative to stand-alone fibrinolysis.²⁴⁴ Early results by O'Neill and coworkers²⁴⁵ in comparisons of angioplasty versus intracoronary SK showed that balloon angioplasty was superior in improving ventricular function and reducing residual stenosis in the setting of acute MI. Over the next 15 years, multiple trials directly comparing stand-alone fibrinolysis with primary PCI were performed, eventually validating the utility of primary PCI and its superiority compared with thrombolysis in inducing more complete and more frequent recanalization of the infarct-related artery.²⁴⁶

Primary Percutaneous Coronary Intervention for Treatment of ST Segment Elevation Myocardial Infarction

Limitations of fibrinolytic therapy include the risk of bleeding and particularly intracranial hemorrhage, especially in patients with recent surgery, previous cerebral vascular insults or head or facial trauma, intracranial neoplasm, aortic dissection, or occult β -amyloid angiopathy. Uncontrolled hypertension is a prominent risk factor for intracranial bleeding.^{247,248} The risks of intracranial hemorrhage with fibrinolysis are particularly high in patients older than 75 years despite the fact that treatment is associated with a lower hospital mortality compared with placebo.²⁴⁹

As investigators of coronary thrombolysis learned, benefit is greatest when the agents are administered within 2 hours after the onset of symptoms.^{31,250} Efficacy of lysis diminishes as clots age; this may contribute to the higher mortality in patients treated later after the onset of symptoms.²⁵¹ Fibrinolytic therapy restores normal flow in less than 65% of treated patients, and reocclusion hours to days after treatment resulting in reinfarction is common.

As PCI evolved, a trial of early PCI with intracoronary SK comprising 56 patients showed improved preservation of left

ventricular function compared with treatment with intravenous SK alone.²⁴⁵ Similar results were obtained in a trial with a slightly larger sample ($N = 156$) of patients.²⁵² In 1993, PAMI, a multicenter randomized trial, compared primary PCI with intravenous t-PA in 395 patients. Although this study found no difference in the primary end point of post-treatment radionuclide left ventricular function, it showed a trend of decreased hospital mortality with primary PCI (6.5% versus 2.6%; $P = .06$), significantly decreased in-hospital and 6-month incidence of death and reinfarction, and a decreased incidence of intracranial hemorrhage (0% versus 2%).²⁵³

Despite the favorable results with PCI in this early trial, primary PCI was not widely adopted immediately as a treatment strategy for patients with STEMI,¹⁷ partly because of the substantial resources required for offering primary PCI around the clock and the relative scarcity of experienced operators able to perform emergency PCI in a high-risk setting. Numerous studies comparing fibrinolytic therapy with primary PCI were performed throughout the late 1990s and early 2000s. The GUSTO-IIb trial randomly assigned 1138 patients to either primary PCI or fibrinolytic therapy with “accelerated” administration of t-PA. With respect to the primary end point, a composite outcome of death, nonfatal MI, and disabling stroke at 30 days, primary PCI was found to be superior to fibrinolytic therapy. The study did not show a reduction in mortality, however, comparable to that seen in the earlier PAMI trial. In subgroup analysis, none of the individualized end points met statistical significance, although all showed trends in favor of primary PCI. The benefit of primary PCI seemed to be short-lived because the composite end point in favor of PCI did not remain significant at 6 months (13.3% versus 15.7%; $P =$ nonsignificant).²⁵⁴

Presently, more than 90% of patients presenting to the hospital with STEMI are considered to be eligible for treatment with primary PCI. PCI results in induction of TIMI 3 grade flow in more than 90% of infarct-related arteries when stents and thrombectomy can be employed if indicated. With stenting, the acute reocclusion rate is less than 5%.²⁵⁵ As stents became available, Schomig and associates²⁵⁶ compared primary PCI with the use of adjunctive GP IIb/IIIa inhibition with fibrinolytic therapy in 140 patients. The primary end point was myocardial salvage as measured by serial nuclear scintigraphy with a secondary end point being composite of death, reinfarction, or stroke at 6 months. Myocardial salvage was greater with primary PCI (salvage index 0.57 versus 0.21; $P < .01$). Evaluation of the 6-month end point strongly supported the use of primary PCI (8.5% versus 23.2%; $P = .02$).²⁵⁶ Results in other studies performed after stents had been developed showed similar benefits.²⁵⁷⁻²⁵⁹

Trials of primary PCI compared with thrombolysis were reviewed by Keeley and colleagues²⁴⁶ in 2003 (Fig. 12-7). The authors evaluated the results of 23 trials involving 7739 patients. Most of the patients (76%) randomly assigned to the thrombolytic arms of these trials were treated with fibrin-specific thrombolytic agents. Primary PCI was superior with respect to short-term mortality (7% versus 9%; $P = .0002$), reinfarction (3% versus 7%; $P < .0001$), and stroke (1% versus 2%; $P = .004$). With long-term follow-up, the benefits of primary PCI remained robust with substantial reduction in mortality ($P = .0019$), nonfatal reinfarction ($P < .0001$), and recurrent ischemia ($P < .0001$). Adjunctive stenting in primary PCI was used in 12 of the 23 trials. The ACC/AHA guidelines in 2004 for the care of patients

Figure 12-7. Short-term outcomes after primary percutaneous coronary intervention (PCI) compared with thrombolysis in the treatment of ST segment elevation myocardial infarction as judged from a meta-analysis of 7739 patients. CVA, cerebrovascular accident; MI, myocardial infarction. (Data from Keeley EC, Boura JA, Grines CL: Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: a quantitative review of 23 randomised trials. *Lancet* 2003;361:13-20.)

with STEMI referred to PCI as a class I recommendation with the highest level of supporting evidence.²⁴⁷

The preponderance of evidence favoring primary PCI was gathered in trials directly comparing it with thrombolysis. Patients who are ineligible for treatment with fibrinolytic drugs seem to benefit from primary PCI as well. Evaluating data from the Second National Registry of Myocardial Infarction (NORMI), Grzybowski and coworkers²⁶⁰ analyzed results from more than 19,000 patients with STEMI who had contraindications to the use of thrombolytic agents; 4705 of these patients underwent immediate primary PCI. The remaining patients were treated medically without attempts at revascularization. As judged from analyses of matched patients characterized with propensity scores, a significant effect was evident on mortality reduction favoring primary PCI (OR 0.64; 95% CI 0.56 to 0.75). The investigators concluded that primary PCI should be strongly considered for patients who have contraindications to fibrinolysis.²⁶⁰

Efforts to Overcome Limitations Discovered in Early Trials of Primary Percutaneous Coronary Intervention

All of the trials included in the meta-analysis by Keeley and colleagues²⁴⁶ were conducted in centers with considerable experience with primary PCI. The patients had been randomly assigned in circumstances in which PCI could be performed with minimal delay. Despite the benefit seen for primary PCI over fibrinolysis, several registries did not confirm the benefit seen in these trials in part because of difference in the circumstances surrounding treatment.^{261,262}

The current ACC/AHA guidelines indicate that PCI should be performed in conditions conforming as closely as possible to the conditions in the clinical trials in which it was shown to be superior to fibrinolysis. Specifically, primary PCI should be performed when patients present with an admission to balloon time of 90 minutes or less by skilled operators who perform more than 75 PCI procedures per year; the procedure should be done in hospitals that perform more than 36 PCI procedures for STEMI annually and have cardiothoracic surgery capability.²⁴⁷ Fulfilling these requirements is not feasible in more than a few

hospitals; in one survey, less than 25% of hospitals in the United States have the needed capabilities.²⁶³

To increase the availability of primary PCI, various strategies have evolved to reduce delay by rapidly bringing patients to hospitals with PCI capability or performing the procedure in smaller hospitals without cardiac surgery capabilities. The PRAGUE-2 trial of 850 patients showed safety and feasibility of rapid transport of patients without antecedent thrombolysis to larger centers for performance of primary PCI, although the decrease in mortality was not statistically significant (6.8% versus 10%; $P = .12$).²⁶⁴ These results presaged the results in the larger DANAMI-2 trial, in which coordinated transport of patients was implemented to PCI centers dispersed throughout Denmark. In this trial, 1572 patients were randomly assigned to treatment with either fibrinolysis or primary PCI. Patients presenting to hospitals without PCI capability were transported immediately by ambulance to the nearest PCI center. The primary end point was the composite of death, reinfarction, or stroke at 1 month. Transport for PCI was superior to fibrinolysis for patients in aggregate presenting to referring hospitals (mortality being 8.5% versus 14.2%; $P = .002$).²⁶⁵

The results from these two trials led some authors to suggest that integrated transport systems involving the bypass of closer non-PCI hospitals should be implemented modeled on the "level 1 trauma center" precedent in place in the United States. The average distance for transport to a PCI center in DANAMI-2 was 35 miles with a very short average transport time (32 minutes; interquartile range 20 to 45 minutes), ensuring a short symptom onset-to-balloon time of 224 minutes for patients requiring transport to a PCI center. Because of the larger geographic distances outside of the densely populated areas of western Europe or the American Atlantic seaboard, and the increase in the direct costs of a regional rapid transport initiative, the implementation of a DANAMI-2 system has not been widespread. Sporadic efforts have been undertaken, however, with good results in the United States.²⁶⁶ The average door-to-balloon time for patients who were initially transported for primary PCI in NORMI was 180 minutes, and only 4.2% were transported in less than 90 minutes.²⁶⁷ When short transfer times are feasible, and primary PCI can be performed without a delay of more than 60 minutes compared with when the patient could have been treated with a fibrinolytic drug, transfer is reasonable.

An alternative to rapid transport of patients for primary PCI is performance of PCI in hospitals that lack cardiac surgery capabilities. In the C-PORT trial, Aversano and colleagues²⁶⁸ conducted a study of 451 patients in rural Massachusetts and Maryland in which patients were randomly assigned to undergo PCI or fibrinolysis at hospitals without cardiac surgery capabilities. Before the study, the 11 centers participating were required to implement a program designed to develop a PCI approach consistent with modifications of the ACC/AHA guidelines. Some modifications, such as those requiring the operators to perform a minimum of only 50 cases per year, differed from the formal guidelines. Other requirements, such as new standards for nursing and catheterization laboratory technicians, were employed by the investigators to ensure quality and safety. The study's primary end point was the composite of death, reinfarction, or stroke at 6 months. In the PCI arm, no patients required emergency cardiac surgery secondary to a complication. Patients who underwent PCI fared better than patients treated with a fibrinolytic drug (12.4% versus 19.9%; $P = .03$).²⁶⁸ The high event rates in both arms of the study have made implementation of the strategy characterized controversial.

The capacity to perform primary PCI without surgical backup has been adopted only on an erratic basis in the United States. The ACC/AHA guidelines recommend primary PCI with the absence of on-site surgery with only a class IIb recommendation. Caveats include the hospital personnel and operators being experienced, and the presence of an established plan for rapid transport to a surgical center if a complication should occur.

In concert, the observations reviewed indicate that primary PCI is the preferred strategy for patients presenting with STEMI as long as the procedure can be implemented promptly (generally considered to be <90 minutes from presentation by experienced operators at experienced facilities). This strategy was given the highest recommendation with the strongest level of evidence by the writing committee of the ACC/AHA in the latest iteration of the consensus guidelines published in 2004.²⁴⁷

Ancillary Therapy for Primary Percutaneous Coronary Intervention

Coinciding with the evolution of sophisticated techniques and technology enhancing the efficacy of primary PCI was the evolution of medical therapy used concomitantly with PCI. The goal of such conjunctive medical therapy is to enhance safety (i.e., minimize hemorrhagic risk and safely inhibit the coagulation system to prevent abrupt thrombotic vessel closure before, during, and in the early interval after PCI). Anticoagulants are agents used to inhibit directly or indirectly individual or multiple plasma proteins in the coagulation cascade. Antiplatelet therapies either prevent platelet activation by antagonizing substances that activate platelets (including ADP, cyclooxygenase, and thrombin) or inhibit platelet aggregation by neutralizing surface antigens that are responsible for platelet-fibrinogen-platelet cross-linking. Effective conjunctive medical therapy should inhibit the plasma protein-based coagulation system and the activation and aggregation of platelets. Adjunctive medical therapy differs from conjunctive therapy and is designed to limit the consequences of myocardial ischemia, enhance myocardial healing, and confer tissue protection.

Orally Active Antiplatelet Agents

Aspirin

Aspirin is an irreversible inhibitor of the cyclooxygenase pathway pivotal in the cascade of platelet activation. Unless they are allergic to aspirin, patients presenting with STEMI should be given 162 to 325 mg of aspirin as early as possible and should continue on aspirin indefinitely. ISIS-2 showed a significant decrease in 35-day mortality (11.1% versus 9.2%; $P < .001$) for patients randomly assigned to aspirin compared with placebo.⁶⁰ In the setting of PCI, aspirin decreases the incidence of periprocedural Q wave MI compared with placebo (6.9% versus 1.6%; $P = .013$).²⁶⁹

Platelet Adenosine Diphosphate Receptor Inhibitors

Results in multiple large trials have established that platelet ADP receptor antagonism with P2Y₁₂ receptor inhibitors is beneficial in the setting of elective PCI and PCI for acute coronary syndromes.²⁷⁰⁻²⁷² The CLARITY trial studied 1863 patients undergoing PCI after mandated angiography in the CLARITY-TIMI 28, a randomized, double-blind, placebo-controlled trial of clopidogrel in patients given fibrinolytic drugs for treatment of STEMI. Results showed that patients given 300 mg initially and 75 mg daily of clopidogrel along with a fibrinolytic drug at presentation to the hospital and who subsequently underwent PCI had lower mortality and incidence of reinfarction or stroke at 30 days (6.2% versus 3.6%; $P = .008$) compared with patients not treated with clopidogrel.²⁷³

Clopidogrel undergoes processing in the liver yielding an active metabolite. Its effect on platelet inhibition may not occur for 12 hours with a load of 300 mg. A 600-mg load has been shown to be more effective in rapidly inhibiting platelet aggregation and improving clinical outcomes in patients with acute coronary syndromes,²⁷⁴ although no further benefit is seen with an increased load of 900 mg.²⁷⁵ The use of clopidogrel before PCI without antecedent fibrinolysis has not been studied in large numbers of patients. Nonetheless, it seems likely that patients who are to undergo primary PCI should be given a loading dose of 600 mg immediately (i.e., in the emergency department) and 75 mg daily thereafter. Two other platelet ADP receptor inhibitors—ASD 6140 and prasugrel—are currently undergoing evaluation in phase III studies under conditions in which patients with acute coronary syndromes are undergoing PCI.

Intravenously Administered Agents

Glycoprotein IIb/IIIa Inhibitors

The only compound in the class of GP IIb/IIIa inhibitors that has been studied in large clinical trials in the setting of primary PCI is abciximab. Abciximab is a chimeric antibody to the GP IIb/IIIa receptor that strongly and irreversibly binds to the receptor. In five trials involving 3666 patients, of which only 1843 patients were enrolled in the abciximab arms,²⁷⁶⁻²⁸⁰ none had power adequate enough to delineate a cardiovascular mortality effect. Patients given abciximab had higher pre-PCI, infarct-related artery patency rates, better 6-month left ventricular ejection fraction, and less need for urgent target vessel revascularization. Controversy still exists regarding the timing of the administration of this agent. Some trials have shown that starting abciximab upstream (in the emergency department) before transport of the patient to the catheterization laboratory improves infarct-related artery patency before definitive revascularization. This benefit has not been reflected by significant differences in 1-year outcomes, however.²⁸¹

Eptifibatide and tirofiban are two other commercially available intravenous GP IIb/IIIa inhibitors available in the United States. Although proven to be effective in the setting of non-STEMI and unstable angina pectoris, definitive studies on outcomes in the setting of STEMI have yet to be performed. Eptifibatide increases the incidence of infarct-related artery patency at angiography when administered before transport of the patient to the catheterization laboratory.²⁸²

Platelet Adenosine Diphosphate Receptor Inhibitors

Cangrelor is an investigational intravenously administered small molecule that is an ADP receptor antagonist that is metabolized by vascular endothelium. Its pharmacokinetics are unique. It has a rapid onset of action, measured in minutes, with a half-life in blood of 3 to 5 minutes and a platelet inhibitory effect of only 50 to 70 minutes' duration after discontinuation. Its advantages over an alternative platelet ADP inhibitor, clopidogrel, include more complete and more rapid inhibition of platelet ADP receptors and potentially lower bleeding risk given the short duration of effect. The CHAMPION-PCI trial is a phase III investigation of the use of cangrelor compared with clopidogrel in 9000 patients undergoing PCI for treatment of acute coronary syndromes, including STEMI.

Intravenously Administered Antithrombotic Therapy

The initiation of the coagulation cascade results ultimately in the formation of thrombin that subsequently converts fibrinogen to fibrin and activates platelets mediated via surface receptors specific for thrombin. Antithrombotic agents include numerous compounds that inhibit the proteins involved in the coagulation cascade, activation of platelets, or both at one or many loci.

Unfractionated Heparin

Despite 40 years of history of the use of unfractionated heparin in treatment of patients with STEMI, little data inform the rationale for its use when primary PCI is to be undertaken. The use of unfractionated heparin plus aspirin as conjunctive therapy is inferior compared with their combination with abciximab, the first platelet GP IIb/IIIa antagonist that became available. When used as conjunctive therapy in combination with GP IIb/IIIa inhibitors, unfractionated heparin should be given as a bolus in a weight-adjusted dose of 50 to 70 U/kg to target an activated coagulation time of 200 seconds.²⁸³

Low-Molecular-Weight Heparins

Compared with unfractionated heparin, LMWH is easier to administer because subcutaneous depot injections with weight-adjusted dosing is effective. Additionally, the anticoagulant effects are more predictable, and use of LMWH does not require frequent partial thromboplastin time testing for monitoring. LMWH has been studied most thoroughly in patients with STEMI with respect to utility as conjunctive therapy with thrombolysis. No large clinical trials have directly compared any of the antithrombins in patients scheduled to undergo primary PCI. There have been some alarming reports of catheter-induced and guidewire-induced thrombosis in patients who were given LMWH as conjunctive antithrombotic therapy for scheduled PCI²⁸⁴ or primary PCI for treatment of STEMI.²⁸⁵

LMWH cannot be strongly recommended based on the limited data available compared with unfractionated heparin when used in conjunction with GP IIb/IIIa inhibitors in the setting of

primary PCI. The ACC/AHA guidelines discourage the use of LMWH for treatment of STEMI in patients older than 75 years or with renal insufficiency.

Direct Thrombin Inhibitors and Pentasaccharides

Bivalirudin is a bivalent direct thrombin inhibitor that is given intravenously, usually with a bolus load and continuous infusion. As is the case with LMWH, it is unnecessary to follow partial thromboplastin times for monitoring. The only currently approved indication for use of bivalirudin is in the setting of PCI in low-risk patients^{286,287} or as conjunctive therapy with thrombolysis for patients with an allergy to heparin or with heparin-induced thrombocytopenia. Bivalirudin has been shown to be equivalent to heparin alone as a conjunctive agent for thrombolysis.²⁸⁸ The ACUITY trial randomly assigned 13,819 patients with high-risk acute coronary syndromes (except STEMI) to bivalirudin or unfractionated heparin plus a GP IIb/IIIa inhibitor. The primary end point of this noninferiority trial was combined efficacy with respect to mortality, reinfarction, or stroke and a safety end point of bleeding. There were no significant differences with respect to the primary end point, and bivalirudin caused significantly less bleeding (3% versus 5.7%; $P < .001$).²⁸⁹

Fondaparinux is a synthetic factor Xa (indirect acting requiring interaction with antithrombin III) inhibitor that is given once daily in a fixed dose without the need for monitoring. Although fondaparinux was proven to be effective in patients who are given thrombolytic drugs in reducing mortality and the incidence of reinfarction compared with conjunctive therapy with heparin, it was found to be inferior to heparin in patients undergoing primary PCI.¹⁸² Because of previous reports of catheter-associated and wire-associated thrombosis when fondaparinux alone was used as conjunctive therapy for PCI, unfractionated heparin was used as conjunctive therapy for PCI that was performed after the index event in this trial. In regions and systems in which most patients with STEMI eventually undergo PCI, either during or after the index event, fondaparinux cannot be recommended as conjunctive therapy either for primary PCI or for use with fibrinolytic agents.

Pharmacoinvasive Strategy for Ensuring Rapid Infarct-Related Artery Patency

The available approaches for urgent treatment of STEMI—fibrinolytics and primary PCI—have been described often as competing strategies. Although numerous trials directly comparing the two have been performed over the last 2 decades, the two approaches are not mutually exclusive. In an editorial in 2003, we used the term *pharmacoinvasive therapy* to describe various iterations of the combination of fibrinolysis and PCI.²⁹⁰

As noted earlier, the most significant factor determining infarct size and risk of mortality in patients with STEMI is the time to induction of patency of the infarct-related artery after the onset of ischemia. Primary PCI (without antecedent fibrinolysis) with a brief door-to-balloon time of less than 90 minutes has proven to be the single approach to reperfusion with the fewest complications and the most preservation of left ventricular function with minimization of the incidence of major adverse events.²⁴⁶ The infrastructure required is not available at many

Figure 12-8. Hospital mortality over time. The reliance on pharmacoinvasive therapy entails the rational use of the combination of percutaneous coronary intervention with thrombolysis.

medical facilities, however; this, combined with long transport times and distances in many areas, precludes widespread use of this therapy.

In terms of sheer numbers, fibrinolytic therapy is still the de facto predominant strategy used for treatment of STEMI in the United States and worldwide. Limitations in terms of the capability of fibrinolysis to restore fully or at least maintain infarct-related artery patency compared with PCI result, however, in more than 80% of patients in the United States undergoing cardiac catheterization after fibrinolysis.²⁹¹ Results of more recent trials show the benefit of delayed PCI after thrombolysis.^{292,293} A pharmacoinvasive strategy that encompasses both is attractive. Application of the combined approach should be based on a rational process focusing on consideration of factors such as time to treatment and the clinical status of an individual patient. Such considerations can maximize the advantages of each of the two strategies—the widespread availability of fibrinolysis and the definitive revascularization of an infarct-related artery with PCI—while the balance is maintained with respect to the risk-benefit equation and minimizing harm to patients.

We and many others have adopted an evolving pharmacoinvasive strategy since the late 1990s, which has periodically changed over the years to incorporate methods and practices based on knowledge gained in the latest trials of treatment of patients with STEMI. Analysis of results in more recent registries suggests that wider adoption of a pharmacoinvasive approach can lead to remarkably low mortality for patients with STEMI (Fig. 12-8).

Given the mounting evidence supporting the practice, we believe that all patients with STEMI—whether or not they are treated with fibrinolytic agents—should undergo coronary angiography and mechanical revascularization if necessary as judged from the anatomy uncovered. Our proposed approach is depicted in Figures 12-9, 12-10, and 12-11. The timing to coronary angiography and intervention is predicated on the clinical status of the patient at the time when reperfusion would be expected after administration of fibrinolytic drugs. The practice of routinely performing PCI for patients immediately after fibrinolysis (so-called facilitated PCI) is not recommended based on results in the ASSENT-4 trial (Fig. 12-12), which was stopped prematurely because of an excess incidence of events in the active arm of the trial.²⁹⁴ As judged from all the data available, however, we believe that all PCI-eligible patients who present to a hospital without PCI capabilities should be transported

immediately to a PCI-capable hospital, either immediately after administration of fibrinolytic drugs or immediately on presentation if transfer times can be anticipated to be short enough to ensure an initial hospitalization door-to-balloon time of less than 90 minutes.

Rescue Percutaneous Coronary Intervention

Many patients treated with modern fibrinolytic drugs manifest prompt reperfusion with normalization of coronary blood flow in the infarct-related artery accompanied by complete resolution of symptoms and ECG changes. Contingency therapy for patients who do not manifest prompt reperfusion has been controversial, however. Until more recently, there has been widespread hesitation to “rescue” patients with failed fibrinolytic therapy because of a perceived increased hazard of major hemorrhage as observed in earlier trials of obligatory PCI after thrombolytic/fibrinolytic therapy.^{242,243} Many investigators advocated reinstallation of fibrinolytic drugs or medical therapy alone and no invasive intervention to modify evolution of the infarct.

Preliminary evidence supporting the strategy of rescue PCI for patients without fibrinolytic drug-induced reperfusion came from the MERLIN trial. It included 307 patients randomly assigned to either conservative therapy, including repeat fibrinolysis, or immediate angiography with or without PCI. Although there was only a numerical trend favoring rescue PCI for the primary end point of 30-day mortality (9.8% versus 11%; $P = .70$), rescue PCI was superior to conservative treatment with respect to the combined secondary end point of death, reinfarction, stroke, heart failure, and urgent revascularization.²⁹⁵ The benefit was driven mostly by a decreased incidence of urgent revascularization that remained robust at 6-month, 1-year, and 3-year follow-up.²⁹⁶

These results were corroborated by results in the larger REACT trial comprising 427 British patients. Results in the REACT trial showed lower mortality in patients undergoing rescue PCI compared with the combined medical therapy or repeat thrombolysis treatment groups (hazard ratio 0.48, 95% CI 0.23 to 0.99).²⁹⁷ A meta-analysis of results from trials addressing rescue PCI when PTCA was prominent and after stents became available was published in 2007. Its results indicated less heart failure and reinfarction in patients who had undergone rescue PCI and a strong trend toward lower mortality (Fig. 12-13) in the trials with stenting.²⁹⁸

Figure 12-9. Overview of pharmacoinvasive therapy.

Figure 12-10. Initial pharmacoinvasive management. PCI, percutaneous coronary intervention.

If a patient who has been given fibrinolytic drugs presents to a hospital with PCI capabilities with ongoing signs or symptoms of ischemia, manifested as persistent angina, unresolved (<70%) ST segment elevation²⁹⁹ on an arrival ECG, or hemodynamic or electrical instability, the patient should be transported

immediately to the cardiac catheterization laboratory for prompt angiography and possible intervention. Conjunctive therapy in this setting is controversial. Patients will likely have been given antithrombotic agents (with the possible exception of patients who had been treated with SK) with either unfractionated

Figure 12-11. Pharmacoinvasive management after fibrinolysis. PCI, percutaneous coronary intervention; STEMI, ST segment elevation myocardial infarction.

Figure 12-12. ASSENT-4 PCI. $P = .0042$ for the two curves, log-rank test. CHF, congestive heart failure; PCI, percutaneous coronary intervention. heparin or LMWH. Additionally, aspirin and clopidogrel are likely to have been given. The controversy focuses on whether to add intravenous GP IIb/IIIa inhibitors to enhance inhibition of platelet aggregation in the face of a potential increase in the risk of bleeding in a patient with an ongoing fibrinolytic state.¹⁸⁰ Our recommendation is to add this therapy in the catheterization laboratory only if massive coronary thrombosis is seen on angiography. Otherwise, PCI should be performed without administration of additional antiplatelet agents.

Consolidation Percutaneous Coronary Intervention

As noted previously, intravenous thrombolysis can increase the risks of coronary angiography and intervention by affecting hemostasis. Thrombolysis and treatment with unfractionated heparin can paradoxically increase platelet activation in this setting.^{300,301} Patients are at increased risks of bleeding and thrombosis if they undergo instrumentation soon after thrombolysis.

Studies of PCI after resolution of the lytic state have shown, however, that PCI induced at this time is safer with less bleeding and lower thrombotic risk.^{242,302} Coronary angiography followed by revascularization was proven to be superior in patients with spontaneous or inducible ischemia in the Danish trial by Madsen and associates.³⁰³ They found that this intervention resulted in a lower incidence of reinfarction and decreased subsequent hospital admissions for unstable angina (10.5% versus 5.6%; $P = .038$ and 29.5% versus 17.9%; $P < .0002$) in contrast to medical treatment alone. Previous guidelines recommended that only patients who have symptomatic or inducible ischemia after thrombolysis undergo angiography and possible PCI. Because PCI early after thrombolysis can establish recanalization when lysis has failed and can consolidate benefit when it has succeeded, we prefer to refer to it as consolidating PCI and support its use.

Under conditions in which coronary stenting and advanced conjunctive therapy are available, the approach may differ. Improved efficacy and safety and a reduction in the incidence of urgent revascularization and reinfarction have been seen in patients undergoing consolidating PCI. Collet and associates³⁰⁴ reported results from the three major trials addressing this issue in a meta-analysis involving a 832 patients. Consolidation PCI was associated with a strong trend of decreasing mortality (OR 0.55, $P = .07$) and significantly lower risk for the combined end point of death and reinfarction (13.2% versus 7.5%; $P = .0067$) without a significant increase of the risk of major hemorrhage or stroke. All three of these recent trials showed similar and a consistent extent of benefit (Fig. 12-14). These results differed markedly from the results in earlier trials of consolidation PCI when PCI meant PCTA. We believe that all patients treated with thrombolytic drugs should undergo angiography early (12 hours is optimal) after initial treatment.

Data from OAT have called into question the practice of “routine” PCI in stable patients presenting at least 3 days after their index event. The patients studied had to have at least one high-risk characteristic, such as diminished left ventricular function or proximal vessel occlusion. Only 20% of the patients in the trial had been treated with antecedent thrombolytic drugs, and none had undergone primary PCI. The patients were not randomly assigned until after angiography. The trial showed no differences in mortality, the incidence of reinfarction, or subsequent heart failure in the routine PCI group compared with the medical therapy group (Fig. 12-15).³⁰⁵

Patients given thrombolytic drugs who experience prompt reperfusion often have residual stenosis in the infarct-related artery. Such patients would not have been randomly assigned in OAT. Results from this trial do not obviate our recommendation for performing consolidating PCI.

Facilitated Percutaneous Coronary Intervention and ASSENT-4

The performance of PCI as soon as possible after thrombolysis has been termed *facilitated PCI*.³⁰⁶ As noted earlier, invasive instrumentation of patients may not be made easier when a lytic state is present, however, and a lytic state may make PCI more difficult and place the patient at higher risk of complications such as bleeding or thrombosis. For this reason, it would seem that only patients in clinical situations of risk that outweigh the procedural risks should undergo immediate postlysis PCI (rescue PCI).

Figure 12-13. Meta-analysis of studies comparing rescue percutaneous coronary intervention (PCI) with medical therapy (including repeat thrombolysis) for failed thrombolysis. PCI seems to be superior. CI, confidence interval; NNT, number needed to treat; RR, relative risk. (Data from Wijeyesundera HC, Vijayaraghavan R, Nallamothu BK, et al: Rescue angioplasty or repeat fibrinolysis after failed fibrinolytic therapy for ST-segment myocardial infarction: a meta-analysis of randomized trials. *J Am Coll Cardiol* 2007;49:422-430.)

The possible use of a combination of half-dose thrombolytic therapy and GP IIb/IIIa inhibitors was anticipated to improve outcomes in patients with STEMI. Encouraging results of the combination from GUSTO V and ASSENT III showed a lower incidence of complications secondary to ischemia and better infarct-related artery flow at follow-up angiography.^{180,307} There was an increased incidence of nonintracranial bleeding, however, especially in elderly patients, which may limit the applicability of the combination. Given the investigators' observation that patients with better pre-PCI infarct-related artery flow had better outcomes, many investigators have been led to believe that the combination would be ideal for pre-PCI pharmacotherapy in all patients.

Facilitated PCI has been examined in two more recent trials. Because of a slow rate of enrollment, the ADVANCE AMI trial was stopped prematurely after only 148 of a planned total of more than 5500 patients had been randomly assigned. This trial

investigated the use of half-dose fibrinolytic therapy in combination with eptifibatide. Despite the low numbers, the study showed increased bleeding risks with the combination and better coronary flow, similar to the patterns of results in previous studies.³⁰⁸ ASSENT IV randomly assigned patients to either primary PCI or PCI "facilitated" by fibrinolytic therapy given immediately before transfer of patients to the catheterization laboratory (Table 12-9). After only 1600 of the planned 4000 patients had been enrolled, the study was stopped prematurely by the data safety monitoring board because of increased in-hospital mortality in the facilitated PCI arm (6% versus 3%; $P = .0105$). The incidences of stroke, reinfarction, and urgent target vessel revascularization were unexpectedly higher as well in the treatment arm.²⁹⁴

Routine use of fibrinolytic therapy immediately before PCI cannot be recommended. Investigation of "facilitated PCI" is still incomplete. The FINESSE study is currently enrolling patients into three arms—primary PCI, half-dose fibrinolytic

Figure 12-14. Meta-analysis of trials of consolidation percutaneous coronary intervention (PCI) compared with ischemia-guided PCI after thrombolysis. There was a nonsignificant trend for less mortality with consolidation PCI after the advent of stenting. There was lower mortality and less reinfarction with consolidation PCI. PTCA, percutaneous transluminal coronary angioplasty. (Data from Collet JP, Montalescot G, Le MM, et al: Percutaneous coronary intervention after fibrinolysis: a multiple meta-analyses approach according to the type of strategy. *J Am Coll Cardiol* 2006;48:1326-1335.)

drug administration plus abciximab, or early administration of abciximab alone before PCI.

Special Considerations

Elderly Patients

Although primary PCI is highly recommended in ACC/AHA clinical guidelines for the treatment of STEMI, data on which the recommendation is based are sparse. Completed trials have included few patients older than 75 years, and many clinical studies have considered advanced age as an exclusion criterion.³⁰⁹ Risks associated with thrombolysis are greater in elderly patients, who exhibit higher incidences of bleeding, intracranial hemorrhage, heart failure, and cardiogenic shock. The frequencies of comorbidities such as cancer and lung disease are also increased. Determinants of complications related to thrombolysis include age older than 75 years as a factor as powerful as

Table 12-9. Results within 90 Days of Randomization in ASSENT-4

	Tenecteplase and PCI (n = 829)	PCI alone (n = 838)	P
Mortality	7%	5%	NS
Congestive heart failure	12%	9%	NS
Shock	6%	5%	NS
Reinfarction	6%	4%	.0279
Repeat target vessel revascularization	7%	3%	.0041
Rehospitalization for congestive heart failure	2%	1%	NS
Rehospitalization for shock	0%	<1%	NS
Rehospitalization for another cardiac reason	10%	11%	NS

NS, nonsignificant; PCI, percutaneous coronary intervention.

Data from Primary versus tenecteplase-facilitated percutaneous coronary intervention in patients with ST-segment elevation acute myocardial infarction (ASSENT-4 PCI): randomised trial. *Lancet* 2006; 367:569.

uncontrolled hypertension or low body weight.^{310,311} Results in some studies have indicated a 10-fold increased risk of adverse events and mortality in very elderly patients (>85 years old).³¹² In national registries, many elderly patients who might otherwise be eligible for thrombolysis are treated instead with a medical regimen devoid of fibrinolytic drugs to circumvent the increased risk.

Subset analyses in large multicenter trials have addressed the issue of primary PCI compared with thrombolysis in patients older than 75 years. Trends were evident in favor of primary PCI with respect to short-term mortality, as were significant decreases in the combined end point of death, recurrent MI, or stroke.^{253,254,313} Results in relatively small trials focusing on elderly patients have shown similar trends with respect to decreased mortality and significantly less reinfarction, urgent revascularization, and stroke.³¹⁴⁻³¹⁶ Registries of patients who may not have been eligible for inclusion in clinical trials have identified a substantial benefit favoring primary PCI in elderly patients with respect to mortality favoring primary PCI compared with thrombolysis (OR 0.62, CI 0.36 to 0.96) after adjustment for baseline differences.³¹⁷ A risk-benefit ratio favoring primary PCI in elderly patients has led to recommendations that it be the primary treatment for elderly patients with STEMI at hospitals that meet the same time to treatment and experience criteria as those applicable to the general population. Because of the greater frequency of comorbidities and increased risk of hemorrhage in elderly patients, conjunctive therapy must be judiciously employed with appropriate dose adjustments for weight and renal function. Decisions regarding interventions must be made in the context of careful consideration of factors such as the quality of life and the impact of comorbidities on outcomes and life expectancy.

Cardiogenic Shock

Patients who develop cardiogenic shock associated with MI are at extremely high risk of in-hospital mortality with data from registries documenting mortality ranging from 45% to 60%.³¹⁸⁻³²⁰ Patients with nonmechanical causes of cardiogenic shock, such as acute severe mitral regurgitation or ventricular septal rupture, exhibit better survival when PCI has been implemented as judged from registry data.³¹⁹ The SHOCK trial showed definitively that patients younger than 75 years with myocardial infarction who undergo PCI have lower mortality than that in patients treated conservatively with medical therapy, including thrombolysis. Patients randomly assigned to the PCI arm of this trial had a 9% absolute risk reduction in short-term mortality and a significant reduction in 6-month mortality (50.3% versus 63.1%; $P = .027$).

Although benefit did not pertain to patients older than 75 years as judged from subset analysis, the small number of elderly patients ($n = 56$) in the study limited power for its detection. Data from registries have shown that elderly patients with shock experience comparable benefit from PCI compared with that seen in the overall population, albeit with a “frame shift” in mortality to a higher range (i.e., 70% to 80%).^{318,321} ACC/AHA guidelines designate PCI for treatment of cardiogenic shock as a class 2 recommendation with the highest level of evidence for patients younger than 75 years. For elderly patients, the designation is class IIa with the caveat that patients should be carefully selected.

Conclusion

Results obtained in studies of coronary thrombolysis established the principle that reperfusion, induced without the need for surgical intervention, improved survival in patients with STEMI. It remains an appropriate approach in settings in which primary PCI cannot be pursued expeditiously. Achieving optimal results with primary PCI depends on inducing revascularization of the infarct-related artery within 90 minutes after presentation of the patient to the hospital. Implementation of primary PCI is appropriate for patients presenting to an interventional center or patients who can be transported to one via helicopter or ambulance within 30 minutes. For patients presenting to institutions that cannot meet these criteria, patients who have no contraindication to thrombolysis should be treated with full doses of fibrinolytic drugs, aspirin, clopidogrel, and heparin.

Thrombolysis is unsuccessful or associated with reinfarction in 30% of patients with STEMI. When thrombolysis fails, the best strategy is induction of reperfusion with PCI. Patients in whom thrombolysis has not induced revascularization should be transferred immediately to an interventional cardiology center. Prompt PCI can be implemented if ischemia persists or recurs in the first 24 hours after the onset of infarction.

In patients who have undergone attempted thrombolysis and transfer, angiography and PCI should be performed immediately if revascularization has not been accomplished or recurrent infarction is imminent or in progress as judged from ST segment elevation or ongoing chest pain. Immediate PCI should not be performed routinely in patients in whom thrombolysis has been successful—an intervention referred to generally as facilitated PCI. Instead, we believe the recommendations of the European PCI Guidelines are most appropriate. They suggest “early, but nonemergency PCI” under these circumstances for

patients with either STEMI or non-ST segment elevated MI: they endorse performance of PCI within 12 to 24 hours after presentation of the patient to the interventional cardiology center to define coronary anatomy and prevent recurrent infarction in susceptible patients who have undergone successful PCI for treatment of STEMI.

In settings in which primary PCI can be implemented consistent with the criteria outlined in the text, it should be the therapeutic modality of choice; we endorse the 2005 ACC/AHA PCI Guidelines, which hold that a volume/outcome relationship applies to PCI in general and primary PCI in particular. Operators should meet specific volume requirements to increase the likelihood that quality would be optimal 24 hours a day, 7 days a week. The volume requirements noted are more than 11 primary PCI procedures annually for the operator, more than 36 primary PCI procedures annually for the institution, and more than 75 general PCI procedures annually for the operator.

Appropriate adjunctive and conjunctive therapy should be implemented, including administration of aspirin, clopidogrel, and heparin for all patients with STEMI. The use of unfractionated heparin as opposed to LMWH depends on the clinical situation, with advanced age, the presence of renal failure, and planned primary PCI rather than fibrinolysis supporting its use. The use of intravenously administered β blockers depends also on the clinical circumstances, with factors likely to precipitate hemodynamic instability, such as advanced age, militating against their use. Generally, the use of statins, orally administered β blockers, and angiotensin-converting enzyme inhibitors in the first 24 hours after the onset of STEMI is appropriate.

With prompt revascularization as the linchpin of therapy for STEMI, 30-day mortality is 2% in clinical trials and is 5% to 10% in clinical practice. The major risk factor for mortality after STEMI is the development of cardiogenic shock. Even in the setting of successful, early infarct artery revascularization, a patient with cardiogenic shock has a mortality risk of 30% or greater (with an increasingly greater risk with advanced age). Because the incidence of cardiogenic shock varies widely from institution to institution, caution must be exercised with respect to the use of absolute mortality as a comparator for programmatic success. Comparisons of the efficacy of diverse programs and the extent to which they meet best practice standards should be based on risk-adjusted mortality and surrogate markers of quality (e.g., time to open artery).

Adjunctive Pharmacologic Therapies in Acute Myocardial Infarction

CHAPTER 13

Jonathan P. Man, Wayne J. Tymchak, Bodh I. Jugdutt

Aspirin	Free Radical Scavengers
Thienopyridines	Morphine
β -Adrenergic Blockers	Glycemic Control and Insulin
Nitrates	3-Hydroxy-3-methylglutaryl Coenzyme A Reductase Inhibitors or Statins
Angiotensin-Converting Enzyme Inhibitors and Other Renin-Angiotensin-Aldosterone System Inhibitors	Anticoagulants
Calcium Channel Blockers	Antioxidants, Vitamins, and Natural Supplements
Magnesium	Conclusion
Lidocaine	

ADJUNCTIVE PHARMACOLOGIC therapies play an important role in the management of patients with acute myocardial infarction (MI). It became increasingly clear 2 decades ago that primary management of patients with acute MI should be aimed at the occlusive coronary thrombus,¹ and should include early reperfusion therapy with thrombolytic agents or mechanical devices.^{2,3} Because not all patients could be reperfused within 2 hours of onset of coronary thrombosis,⁴ however, the goal of early and complete reperfusion could not be achieved in everyone.^{5,6} Late reperfusion is associated with myocardial stunning or persistent left ventricular dysfunction,^{7,8} and early but incomplete reperfusion might be harmful.⁶

Evidence accrued during the last 2 decades supports the use of adjunctive pharmacologic therapies in addition to therapies used to reperfuse directly the infarct-related artery and tissue (i.e., conjunctive) for managing acute MI patients.⁹⁻¹² These adjunctive therapies should be considered as alternative therapy for patients in whom thrombolytics are contraindicated, for widening the time window for reperfusion when therapy cannot be instituted early, for reducing reperfusion injury in patients given late reperfusion therapy, and for achieving complete reperfusion. The ultimate goal of therapy for acute MI, whether primary or adjunctive, is to preserve myocardium and myocardial geometry and function, decreasing cardiovascular morbidity and mortality. Specifically, the aims of adjunctive therapy are to limit consequences of ischemia or infarction, optimize healing, and reduce adverse and recurrent events.

The scope of post-MI adjunctive therapy has expanded as a result of evidence accrued over the last decade related to the following five main factors: (1) the redefinition of acute coronary syndromes to include unstable angina, non-ST segment elevation MI (NSTEMI), and ST segment elevation MI (STEMI)¹³⁻¹⁵; (2) the implementation of troponin as the preferred novel biomarker of necrosis¹⁶; (3) the implementation of novel therapeutic strategies for limiting adverse remodeling during and after

healing post-MI¹⁷⁻²⁵; (4) recognition that MI is the central event in the cardiovascular disease continuum extending from risk factors and coronary atherosclerosis to heart failure and death²⁶; and (5) recognition of the higher risk of elderly patients with MI.^{27,28}

Acute coronary syndromes result from plaque disruption leading to thrombus formation.²⁹ Most patients with STEMI have an occlusive thrombus^{1,30} and develop a Q wave MI (previously termed *transmural*), whereas most patients with NSTEMI have a nonocclusive or mural thrombus and develop non-Q wave MI (previously termed *nontransmural* or *subendocardial*).³¹⁻³³ A few patients with ST segment elevation may develop non-Q wave MI, and a few with non-ST segment elevation may develop Q wave MI. More patients present with NSTEMI than STEMI, and NSTEMI can be difficult to differentiate from unstable angina on presentation. Transmural or Q wave MIs, or STEMI, result in more severe ventricular remodeling and dysfunction,^{17,34,35} however, and high mortality and morbidity.³³ Early and successful reperfusion interrupts the “march to necrosis” and transmural extension as a “wavefront” from endocardium to epicardium,³⁶ preserving most epicardial and some subendocardial myocardium and extracellular matrix and limiting ventricular remodeling.¹⁹⁻²¹

In the era before reperfusion, most MI studies focused on STEMI or Q wave MI. Ideally, all STEMI patients should receive immediate pharmacologic or catheter-based reperfusion therapy,⁹⁻¹¹ whereas NSTEMI patients are not considered candidates for immediate catheter-based reperfusion and should have received anti-ischemic, antiplatelet, and antithrombotic therapy, and may subsequently require catheter-based therapy.¹² Patients with new bundle branch block are considered candidates for reperfusion based on fibrinolytic trial data.³⁷

In a national registry of 240,980 patients with acute MI from 1073 hospitals in the United States during 1990-1993, only 35% received thrombolytic therapy.⁴ The patients who were given thrombolytics in the study⁴ also received concomitant

pharmacotherapy with intravenous heparin (96.9%), aspirin (84%), intravenous nitroglycerin (76%), oral β -blockers (36.3%), calcium channel blockers (29.5%), and intravenous β -blockers (17.4%). In the study,⁴ 65% of the patients were not given thrombolytic therapy and were treated entirely with adjunctive pharmacologic therapies.

Use of reperfusion therapy in acute MI and adjunctive therapy after MI have increased over the last decade. In one registry from 1994-2003,³⁸ nearly 90% of STEMI patients received acute reperfusion. In another registry of NSTEMI and STEMI patients receiving acute percutaneous coronary intervention (PCI) during 1999-2004,³⁹ the discharge medications in the two groups were angiotensin-converting enzyme (ACE) inhibitor, 50.3% versus 63%; aspirin, 95.1% versus 95.8%; β -blocker, 83.8% versus 88.6%; statin, 71.1% versus 73.4%; and thienopyridine, 89.6% versus 88.2%. In the national registry of MI during 1994-2003,⁴⁰ there was a steady increase in the use of adjunctive agents such as aspirin, β -blockers, ACE inhibitors, other antiplatelet agents, and antithrombins within the first 24 hours of STEMI (Fig. 13-1).

Published American College of Cardiology and American Heart Association (ACC/AHA) practice guidelines for management of MI⁹⁻¹² provide expert panel recommendations for initial reperfusion and concurrent or subsequent adjunctive therapies based on a ranking of the clinical evidence into class I, with benefit >>> risk ("should" be used); class II, with benefit >> or $\geq$ risk ("reasonable" or "might be reasonable"); and class III, with risk $\geq$ benefit ("should not" be used, "may be harmful"). There are clinical scenarios, however, in which deviations from these guidelines are considered appropriate.^{11,12} Ultimately, therapy should be tailored to the individual patient profile.

Consistent with the updated guidelines,¹⁰⁻¹² unstable angina/NSTEMI¹² is addressed separately in Chapters 8 and 16, whereas STEMI^{10,11} is addressed here. It is useful to time phases of adjunctive

therapy according to temporal changes after MI, as follows: a very early or acute phase, in the first 12 to 24 hours; a subacute phase during healing, over 1 week to between 6 weeks and 6 months depending on infarct size and other factors; and a posthealing phase, after 1.5 to 12 months.^{19,23} Survivors of STEMI represent a special group of patients at double jeopardy for increased morbidity and mortality, and they stand to benefit from adjunctive therapies and comprehensive secondary prevention (Fig. 13-2).⁴¹

Practice pattern studies reveal suboptimal use of medications and invasive strategies in elderly MI patients (STEMI or NSTEMI) and lack of evidence-based data.^{27,28} Contraindications to reperfusion increase with age, and eligible elderly patients with STEMI are more likely to receive conservative than aggressive reperfusion therapy.²⁸ Most first MIs occur in patients older than 65 years; the average age for a first MI is 66 in men and 70 in women.⁴² Adjunctive therapy plays an important role in elderly patients, but close attention to dosing and complications is needed pending more data. Results of studies on novel adjunctive therapies during the healing phase after reperfused STEMI in elderly patients are awaited.

Aspirin

Low-dose aspirin (acetylsalicylic acid) should be prescribed as adjunctive therapy to all acute MI patients who can tolerate it, including patients with STEMI, NSTEMI, and unstable angina. Platelets are important in thrombus formation after plaque rupture.^{29,43} Early thrombus is composed of a white clot consisting of aggregated platelets and a red clot consisting of fibrin and erythrocytes. Platelets are activated by fibrinolysis, and platelet-rich clots are more resistant to fibrinolysis than fibrin and erythrocyte thrombi. Aspirin is an effective antiplatelet agent that inhibits platelet aggregation.

Figure 13-1. Medications received within the first 24 hours. ACE, angiotensin-converting enzyme. (From Gibson CM: *NRMI and current treatment patterns for ST-elevation myocardial infarction*. *Am Heart J* 2004;148:S29-S33.)

Figure 13-2. Double jeopardy in myocardial infarction (MI) survivors. CAD, coronary artery disease; CV, cardiovascular; CVD, cerebrovascular disease; PAD, peripheral artery disease. (Modified from Jugdutt BI: Valsartan in the treatment of heart attack survivors. *Vasc Health Risk Management* 2006;2:125-138.)

Mode of Action

Taken orally, aspirin is rapidly absorbed in the stomach and small intestine. Aspirin is the only nonsteroidal anti-inflammatory drug (NSAID) to react covalently with the cyclooxygenase (COX) channel of prostaglandin (PG) G/H synthase-1 (now referred to as COX-1 and COX-2) through selective acetylation of serine residues Ser⁵²⁹ in human COX-1⁴⁴ and Ser⁵¹⁶ in human COX-2.⁴⁵ Constitutive COX-1 promotes platelet aggregation, thrombosis, and vasoconstriction, and protects gastrointestinal mucosa (Fig. 13-3).⁴⁶ In contrast, inducible COX-2 is proinflammatory via PGE₂ and antithrombotic and vasodilatory via PGI₂ (prostacyclin) (see Fig. 13-3).⁴⁶

Only a low dose is required to achieve irreversible acetylation of COX-1 in platelets and to block thromboxane A₂ (TXA₂) production and spare PGI₂ synthesis.⁴⁷ Higher doses are not more

effective and might not spare PGI₂.⁴⁷ The effect of aspirin begins within 30 to 40 minutes and lasts for the life of the platelet (7 to 10 days).^{48,49} Nearly complete blockade of TXA₂ can be achieved after 7 to 10 days of a daily dosage of 162 mg or more of aspirin. Side effects with low-dose aspirin, especially buffered tablets, are minimal. The cost is also low.

Dose, Timing, and Benefits

The efficacy of low-dose aspirin in acute STEMI was established in the randomized ISIS-2 trial, which assessed the effects of a 1-hour intravenous infusion of streptokinase (1.5 million U) or oral aspirin (160 mg) or both for 1 month in patients with acute MI presenting within 24 hours of the onset of symptoms.³ By 5 weeks, aspirin reduced nonfatal reinfarction by 50%, nonfatal stroke by 46%, total cardiovascular mortality by 23% (absolute

Figure 13-3. Pathways of prostanoide formation and role of cyclooxygenase-2 (COX-2) in vascular pathophysiology. +, stimulation; -, inhibition; CRP, C-reactive protein; IL-1 β , interleukin-1 β ; iNOS, inducible nitric oxide synthase; MI, myocardial infarction; NF- κ B, nuclear factor- κ B; NO, nitric oxide; PG, prostaglandin; ROS, reactive oxygen species; TNF- α , tumor necrosis factor- α ; TX, thromboxane. (Modified from Jugdutt BL: Cyclooxygenase inhibition and adverse remodeling during healing after myocardial infarction. *Circulation* 2007;115:288-291.)

risk reduction of 2.4%), and the risk of any vascular event by 23%. Reduction of cardiovascular mortality was enhanced by the combination of antiplatelet and fibrinolytic therapy, and cardiovascular mortality was decreased by 25% with streptokinase alone and by 42% with streptokinase and aspirin combined (absolute risk reduction of 5.2%), indicating that low-dose aspirin alone was as effective as streptokinase, and the combination produced synergism. Aspirin therapy might reduce the rate of reocclusion.³ Patients taking aspirin had fewer cardiac arrests, but slightly more minor bleeding. Aspirin did not increase the risk of cardiac rupture or bleeding requiring transfusion.

ISIS-2 was not only the largest aspirin trial in STEMI patients, but also the trial with the most robust evidence that aspirin reduces mortality in STEMI patients.³ Mortality reduction was similar in patients treated within 4 hours (by 25%), between 5 and 12 hours (by 21%), and between 13 and 24 hours (by 21%). A subsequent meta-analysis of MI trials using aspirin and the thrombolytics streptokinase and alteplase showed that aspirin reduces coronary reocclusion and recurrent ischemic events.⁵⁰

On presentation, STEMI patients should be started on 162 to 325 mg of aspirin followed by 81 to 162 mg daily indefinitely (Table 13-1).^{10-12,51} Non-enteric-coated aspirin should be used initially and chewed to ensure rapid buccal absorption.^{52,53} Long-term aspirin therapy for secondary and primary prevention has

Table 13-1. Dosing for Oral Antiplatelet Therapy

Drug	Loading Dose (mg)	Maintenance
Aspirin	162-325	75-81 mg or 162 mg daily
Clopidogrel	300-600*	75 mg daily
Prasugrel	60	10 mg daily
Ticlopidine	500	250 mg twice daily

Note: Drugs are listed alphabetically and not in order of preference.

*Depending on interventionalist's preference.

tended to use higher doses,⁵⁴ although a low dose might be equally effective.⁵¹ A meta-analysis of small randomized trials of antiplatelet agents (aspirin, dipyridamole, or sulfinpyrazone, alone or in combination) for secondary prevention in survivors of previous cardiovascular events including acute MI indicated reduction in the risk of nonfatal acute MI by 32%, nonfatal stroke by 27%, total cardiovascular death by 15%, and vascular event by 25%. Aspirin alone was as effective as aspirin combined with another antiplatelet agent.⁵⁵ A lower dose (300 mg daily) was as effective as higher doses (1000 to 1500 mg daily) for secondary prevention. A large U.S. trial on primary prevention showed that a low dose of aspirin (325 mg on alternate days) was highly

effective and decreased the risk of acute MI by 44%.⁵⁶ The resulting recommendation was that 160 mg of aspirin daily be given immediately after acute MI and be considered for primary prevention.

In STEMI patients who have received stents for reperfusion, a higher dose regimen is recommended. Patients with bare metal stents should be given 325 mg of aspirin daily for 1 month; patients with drug-eluting stents should be given 325 mg aspirin daily for 3 to 6 months.⁵⁷ In patients with unstable angina or NSTEMI, aspirin trials show mortality benefit independent of dose, initial timing, and duration of follow-up,⁵⁸⁻⁶¹ and the 2007 ACC/AHA guideline panel recommended decreasing the post-stent aspirin dose from 325 mg to between 162 to 325 mg daily.¹² Aspirin does not prevent restenosis, and its benefits are attributed to prevention of in-stent thrombosis and secondary prevention.⁶² Based on evidence that lower doses of 75 to 150 mg are effective for secondary prevention,^{51,63} a daily dose of 75 to 162 mg indefinitely is recommended for secondary prophylaxis in patients without stents,⁵⁷ and a similar dose is recommended after finishing the higher dose schedule in patients with stents.⁵⁷

The dose range in aspirin recommendations is due to the lack of head-to-head trials comparing the low doses and high doses in patients with acute MI. Although there have been no randomized controlled trials on differing lengths of therapy, STEMI, unstable angina/NSTEMI, and chronic angina guidelines all state that aspirin for secondary prevention should be continued indefinitely.^{10-12,64} Evidence for this recommendation comes from the Antiplatelet Trialists' Collaboration review of 145 randomized controlled trials with aspirin over the long-term in patients with known coronary artery disease, prior stroke, or transient ischemic attack.⁶⁵ There was statistically significant benefit for 2 years, although there was no statistically significant benefit in the third year. There was a 22% reduction in the composite end point of death, nonfatal recurrent infarction, and nonfatal stroke in patients with acute STEMI, patients at risk for STEMI, and patients with documented prior STEMI, with superior benefit in patients with the highest baseline risk.⁶⁵

Adverse Effects

Aspirin can cause gastrointestinal bleeding and intracranial hemorrhage. Long-term or high-dose aspirin and other NSAIDs are associated with increased risk of gastrointestinal bleeding.⁶⁶ Although several studies did not find increased bleeding risk from aspirin dosages of 75 to 325 mg daily,^{51,65,67-69} subset analyses from the nonrandomized CURE and BRAVO trials showed increased risk of bleeding from the low-dose to mid-dose range.^{68,69} Although the Antithrombotic Trialists' Collaboration found no difference in bleeding between aspirin groups given less than 75 mg versus greater than 75 mg daily, there was still a small statistically nonsignificant increase in the risk of bleeding.⁵¹ A meta-analysis of aspirin dosing in cardiovascular prevention and side effects revealed no difference in bleeding risk with daily dose ranging from medium (75 to 162 mg) to low (<75 mg).⁶⁷ Collective evidence supports low-dose aspirin (75 to 81 mg) for long-term use.⁷⁰

Patients unable to tolerate oral medications because of severe nausea can be given a 300-mg aspirin suppository.⁶¹ An absolute contraindication to aspirin is evidence of hypersensitivity to salicylates⁶¹; most such patients manifest the Samter's triad (sensitivity to salicylates, asthma, and nasal polyps).¹² Patients with true allergy to aspirin can be given the thienopyridine

clopidogrel or ticlopidine.¹⁰⁻¹² Aspirin is also contraindicated in patients with bleeding conditions (e.g., retinal hemorrhage, active peptic ulcer, other serious gastrointestinal or urogenital bleeding, hemophilia, and untreated severe hypertension).¹² In patients with prior gastrointestinal bleeding owing to ulcer after long-term use of low-dose aspirin and evidence of healed ulcer and eradication of *Helicobacter pylori*, 100 mg daily of aspirin plus the proton pump inhibitor lansoprazole for 12 months resulted in marked reduction of recurrent bleeding.⁷¹ In another study of patients with ulcer bleeding during aspirin therapy and evidence of healed ulcer and *H. pylori* eradication, comparison of clopidogrel plus the proton pump inhibitor esomeprazole versus low-dose aspirin (75 mg daily) plus a proton pump inhibitor showed the aspirin plus proton pump inhibitor combination to be superior in preventing recurrent ulcer bleeding.⁷²

Based on these results,^{71,72} and evidence of the large benefit of aspirin after MI,⁵¹ aspirin combined with a proton pump inhibitor should be continued if possible, unless the bleeding is life-threatening or cannot be controlled otherwise. It is reasonable to use acetaminophen initially in patients at risk for gastrointestinal bleeding for pain control.⁶⁶ If use of acetaminophen is impossible, it may be reasonable to use a selective COX-2 inhibitor in the short-term pending more long-term clinical data.⁶⁶

The use of selective COX-2 inhibitors (COXIBs) and nonselective NSAIDs has been reviewed elsewhere.^{46,66,73-75} COXIBs in all dosages and nonselective NSAIDs in high doses increase mortality in patients with previous MI and should be avoided.⁷³ Adverse effects of nonselective NSAIDs are attributed to loss of gastrointestinal protection and hemostasis via COX-1 and loss of anti-inflammatory activity via COX-2.⁴⁶ COXIB-induced reduction of PGI₂ and unchecked COX-1 activity result in continued TXA₂ production and increased risk of thrombosis, which may be harmful during acute MI.⁴⁶ COXIB-induced anti-inflammatory effects may be beneficial for progression of atherosclerosis, but harmful during infarct healing.⁴⁶ Suppression of inflammation by COX inhibitors can impair infarct healing after STEMI and lead to infarct thinning, adverse left ventricular remodeling, aneurysm, decreased resistance to rupture, and cardiac rupture,^{46,76-80} suggesting the need for caution.

The U.S. Food and Drug Administration (FDA) issued a warning on the concomitant use of aspirin and the NSAID ibuprofen.⁷⁵ Ibuprofen (but not rofecoxib, acetaminophen, or diclofenac) interferes with aspirin-induced acetylation of COX-1.⁷¹ The FDA also warned that COXIBs increase cardiovascular risk; rofecoxib (Vioxx) was withdrawn, although celecoxib and valdecoxib remain on the market.⁷¹ STEMI patients taking ibuprofen and requiring aspirin either should switch to another NSAID or should take ibuprofen 30 minutes after taking an immediate-release aspirin tablet or 8 hours before taking aspirin.⁷⁵ Data on the concomitant use of enteric-coated aspirin and ibuprofen are lacking.⁷⁵ One study showed, however, that the antiplatelet effect of enteric-coated low-dose aspirin was attenuated by ibuprofen (400 mg daily) given 2, 7, and 12 hours after aspirin.⁷¹

If COXIBs are used for pain control, they should be given "at the lowest possible dose and for the shortest time necessary."⁷¹ In the 2007 guideline update, morphine is recommended for pain control in patients with acute STEMI whether reperfused or not (class I, evidence level C).¹¹ On the basis of evidence that patients taking NSAIDs within the week before MI have an increased risk of death, hypertension, reinfarction, heart failure, myocardial rupture or shock,^{66,73,81-83} NSAIDs and COXIBs

should be stopped in patients who develop acute STEMI (class I, evidence level C), and should not be given to them during hospitalization (class III, evidence level C).^{11,66} Data from a substudy of the ExTRACT TIMI-25 trial showed that STEMI patients taking NSAIDs within 7 days of enrollment were at increased risk of death, reinfarction, heart failure, or shock.⁸³ A stepped-care approach has been recommended and is useful.⁶⁶

The role of other antiplatelet agents, such as prostacyclin analogues, thromboxane antagonists, phosphodiesterase inhibitors, serotonin receptor antagonists, fibrinogen receptor antagonists, monoclonal antibodies directed against glycoprotein (GP) IIb/IIIa, von Willebrand factor inhibitors, thienopyridines, thrombin inhibitors, and nitrates, in treating and preventing acute MI and other acute coronary syndromes continues to be evaluated.⁸⁴

Although aspirin is an effective antiplatelet drug, five points warrant mention. (1) Aspirin does not inhibit platelet degranulation in response to various stimuli or platelet adhesion to damaged endothelium.⁸⁵ (2) Aspirin resistance develops in 40% of patients, mostly women and elderly patients.^{86,87} (3) Patients with PGI₂ polymorphism for GP IIb/IIIa show an enhanced platelet aggregation response to aspirin.⁸⁸ (4) Aspirin has non-platelet effects, such as inhibition of interleukin-6 synthesis in leukocytes⁸⁹ and inhibition of endothelial nitric oxide inhibitors.⁹⁰ (5) Low-dose aspirin inhibits platelet and vascular COX activity.⁹¹

Pericarditis is common after STEMI.⁷⁹ Its timing coincides with the subacute phase during healing.^{19,23} Successful early reperfusion attenuates transmural extension and explains why Dressler's syndrome is rare in the reperfusion era.⁹² Although NSAIDs, such as ibuprofen and indomethacin, and corticosteroids have been effective for pericarditis, they can cause infarct expansion and thinning and cardiac rupture,^{76-79,93-95} and should be avoided or used as a last resort. High-dose aspirin (650 mg every 4 to 6 hours) may be used for pain control.^{10,96,97} Alternatively, colchicine⁹⁸⁻¹⁰⁰ or acetaminophen¹⁰ may be used. Short-term corticosteroids and NSAIDs may be used with extreme caution.^{10,66,83} Ibuprofen should not be used because it attenuates the antiplatelet effect of aspirin⁷¹ and causes infarct thinning.^{76-79,97} Misoprostol may be added for gastric and renal protection when NSAIDs are used.^{101,102} Data on the optimal management of pericarditis occurring in STEMI patients after reperfusion are awaited.

Summary of ACC/AHA Task Force Recommendations for Aspirin in ST Segment Elevation Myocardial Infarction

The ACC/AHA Task Force recommendations for aspirin in STEMI are summarized as follows.^{10,11}

- For convalescence and secondary prevention after STEMI, aspirin (75 to 162 mg daily) should be given indefinitely (class I, evidence level A). Patients with true aspirin allergy should preferably be given clopidogrel (75 mg daily) with ticlopidine (250 mg twice daily) as an alternative (class I, evidence level C). Also for patients with true aspirin allergy, warfarin (Coumadin) therapy (target international normalized ratio [INR] 2.5 to 3.5) is a useful alternative to clopidogrel in patients younger than 75 years old and at low risk of bleeding, provided that the INR can be monitored (class I, evidence level C). Ibuprofen should not be used because it blocks antiplatelet effects of aspirin (class III, evidence level C).

- Aspirin should be given promptly to all patients with suspected STEMI and no evidence of allergy, starting with a dose of 162 (class I, evidence level A) to 325 mg (class I, evidence level C), preferably non-enteric-coated and chewed, regardless of the reperfusion strategy or adjunctive therapies used. A maintenance dose of 75 to 162 mg daily (class I, evidence level A) should be given indefinitely.
- Patients with aspirin allergy or gastrointestinal intolerance should be given a thienopyridine, preferably clopidogrel, 75 mg daily (class I, evidence level C), rather than ticlopidine, 250 mg twice daily. In STEMI patients with planned PCI, clopidogrel should be given and continued for at least 1 month after bare metal stents and for 3 to 12 months after drug-eluting stents (class I, evidence level B).
- STEMI patients who develop pericarditis may be given high-dose aspirin, 650 mg orally every 4 to 6 hours (class I, evidence level B), although 162 to 325 mg is preferred. If aspirin does not control pain, oral colchicine, 0.6 µg every 12 hours (class IIa, evidence level B), or oral acetaminophen, 500 mg every 6 hours (class IIa, evidence level C), may be used. As a last resort, corticosteroids (class IIb, evidence level C) may be used. Except for aspirin, NSAIDs previously recommended (class IIa, evidence level B)¹⁰ should not be given to STEMI patients including during convalescence (class III, evidence level C).¹¹ Nonselective and COX-2-selective NSAIDs should be discontinued after acute STEMI in patients taking them before because of the amplified cardiovascular risk associated with their use (class I, evidence level C).¹¹ Ibuprofen should not be used (class III, evidence level B).¹⁰ If NSAIDs are used, misoprostol, 200 mg every 6 hours, should be added.¹⁰ Because analgesic doses of aspirin provide an antiplatelet effect but also increase the risk of bleeding compared with low-dose aspirin with another analgesic⁵¹ or without,⁷⁰ a proton pump inhibitor may be added to the analgesic dose of aspirin.
- A proton pump inhibitor should be added if patients develop gastrointestinal bleeding while taking aspirin (class I, evidence level B).¹²

Thienopyridines

The thienopyridines, such as clopidogrel and ticlopidine, are antiplatelet drugs and are useful as adjunctive therapy after MI. The rationale is that, despite COX inhibition by aspirin, platelet activation can continue through TXA₂-independent pathways leading to platelet aggregation and thrombin formation. Thienopyridines are recommended by the ACC/AHA management guidelines for STEMI and unstable angina/NSTEMI.¹⁰⁻¹² Clopidogrel is preferred over ticlopidine because it has fewer side effects.^{103,104}

Mode of Action

Thienopyridines block binding of adenosine 5'-diphosphate (ADP) to the low-affinity type 2 purinergic (P2Y₁₂) receptor, inhibiting the binding of fibrinogen to the GP IIb/IIIa complex and preventing its activation, and resulting in inhibition of platelet aggregation (Fig. 13-4).¹⁰⁵ Clopidogrel and ticlopidine do not affect the second type of high-affinity purinergic (P2Y₁) receptor and do not affect COX. They have a more potent antiplatelet effect than aspirin. Both agents can be given orally, preferably after meals for maximal bioavailability. They are prodrugs and are activated in the liver and excreted by the kidneys.

Figure 13-4. Sites of action of antiplatelet and antithrombin agents. Low-molecular-weight heparin produces more potent inhibition of factor Xa than thrombin, whereas unfractionated heparin produces equal inhibition of factor Xa and thrombin. Direct thrombin inhibitors inhibit thrombin, but have little effect on its generation. Thrombin amplifies generation of factors VIIa and Va, enhancing thrombus formation. Thrombin also promotes platelet activation by binding to platelet thrombin receptor. Cross-links, via ligands such as fibrinogen (factor I) to platelet glycoprotein (GP) IIb/IIIa receptors, lead to platelet aggregation. GP IIb/IIIa inhibitors act at these sites. ADP, adenosine triphosphate; PAF, platelet-activating factor; TXA₂, thromboxane A₂.

Clopidogrel and ticlopidine have similar efficacy as aspirin for long-term prevention^{106,107} and may be substituted in patients with aspirin allergy or intolerance.¹² In contrast to aspirin, thienopyridines produce significant inhibition after 2 to 3 days, and may take 4 to 7 days to achieve their full effect.¹⁰⁵ Their platelet-inhibiting effects are long-lasting and persist for 7 to 10 days after therapy is stopped¹⁰⁵; this corresponds to the life span of the platelet.

Dosing, Timing, and Benefits

Pending more data on the optimal loading dose of clopidogrel, 300 mg is used on the first day and followed by 75 mg daily in STEMI patients undergoing PCI and in unstable angina/NSTEMI patients being managed conservatively or undergoing PCI.^{10,12} A dose of 75 mg of clopidogrel is used in patients with aspirin allergy or intolerance.^{10,12} Clopidogrel should not be administered for 5 to 7 days before coronary artery bypass graft (CABG) surgery^{10,12,108} because of increased risk of bleeding with clopidogrel plus aspirin.¹⁰⁸⁻¹¹⁰ Clopidogrel doses of 600 to 900 mg have been studied, and small to moderate size trials have compared 600 mg with 300 mg.^{12,111-113} Ticlopidine (loading dose 500 mg; maintenance dose 250 mg twice daily) is used in patients with allergy to clopidogrel.

Pending more data on optimal timing of clopidogrel in PCI, and based on data from PCI-CURE,¹¹⁴ the ACC/AHA guidelines recommend initiating therapy even if a conservative strategy is planned.¹⁰ The CURE trial showed benefit with clopidogrel started on hospital admission despite the need for cardiac surgery in some patients.¹¹⁵ Clopidogrel also benefited patients with low 0-2 Thrombolysis In Myocardial Infarction (TIMI) risk scores, although the largest benefit in terms of the primary end point of MI, stroke, or death occurred in the highest risk patients.¹¹⁶ Clopidogrel should no longer be considered only for patients undergoing PCI. At hospitals that have rapid access to the cardiac catheterization laboratory, clopidogrel is withheld until there is confirmation of the coronary anatomy and that the patient needs PCI rather than CABG surgery. The loading dose of clopidogrel (300 to 600 mg) is given on the catheterization table just before PCI.¹² This approach is acceptable because of the increased risk of bleeding if the patient were to require urgent CABG surgery.

Based on findings of the PCI-CLARITY study in CLARITY-TIMI 28,¹¹⁷ clopidogrel should be started early (i.e., pretreatment) in cases of STEMI where angiography is delayed by 2 to 8 days because it results in a better outcome without increased risk of major or minor bleeding than when it is given just before

angiography. In the CLARITY-TIMI 28 study,¹¹⁷ the addition of clopidogrel to background aspirin therapy in STEMI patients reduced the risk of clinical events (i.e., death, reinfarction, stroke). Because the patients enrolled in CLARITY^{117,118} were 75 years old or younger, guidance on whether STEMI patients older than 75 years should receive a loading dose of clopidogrel is awaited.

Data on the risks and benefits of performing early versus delayed CABG surgery in STEMI patients receiving clopidogrel are lacking. Evidence from the CRUSADE registry showed no difference, however, in death, reinfarction, or stroke in NSTEMI patients who did versus patients who did not receive clopidogrel and went for early CABG surgery, despite an increase in blood transfusion requirements associated with failure to delay surgery.^{12,108}

Collective evidence indicates that all patients undergoing PCI should receive dual antiplatelet therapy with clopidogrel and aspirin.^{10,12,54,103,114,117-119} The length of clopidogrel therapy varies depending on the type of stent. For bare metal stents, aspirin at a dose of 162 to 325 mg daily plus clopidogrel at a dose of 75 mg daily for 1 month is necessary.^{12,54} Ideally, clopidogrel can be continued for 1 year if the risk for bleeding is low.⁵⁴ Clopidogrel and aspirin may be continued for other reasons. There is controversy regarding the length of clopidogrel therapy with drug-eluting stents. The old PCI guidelines stated that clopidogrel should be given for at least 3 months for sirolimus-eluting stents and at least 6 months for paclitaxel-eluting stents, but ideally therapy should be continued for 1 year if the risk of bleeding is low.¹⁶

STEMI patients who have not undergone revascularization may also benefit from clopidogrel therapy. The COMMIT/CCS-2, in which half of the patients did not undergo revascularization, showed benefit of clopidogrel therapy in STEMI.¹²⁰ Clopidogrel-treated patients in that study had a lower rate of the composite end point (death, reinfarction, stroke) and death (7.5% versus 8.1%), with no excess bleeding. In the CURE trial, NSTEMI patients who did not undergo stenting also benefited from clopidogrel therapy.¹⁰⁹

The optimal length of clopidogrel therapy for secondary prevention in patients with acute coronary syndromes is not well defined.^{12,121,122} For a noninvasive strategy, the ACC/AHA guidelines for unstable angina/NSTEMI recommend clopidogrel for 1 month to 1 year after the event.¹² The advice to extend therapy beyond 1 month is based primarily on data from the CURE trial.¹²³ There is no evidence to support prolonging therapy beyond 1 year, however. Because the 2004 STEMI guidelines¹⁰ do not give advice for patients managed conservatively with thienopyridines, it is reasonable to follow the 2007 unstable angina/NSTEMI guidelines¹² and recommend clopidogrel for at least 1 month and up to 1 year.

Adverse Effects

Ticlopidine therapy is associated with gastrointestinal upset, neutropenia, agranulocytosis, aplastic anemia, and rarely thrombotic thrombocytopenic purpura,^{103,104,124} requiring complete and differential blood counts every 2 weeks for 3 months. Clopidogrel therapy is associated with gastrointestinal upset and a low risk of thrombotic thrombocytopenic purpura but no neutropenia.^{106,125} Advantages of clopidogrel, such as once-daily dosing and no need for repeated laboratory monitoring, make it the preferred thienopyridine for the management of STEMI and NSTEMI and unstable angina.^{10,12,126,127} Typically, neutropenia

from ticlopidine resolves within 1 to 3 weeks after stopping the drug and may rarely be fatal.¹² Plasma exchange is required if thrombotic thrombocytopenic purpura develops.¹²⁴⁻¹²⁶ Ticlopidine is discouraged in patients with renal and hepatic dysfunction.

Although there is evidence that dual antiplatelet therapy with low-dose aspirin and clopidogrel reduces repeat cardiac events,^{109,114,128} the combination of aspirin and clopidogrel was not more effective than aspirin for primary prevention in high-risk patients in the CHARISMA trial.¹²⁹ The primary end point in that study was MI, stroke, or cardiovascular death. There was a moderate benefit in the secondary end point of MI, stroke, cardiovascular death, or hospitalization for unstable angina, transient ischemic attack, or revascularization. Although there was no significant difference in severe bleeding, there was an increased risk of moderate bleeding in the group treated with aspirin plus clopidogrel. Moderate bleeding was defined as nonsevere bleeding requiring transfusion. The study showed that clopidogrel plus aspirin prevented 94 ischemic (secondary) end points at the cost of 93 moderate or severe bleeds.¹²⁹ The patients with prior MI, ischemic stroke, and peripheral arterial disease derived significant benefit from dual therapy.¹³⁰ A large international study in outpatients with atherothrombosis (coronary, cerebrovascular, and peripheral arterial) revealed high annual cardiovascular event rates and increased 1-year risk of events with multiple disease locations.¹³¹ Although evidence shows that patients may experience large interpatient responses to clopidogrel, with increased risk of thrombotic events if they have less than expected inhibition of platelet aggregation,¹³²⁻¹³⁴ a standardized monitoring technique and appropriate management still need to be determined.¹²

Summary of ACC/AHA Task Force Recommendations for Thienopyridines in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for thienopyridines in STEMI are summarized as follows.¹⁰

Early Phase

- STEMI patients should receive clopidogrel, 75 mg daily, in addition to aspirin (class I, evidence level A), and clopidogrel treatment should be continued for at least 14 days (class I, evidence level B).¹¹ Since the 2004 ACC/AHA guidelines,¹⁰ the use of clopidogrel in STEMI was supported by two additional studies (COMMIT-CCS-2 and CLARITY-TIMI 28)^{118,135} and subsequently endorsed.^{136,137} Clopidogrel is preferred to ticlopidine because of fewer side effects, and is used as an alternative to aspirin in aspirin-intolerant patients receiving fibrinolytics (class IIa, evidence level C).
- STEMI patients younger than 75 years old who received fibrinolysis or who did not receive reperfusion therapy can have an oral loading dose of clopidogrel of 300 mg (class IIa, evidence level C).¹¹ Data for patients older than 75 years are awaited.

Convalescent and Postdischarge Phases

- STEMI patients who have undergone angiography and for whom PCI is planned should have a loading dose of 300 to 600 mg of clopidogrel before PCI. For patients with bare metal stents, clopidogrel (at least 75 mg daily) should be continued for 1 month. For patients with drug-eluting stents,

clopidogrel (at least 75 mg daily) should be continued for 3 months with sirolimus and 6 months with paclitaxel drug-eluting stents and 1 year in patients who are not at high risk for bleeding (class I, evidence level B).

- Continuation of clopidogrel, 75 mg daily, for 1 month to 1 year can be considered for secondary prevention in STEMI patients regardless of whether they undergo reperfusion with fibrinolytic therapy or do not undergo revascularization (class IIa, evidence level C).¹¹
- STEMI patients who are taking clopidogrel and are going for CABG surgery should have clopidogrel withheld for at least 5 to 7 days before CABG surgery, unless the urgency for revascularization outweighs the risk of excess bleeding (class I, evidence level B).¹¹
- STEMI patients with allergy to clopidogrel can be given ticlopidine (loading dose 500 mg; maintenance dose 250 mg twice daily).

β-Adrenergic Blockers

The rationale for β-blockade in acute MI is that it decreases myocardial oxygen demand (by decreasing heart rate, blood pressure, and contractility); improves the distribution of myocardial blood flow; and exerts desirable antiplatelet and antiarrhythmic effects. β-blockade has the potential for limiting infarct size, decreasing wall stress, and decreasing mortality. It is used in very early MI and over the long-term for secondary prevention after MI, regardless of the type (STEMI, NSTEMI, and unstable angina) or concomitant fibrinolytic therapy or primary PCI.^{10,12}

Mode of Action

β-blockers compete with catecholamines for two β-adrenergic receptors; β₁ receptors are primarily located in the myocardium and affect sinus node rate and atrioventricular (AV) node conduction velocity, and β₂ receptors are primarily located in bronchial and vascular smooth muscle. β-blockers act on the cardiovascular system to slow heart rate, reduce blood pressure, and reduce cardiac contractility, resulting in decreased cardiac workload, myocardial oxygen consumption, and prolongation of diastolic filling time and coronary perfusion. Given acutely, β-blockers decrease infarct size in patients who do not receive reperfusion therapy, reduce the rate of reinfarction in patients who receive reperfusion therapy, and decrease the frequency of arrhythmias.¹⁰

Low doses of selective β-blockers block β₁ more than β₂ receptors, and may be preferable for patients with pulmonary and peripheral vascular disease. Some β-blockers have intrinsic sympathomimetic activity, resulting in activation of the β receptor, and less slowing of heart rate, less prolongation of AV node conduction time, and less depression of left ventricular function. Only nonselective β-blockers without intrinsic sympathomimetic activity were shown to reduce mortality after MI,¹³⁸ and β-blockers with intrinsic sympathomimetic activity were unfavorable for secondary prevention.¹³⁹ Two large post-MI trials of oral β-blockers in the era before reperfusion showed mortality benefit.^{140,141}

Dosing, Timing, and Benefits

A meta-analysis of trials in the prethrombolytic era revealed a 7% reduction (not statistically significant) in mortality with oral β-blockade and 9% reduction (not statistically significant) in

mortality with intravenous β-blockade.¹³⁹ The β-blocker in the early studies was started within 24 hours, and the initial intravenous dose was 5 to 10 mg for propranolol,¹⁴² 5 to 10 mg for atenolol,¹⁴³ or 10 to 15 mg for metoprolol.^{144,145} In the largest trial,¹⁴³ acute intravenous atenolol was followed by an oral dose of 100 mg for 1 week, and the mortality at 7 days was reduced by 14% (from 4.3% to 3.7%). In the MIAMI study,¹⁴⁴ acute intravenous metoprolol was followed by 25 to 50 mg taken orally four times daily for 2 days and 100 mg twice daily thereafter, and the mortality at 15 days was decreased by 12% (from 4.9% to 4.3%). A substudy of MIAMI patients showed limitation of left ventricular remodeling and improved left ventricular function.¹⁴⁵ A trial of β-blockade and concomitant thrombolytic therapy suggested a reduction in reinfarction rate.¹⁴⁶ Several secondary prevention trials^{139,145,146} have shown improved survival and decreased reinfarction rate with long-term β-blocker therapy after acute MI.

In the ACC/AHA guidelines, intravenous β-blocker followed by oral dosing is recommended for acute MI patients without contraindications.^{9,10,12} In the absence of contraindications, β-blockers should be given to patients with hypertension, reflex tachycardia, rapid atrial fibrillation, or postinfarction angina. Agents with less intrinsic sympathomimetic activity and short duration of action are preferred.⁹ If tolerated, oral therapy should be continued for 2 years. Relative contraindications to β-blocker therapy include heart rate less than 60 beats/min, systolic blood pressure less than 100 mm Hg, moderate to severe left ventricular failure, signs of peripheral hypoperfusion, shock, PR interval greater than 0.24 second, second-degree or third-degree AV node block, active asthma, reactive airways disease, and MI induced by cocaine use.^{10,12}

Intravenous β-blockers should be considered in all patients with STEMI who are not receiving fibrinolytic therapy or in patients who have ongoing resting chest pain.^{10,12} Patients who do not receive fibrinolytic therapy but receive intravenous β-blockers have been shown to have decreased infarct size and mortality.^{139,143,144} The ISIS-1¹⁴³ and MIAMI¹⁴⁴ trials showed a significant, sustained benefit in mortality after day 1 when patients were given either intravenous atenolol or intravenous metoprolol initially followed by oral dosing. Although patients who receive early fibrinolytic therapy may not be expected to benefit as much from intravenous β-blockers, the TIMI-II trial showed a benefit associated with the early use of intravenous β-blockers in terms of reduced recurrent ischemia and non-fatal reinfarction.¹⁴⁴ Early administration of β-blockers within 2 hours of symptom onset reduced the composite end point of death or reinfarction.¹⁴⁴

The routine use of intravenous β-blockers in patients receiving fibrinolytic therapy has been questioned on the basis of two randomized trials^{147,148} and a post-hoc analysis from the first GUSTO-1 trial showing no benefits.¹⁴⁹ A review of early β-blockers in STEMI found no mortality benefit.¹⁵⁰ Subsequently, the COMMIT/CCS-2 trial addressed the issue of early intravenous β-blockers in acute STEMI, randomly assigning 45,582 patients (93% STEMI or new left bundle branch block on electrocardiogram [ECG]), half of whom had fibrinolytic therapy, to three 5-mg intravenous metoprolol boluses followed by oral metoprolol extended-release, 200 mg daily for 28 days, or placebo; the trial found no difference in mortality.¹²⁰ The β-blocker group in that study showed an increase in mortality, however, among patients who were hemodynamically unstable

that was balanced by a decrease in mortality among patients who were hemodynamically stable.¹²⁰ The β -blocker group also showed a decrease in ventricular fibrillation rate.¹²⁰ For every 1000 metoprolol-treated patients, however, there were 5 fewer episodes of reinfarction and 5 fewer episodes of ventricular fibrillation (mostly on day 2 onward), but 11 more episodes of cardiogenic shock (mostly on days 0 to 1).¹²⁰

The overall lack of benefit in COMMIT/CCS-2¹²⁰ may have been due to the high dose of β -blocker given to patients who were hemodynamically unstable. Risk factors for cardiogenic shock from this study included older age, female sex, evidence of congestive heart failure (CHF), time delay in presentation, lower blood pressure, prior history of hypertension, and elevated heart rate.¹²⁰ One key point from that study is that the administration of intravenous β -blockers should be targeted for specific indications, such as patients with ongoing chest pain at rest and no contraindications such as evidence of CHF. The 2007 update of the ACC/AHA guidelines recommends caution with the use of intravenous β -blockade, especially in patients who are at risk for cardiogenic shock.¹¹ Data on the short-acting intravenous β -blocker esmolol in STEMI are awaited. The long-term use of oral β -blockers is recommended for secondary prevention in high-risk patients, after they have been stabilized, with gradual dose titration.¹⁵¹

The STEMI guidelines¹⁰ assign a class IIb recommendation for intravenous β -blockers, whereas the NSTEMI guidelines¹² do not recommend early routine administration and support targeting use of β -blockers for specific indications. Both guidelines^{10,12} assign a class I recommendation for oral β -blockers. In patients receiving thrombolytics, there may be a potential benefit of early intravenous β -blockade in reducing the rate of intracranial hemorrhage.^{147,152} Data from a national registry on 60,532 patients treated with tissue-type plasminogen activator found that patients who received immediate intravenous β -blockers had lower rates of intracranial hemorrhage by 31%.¹⁵²

Patients who undergo PCI should also receive β -blockers. Although no large randomized trials of intravenous β -blocker use before PCI have been performed, it is reasonable to extrapolate benefits in patients who received fibrinolytics to the primary PCI population.^{10,153} Preprocedural intravenous β -blockers have been shown to be beneficial in a retrospective analysis from the CADILLAC trial.¹⁵⁴ Patients who received intravenous β -blockers had a lower mortality rate than patients who did not, although this benefit was limited to patients who were not taking β -blockers before admission. There is also evidence of benefits of β -blockers after PCI in terms of reduction of 6-month mortality, especially in patients with evidence of reduced ejection fraction or multivessel coronary artery disease.¹⁵⁵

There have been no trials of head-to-head comparison of different β -blockers, so the choice of agent depends on local availability and physician preference.¹² Intravenous β -blockers that have been studied in the acute phase of MI include atenolol, metoprolol, and propranolol.¹² Studied oral β -blockers administered later (i.e., 6 hours after presentation) include propranolol, timolol, atenolol, metoprolol, and acebutolol.¹⁵⁰ Despite being given later in MI, one meta-analysis showed an association with lower mortality rates, with a relative risk reduction of 21%.¹⁵⁶ A retrospective analysis from BHAT showed that patients with persistent ST segment depression on ECG benefited from the addition of propranolol at a mean of 10 days after MI.¹⁵⁷

The oral β -blocker of choice should be one without intrinsic sympathomimetic activity.^{10,12} Evidence of an almost statistically significant lesser benefit of β -blockers with intrinsic sympathomimetic activity was reported.¹⁵⁰ A large retrospective observational study of 69,338 patients found that metoprolol, atenolol, and propranolol had very similar rates of mortality reduction after 2 years, although slightly less reduction with propranolol was attributed to unmeasured differences at baseline.¹⁵⁸ In patients with depressed left ventricular ejection fraction, carvedilol may be considered.^{12,159}

One therapeutic target is a heart rate of 50 to 60 beats/min, unless there are side effects.¹² The dose of β -blocker can be titrated up to specified targets (Table 13-2).⁶⁴ Regarding the length of therapy, a meta-analysis showed that β -blockers exert their effect over time, and potentially 1 year of therapy is necessary before mortality benefits can be appreciated.¹⁵⁰ Patients with other indications for β -blocker therapy, such as left ventricular ejection fraction less than 40%, benefit from long-term therapy in various trials.¹⁶⁰⁻¹⁶³ Although most trial data were collected in patients in eras when revascularization was uncommon, evidence from MUSTT showed that high-risk patients benefited from β -blocker therapy for many years (3 to 8 years), although the benefit was mitigated by an implantable cardiac defibrillator.¹⁶³ In patients at low risk (preserved ejection fraction), the evidence for continued long-term β -blocker therapy is controversial, but there is some evidence of a mortality

Table 13-2. Target Doses for β -Blockers

β -Blocker	β Selectivity	Agonist Activity	Target Dose
Acebutolol	β_1	Yes	200-600 mg twice daily
Atenolol	β_1	No	50-200 mg daily
Betaxolol	β_1	No	10-20 mg daily
Bisoprolol	β_1	No	10 mg daily
Carvedilol*	None	Yes	6.25 mg twice daily up to 25 mg twice daily
Esmolol (intravenous)	β_1	No	50-300 μ g/kg/min
Labetalol*	None	Yes	200-600 mg daily
Metoprolol	β_1	No	50-200 mg twice daily
Nadolol	None	No	40-80 mg daily
Pindolol	None	Yes	2.5-7.5 mg three times daily
Propranolol	None	No	20-80 mg daily
Timolol	None	No	10 mg twice daily

*Labetalol and carvedilol are combined α and β -blockers. Drugs are listed alphabetically and not in order of preference.

Adapted from Gibbons PJ, Abrams J, Chatterjee K, et al: ACC/AHA 2002 guideline update for the management of patients with chronic stable angina. *J Am Coll Cardiol* 2002;41:159-168.

benefit.¹⁶² The Cardiovascular Cooperative Project showed a reduction of mortality at 2 years even in low-risk patients.¹⁶⁴ Overall, in the absence of side effects, β -blocker therapy should be continued indefinitely.

Adverse Effects

Major side effects of β -blocker therapy include hypotension, bradycardia, AV block, worsening of CHF, and exacerbation of reactive airways disease. It can cause acute heart failure with pulmonary edema, active bronchospasm, hypotension, and severe bradycardia. β -blocker therapy is contraindicated in MI secondary to cocaine use because β -blockers may exacerbate coronary vasospasm.¹⁶⁵

Relative contraindications include chronic obstructive pulmonary disease (COPD) or asthma, reduced left ventricular ejection fraction, and peripheral artery disease. Patients with mild pulmonary disease not taking β agonists benefit from β -blockers after acute MI, but patients with severe COPD or asthma or taking β agonists do not benefit.¹⁶⁶ After 2 years, patients with COPD receiving β -blocker therapy had a higher survival rate than patients who did not receive therapy.¹⁶⁴ The concern that β -blocker therapy might worsen COPD or reactive airways disease has been addressed by one meta-analysis showing that cardioselective β -blockers do not worsen pulmonary function tests in patients with mild to moderate COPD or reactive airways disease.¹⁶⁷ Because the benefit of β -blockers is significant, it is recommended that lower initial doses of cardioselective β -blockers and careful titration upward be used,¹² and confirmation of COPD or reactive airways through pulmonary function testing be done if there is any question of the diagnosis.

In patients with decreased left ventricular function or evidence of heart failure, acute β -blocker therapy is contraindicated, although long-term therapy is beneficial.^{10,12} Older β -blocker trials were done without ACE inhibitors and did not assess patients with asymptomatic left ventricular dysfunction.^{143,144,168} Data from several ACE inhibitor trials in patients with asymptomatic left ventricular dysfunction (e.g., SAVE and SOLVD) and symptomatic left ventricular dysfunction (e.g., AIRE) show that β -blockers do have additive benefit to ACE inhibitors.¹⁶⁹⁻¹⁷¹ Regardless of the level of left ventricular dysfunction, β -blockers improve survival and produce benefits in post-MI patients with ejection fraction greater than and less than 20%.¹⁶⁴

The CAPRICORN trial also showed that there is an additive benefit of β -blockers and ACE inhibitors in patients with post-MI left ventricular dysfunction.¹⁷¹ Although there was no significant difference in the primary combined end point of mortality and rehospitalization for cardiovascular problems, there was a statistically significant difference in mortality and nonfatal MI.¹⁷² Analysis of acute β -blocker therapy in 17,809 STEMI patients receiving aspirin and ACE inhibitors was associated with an independent decrease in hospital mortality regardless of reperfusion therapy.¹⁷³ Greater benefit was found in high-risk STEMI patients, such as elderly patients and patients without reperfusion, than low-risk patients.¹⁷³ A better survival rate is found in elderly acute MI patients prescribed β -blockers at discharge.¹⁷⁴

In patients with peripheral artery disease, there has been some concern about worsening of claudication with β -blockers; however, multiple meta-analyses and a placebo-controlled trial have shown this worry to be unfounded.¹⁷⁵⁻¹⁷⁷ Long-term β -blocker therapy in STEMI survivors shows mortality benefit despite revascularization with CABG surgery or PCI.¹⁷⁸

Summary of ACC/AHA Task Force Recommendations for β -blockers in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for β -blockers in STEMI are summarized as follows.^{10,11}

Early Phase

- STEMI patients should be promptly started within the first 24 hours on an oral β -blocker in the absence of contraindications, such as evidence of CHF, low output state, increased risk of cardiogenic shock (i.e., age >70 years, systolic blood pressure <120 mm Hg, sinus tachycardia >120 beats/min, heart rate <60 beats/min, or increased time of onset since symptoms), PR interval greater than 0.24 second, third-degree heart block, or active asthma or reactive airways diseases, regardless of concomitant fibrinolytic therapy or primary PCI (class I, evidence level A).¹¹
- STEMI patients without the same aforementioned contraindications can be reasonably given prompt intravenous β -blocker at the time of presentation if they have hypertension or tachyarrhythmia (class IIa, evidence level B).^{10,11}

Convalescence

- STEMI patients who received and tolerated a β -blocker in the first 24 hours without adverse reactions should continue to receive the drug; patients without contraindications who did not receive a β -blocker in the first 24 hours should be started on one (class I, evidence level A).¹⁰
- STEMI patients with contraindications in the first 24 hours should be re-evaluated for β -blocker therapy (class I, evidence level C).¹¹

Postdischarge

- All STEMI survivors should receive a β -blocker except patients at low risk (i.e., normal ejection fraction, successful reperfusion, no ventricular arrhythmias) or with contraindications, and treatment should be started promptly and continued indefinitely (class I, evidence level A).¹⁰
- STEMI patients with moderate to severe left ventricular failure should receive β -blocker therapy with gradual titration as a secondary prevention (class I, evidence level B).¹¹
- β -blocker therapy is considered reasonable for low-risk STEMI patients without contraindications (class IIa, evidence level A).¹⁰

Nitrates

Nitrates have been used for the management of acute ischemic syndromes for more than a century. More than 2 decades ago, nitroglycerin was given to patients with acute MI to improve hemodynamics.¹⁷⁹ Subsequently, low-dose intravenous nitroglycerin in patients with acute STEMI was shown to be safe,^{180,181} to limit infarct size,¹⁸¹⁻¹⁸⁵ to reduce infarct-related complications,^{181,183} to limit left ventricular remodeling,¹⁸¹ to improve function,¹⁸¹⁻¹⁸⁸ and to improve survival in high-risk anterior STEMI patients.¹⁸¹ A meta-analysis of randomized trials before the use of thrombolysis showed a 35% mortality reduction with intravenous nitrates and 25% reduction with oral nitrates.¹⁸⁹ Concurrent low-dose intravenous nitroglycerin and late reperfusion therapy limited remodeling and resulted in early recovery of ventricular function.^{190,191} After acute STEMI, 6 weeks of nitrate therapy

(initial low-dose intravenous nitroglycerin followed by buccal nitrate in an eccentric dosing schedule), in patients with¹⁹² and without¹⁹³⁻¹⁹⁶ thrombolytics after admission, limited left ventricular remodeling and improved function. Two large thrombolytic trials (GISSI-3 and ISIS-4) confirmed the safety of intravenous nitroglycerin in patients with acute MI¹⁹⁷ or suspected MI,¹⁹⁸ but did not show significant benefit of long-term nitrates on survival.

Mode of Action

The beneficial effects of nitrates primarily result from the endothelium-independent release of nitric oxide, direct relaxation of vascular smooth muscle, and dose-related vasodilation leading to left ventricular unloading, decreased wall stress, and improved myocardial perfusion.¹⁹⁹⁻²⁰¹ The role of nitric oxide in cardioprotection is reviewed elsewhere.²⁰²⁻²⁰⁴ Nitrates also produce vasodilation indirectly through the endothelial release of PGI₂¹⁹⁹⁻²⁰¹ and exert antiplatelet and antithrombotic effects.^{205,206} Nitroglycerin dilates coronary arteries and promotes collateral flow to ischemic regions.²⁰⁷⁻²¹⁰ Low-dose nitroglycerin produces maximal venodilation and marked reduction in left ventricular preload, chamber size, and wall stress.¹⁹⁹⁻²⁰¹ Higher doses decrease blood pressure, dilate coronary resistance vessels, can cause hypotension and decrease perfusion,^{211,212} and produce tolerance.²¹³ Reducing preload and afterload decreases myocardial oxygen demand.

After thrombolytic therapy, the combined beneficial effects of nitrates (e.g., dilation of large coronary vessels, relief of coronary spasm, antiplatelet and antithrombotic effects) can potentially prevent reocclusion, infarct extension, and postinfarction angina. Nitroglycerin-induced vasodilation of atherosclerotic arteries may benefit patients with STEMI caused by coronary spasm.¹⁰ In the conscious dog model of inferior MI, low-dose intravenous nitroglycerin increased collateral blood flow and reduced infarct size.²¹⁰ In the conscious dog model of anterior MI, administration of long-term nitrates (6 weeks) limited left ventricular remodeling and was more effective than short-term therapy (2 weeks).²¹⁴ In the same model, prolonged unloading with long-term nitrate therapy (6 weeks) after reperfused anterior MI limited left ventricular remodeling and dysfunction.²¹⁵

Low-dose intravenous nitroglycerin can be administered safely to patients with evolving anterior STEMI; dose titration avoids hypotension, tachycardia, or bradycardia.^{181,213} Patients with inferior STEMI are more sensitive to preload reduction, especially if right ventricular infarction is present.^{181,213}

Cumulative basic research evidence indicates that organic nitrates are rapidly converted to nitric oxide after entering the cell wall, and nitric oxide activates guanylate cyclase, leading to increased intracellular cyclic guanosine monophosphate (cGMP), which mediates smooth muscle relaxation and inhibition of platelet aggregation. The hypothesis that nitrates may provide an exogenous source of nitric oxide has been challenged. Nitroglycerin biotransformation occurs through reduction of mitochondrial aldehyde dehydrogenase (ALDH-2), and attenuation of ALDH-2 may explain nitrate tolerance. Chinese subjects who lack ALDH-2 show almost normal vascular and platelet responses to nitroglycerin, however. Nitrate uptake is greater in veins, but the rate of cGMP formation is greater in arteries.

Dosing, Timing, and Benefits

The 1990 ACC/AHA guidelines⁹ recommended low-dose intravenous nitroglycerin in the treatment of acute MI, provided that the initial systolic blood pressure is not less than 90 mm Hg.

The guidelines supported use of nitroglycerin for suppressing ongoing myocardial ischemic pain and for managing acute MI complicated by CHF or pulmonary edema. The guidelines also supported monitoring of blood pressure and heart rate to detect hypotension, tachycardia, or bradycardia and to avoid myocardial hypoperfusion, and recommended intravenous or topical nitroglycerin for 24 to 48 hours after thrombolysis. The 1990 ACC/AHA guidelines⁹ also cautioned against unreasonably delaying analgesia (e.g., morphine) while the anti-ischemic effect of intravenous nitroglycerin is being evaluated, the use of long-acting nitrates in the early stages of acute MI, and the use of intravenous doses of more than 200 µg/min because they are associated with the development of tolerance.

The 2004 ACC/AHA guidelines¹⁰ recognized the usefulness of low-dose intravenous nitroglycerin infusion in titrating therapy to the blood pressure response,^{199-201,216} and suggested that the infusion should begin at 5 to 10 µg/min with increases of 5 to 20 µg/min (rather than 15 µg and be titrated upward by 5 to 10 µg/min every 5 to 10 minutes as in the previous guidelines)⁹ until symptoms are relieved or mean blood pressure is reduced by 10% of the baseline level in normotensive patients and by up to 30% in hypertensive patients, but not below a systolic pressure of 90 mm Hg or a decrease greater than 30 mm Hg below baseline. In a large randomized, placebo-controlled, single-blinded trial of low-dose intravenous nitroglycerin infusion in 310 patients,^{181,213} a similar regimen was used, but began at 5 µg/min. Using this regimen, the infusion was safely continued for more than 12 hours in 89% of patients, more than 24 hours in 75% of patients, and more than 48 hours in 27% of patients. The average duration was 39 ± 25 (standard deviation) hours, and the longest infusion was 154 hours. The initial decrease in mean blood pressure was 10 ± 8% in normotensive patients (blood pressure <140/90 mm Hg) and 19 ± 9% in hypertensive patients (blood pressure >140/90 mm Hg). None of the patients in that study developed hypotension requiring alternative therapy.^{181,213} Partial tolerance developed in 24% and did not reduce the benefits.²¹³

In studies of about 200 patients, long-term nitrate therapy delivered over 6 weeks after acute MI was effective in preserving left ventricular geometry and improving function measured by echocardiography and radionuclide imaging.¹⁹²⁻¹⁹⁴ The GISSI-3¹⁹⁷ and ISIS-4¹⁹⁸ megatrials studied a different selected population (i.e., with lower mortality and with >50% receiving nitrates and other therapies) than the populations in the prethrombolytic trials.¹⁸⁹

In GISSI-3,¹⁹⁷ nitrates (intravenously for 24 hours and 10 mg transdermally for 6 weeks) did not reduce mortality significantly. The combination of nitrate and lisinopril (5 mg initially and 10 mg four times daily for 6 weeks) decreased total mortality, however, by 17% (compared with 11% with lisinopril alone), and decreased the combined end point of mortality and ventricular dysfunction in elderly patients by 21% and in women by 21%. These benefits were found despite the fact that 57% to 61% of the control patients received nitrates. Nevertheless, the nitrate group had less postinfarction angina and less cardiogenic shock.

In ISIS-4,¹⁹⁸ the 5-week mortality with mononitrate and placebo was not significantly different (7.34% versus 7.54%). The mortality rate on the first 2 days was less, however, with nitrates.

In contrast to acute STEMI, high doses of nitrates have been used in unstable angina^{200,217,218} and CHF.²⁰⁰ Nitrates are available in many forms, including intravenous, sublingual sprays,

rapid-acting and dissolving tablets, long-acting tablets, and slow-release patches.²⁰⁰ Use of nitrates does not preclude use of other antianginal drugs such as β -blockers. Patients with CHF also benefit from nitrates. Nitrates should be avoided in STEMI patients with hypotension, bradycardia, or tachycardia,²¹⁹ or with right ventricular infarction.²²⁰ They are contraindicated in patients taking phosphodiesterase inhibitors, which inhibit the breakdown of cGMP, and should not be given within 24 hours of taking sildenafil or 48 hours of taking tadalafil, and probably within 24 hours of taking vardenafil.²²¹⁻²²⁴ Tolerance to nitrate therapy typically develops after 24 hours. If intravenous nitroglycerin is still required after tolerance develops, the dosage may need to be increased. Lower doses or nitrate-free intervals prevent the development of tolerance. The steps for weaning patients off intravenous nitroglycerin and switching to oral or topical nitrates are reviewed elsewhere.¹²

In the prethrombolytic era, a meta-analysis of nitrate trials in STEMI showed a 35% reduction in mortality.¹⁸⁹ In the postthrombolytic era, the mortality benefit of nitrate therapy was small in ISIS-4 (7.4% with nitrate versus 7.7% without nitrate)¹⁹⁸ and nil in GISSI-3.¹⁹⁷ The proportion of patients with STEMI was approximately 60% in GISSI-3 and 80% in ISIS-4.

Based on lack of a proven long-term survival benefit in those large trials, the ACC/AHA guidelines¹⁰ do not recommend routine nitrate therapy in STEMI patients, although the trials were confounded by nitrate use in the control groups, and the proportion of patients with STEMI was approximately 60% in GISSI-3 and 80% in ISIS-4. A trial of long-term intermittent transdermal nitroglycerin in survivors of acute STEMI showed improvement of left ventricular function and prevention of remodeling, although the beneficial effects were limited to patients with depressed ventricular function and receiving a low dose.^{225,226} A trial with the addition of isosorbide dinitrate and hydralazine to standard CHF therapy showed improved survival in black patients.²²⁷ A trial of intravenous versus buccal nitroglycerin in unstable angina showed no mortality benefit.²²⁸ STEMI¹⁰ and unstable angina/NSTEMI guidelines¹² recommend targeted over routine nitrate therapy.

Adverse Effects

The side-effect profile includes hypotension, tachycardia, bradycardia, and headache. Rarely, methemoglobinemia can develop. Patients with inferior STEMI, especially right ventricular infarction, are more sensitive to preload reduction. Continuous long-term use results in the development of tolerance.

Summary of ACC/AHA Task Force Recommendations for Nitrates in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for nitrates in STEMI are summarized as follows.¹⁰

Early Phase

- STEMI patients with ongoing ischemic pain first should receive 0.4 mg of sublingual nitroglycerin every 5 minutes for a total of three doses and be assessed for intravenous nitroglycerin after that (class I, evidence level C) to relieve ongoing ischemic pain, control hypertension, and manage pulmonary hypertension (class I, evidence level C).
- STEMI patients should not be given nitrates if systolic blood pressure is less than 90 mm Hg or 30 mm Hg or more below

baseline, heart rate is less than 50 beats/min or greater than 100 beats/min, or right ventricular infarction is suspected (class III, evidence level C), and if a phosphodiesterase inhibitor was used in the preceding hours (24 hours for sildenafil and vardenafil; 48 hours for tadalafil) (class III, evidence level B). Nitrates should not be used if hypotension limits the use of β -blockers.¹⁰

- Nitrates should be used for pulmonary congestion in STEMI patients, unless systolic blood pressure is less than 100 mm Hg or more than 30 mm Hg below baseline (class I, evidence level C).

Convalescence

- In the first 48 hours after STEMI, intravenous nitroglycerin therapy should be used for persistent ischemia, CHF, or hypertension, but should not preclude β -blocker and ACE inhibitor therapy, which have been proven to reduce mortality. Beyond 48 hours, intravenous, oral, or topical nitrates should be used for recurrent angina or persistent CHF if their use does not preclude β -blocker or ACE inhibitor therapy (class I, evidence level B). Beyond 24 to 48 hours, continued nitrate therapy may be helpful, but benefit is not established (class IIb, evidence level B). Nitrates should not be used in patients with hypotension, severe bradycardia, tachycardia, or right ventricular infarction (class III, evidence level C).

Postdischarge

- There is no advice in the guidelines for use of nitrates after discharge. Nitrates are not approved for secondary prevention after STEMI. They are used for anti-ischemic therapy and left ventricular failure.

Angiotensin-Converting Enzyme Inhibitors and Other Renin-Angiotensin-Aldosterone System Inhibitors

ACE inhibitors are recommended for the early management of acute STEMI in the 2004 ACC/AHA guidelines.¹⁰ Although ACE inhibitors were not recommended for acute MI by the 1990 guidelines,⁹ they have undergone extensive experimental and clinical evaluation in the course of acute MI and for the limitation of left ventricular remodeling after MI.^{18,19,197,198,229-241} They have emerged as effective adjunctive agents for preventing left ventricular remodeling and improving survival.

Mode of Action

The renin-angiotensin-aldosterone system (RAAS), reviewed elsewhere,^{47,242} regulates blood pressure and extracellular volume. The pathway for the formation of angiotensin II (the primary effector molecule of the RAAS) begins with angiotensinogen, secreted by the liver, and its conversion to angiotensin I by renin, and conversion of angiotensin I to angiotensin II by ACE, and subsequent degradation of angiotensin II (Fig. 13-5). Angiotensin II, acting mainly via angiotensin II type 1 (AT₁) receptors,²⁴³ exerts several physiologic actions, including vasoconstriction and aldosterone and catecholamine release (Fig. 13-6).

The beneficial effects of ACE inhibitors are related mainly to inhibition of ACE and kininase (Fig. 13-7).^{41,242} ACE inhibition results in decreased activity of RAAS; decreased formation of

Figure 13-5. Angiotensin II formation and degradation pathways. ACE, angiotensin-converting enzyme; CAGE, chymostatin-sensitive angiotensin II generating enzyme; t-PA, tissue plasminogen activator. angiotensin II; decreased catecholamine secretion, inotropic stimulation, heart rate, and vasoconstrictor tone; and improved collateral flow. Kininase inhibition contributes to vasodilation. The results are increased venous capacitance and decreased preload, decreased afterload, improved perfusion, decreased

infarct size, decreased chamber size and wall stress, and decreased ventricular dilation. As with other vasodilators,²¹¹ however, treatment with high doses of the ACE inhibitor captopril fails to decrease infarct size.^{212,231} The antigrowth effects of ACE inhibitors result in inhibition of myocyte hypertrophy^{232,233}

Figure 13-7. Pathways of angiotensin-converting enzyme (ACE) inhibitor–induced and angiotensin receptor blocker (ARB)–induced cardiovascular protection. cGMP, cyclic guanosine 3′ 5′ monophosphate; EDHF, endothelin-derived hyperpolarizing factor; eNOS, endothelial nitric oxide synthase; NADPH, nicotinamide adenine dinucleotide phosphate; NO, nitric oxide; PAI-1, plasminogen activator inhibitor-1; PGI₂, prostacyclin; PKCε, protein kinase Cε; t-PA, tissue plasminogen activator. and collagen deposition in the noninfarct²³² and infarct zones,^{233,244-246} suggesting the need for caution when using these agents after MI.

ACE inhibitors do not block the formation of angiotensin II via alternative pathways (see Fig. 13-5) or all aldosterone formation. Angiotensin receptor blockers (ARBs) selectively block the effects of angiotensin II via AT₁ receptors,²⁴³ and aldosterone antagonists block the mineralocorticoid receptor.^{247,248} Angiotensin II degradation by ACE2 leads to formation of angiotensin-(1-7) (see Fig. 13-5), a vasodilator that is increased during ACE inhibitor and ARB therapy and may contribute to their cardioprotective effects.²⁴⁹ The rationale for using aldosterone blockade is that angiotensin II stimulates the release of aldosterone, activating the mineralocorticoid receptor. The activation of the mineralocorticoid receptor persists despite the use of ACE inhibitors, ARBs, and β-blockers.

Dosing, Timing, and Benefits

Several clinical studies tested the effect of very early and prolonged ACE inhibition after MI.²³⁴⁻²³⁶ In a study combining thrombolysis with recombinant tissue plasminogen activator and captopril (2 mg intravenously followed by incremental oral doses of 12.5 to 50 mg twice daily for 3 months), only one patient developed hypotension, and the overall effect was a greater limitation of progressive left ventricular dilation with captopril.²³⁴ It has been suggested that sulfhydryl-containing ACE inhibitors such as captopril may also act as free-radical scavengers and reduce reperfusion injury.²³⁵ In CONSENSUS II,²³⁶ the ACE inhibitor enalapril, given as 1 mg intravenously on the first day followed by oral dosing from 2.5 mg twice daily to 20 mg daily for

6 months, resulted in early hypotension in 12% and no improvement in survival. Nevertheless, 11 other ACE inhibitor studies showed improved survival (Table 13-3).^{197,198,237-240,250-254} HEART was terminated prematurely.²⁵⁵ All the trials were completed in the thrombolytic era and were conducted on selected patients. The overall results underscore the fact that final outcome represents a balance of effects and support the use of ACE inhibitors as adjunctive therapy in acute STEMI. Their overall safety in treating very early and convalescent phases of STEMI is supported by extensive trial data with the caveat that hypotension should be avoided.

SAVE showed a close correlation between limitation of left ventricular dilation and clinical benefits.²⁴¹ The collective evidence indicates that ACE inhibitor therapy after MI attenuates or delays the rate of ventricular remodeling.²⁵⁶⁻²⁵⁹ This therapeutic benefit is attributed in major part to inhibition of the effects of angiotensin II, and is supported by findings of increased ACE expression at the edge of infarct scars²⁶⁰ and markedly increased left ventricular dilation in patients with the ACE-DD genotype, which is associated with increased ACE activity.²⁶¹

The general consensus, based on trial data showing early benefit of oral ACE inhibitor therapy in STEMI, is that therapy should be given early, within 24 hours, provided that there is no evidence of hypotension or other contraindications or allergy to ACE inhibitors.¹⁰ In ISIS-4,¹⁹⁸ patients given captopril within 24 hours of their presentation showed early benefit, with separation of the survival curves within the first 5 weeks and greatest benefit in anterior MI. In patients treated early with captopril, 44 deaths were prevented on days 0 to 1, 37 deaths were prevented on days 2 to 7, and 62 deaths were prevented later on.²⁶²

Table 13-3. Major Trials of Angiotensin-Converting Enzyme Inhibitors in Heart Failure and Myocardial Infarction

Trial, Year	N	Disease	Drug	Onset	Duration	Outcome
CONSENSUS, 1987 ²⁵⁰	253	HF	Enalapril	—	20 mo	27% ↓ mortality; ↓ morbidity
SOLVD (symptomatic), 1991 ²³⁸	2569	HF	Enalapril	≥4 wk	41.4 mo	16% ↓ mortality; ↓ morbidity
SOLVD (asymptomatic), 1992 ²³⁹	4228	HF	Enalapril	≥4 wk	37.4 mo	8% ↓ mortality (NS); ↓ morbidity
CONSENSUS II, 1992 ²³⁶	6090	MI	Enalapril	<24 hr	6 mo	No decrease in mortality; hypotension
SAVE, 1992 ²³⁷	512	MI	Captopril	3-16 days	42 mo	19% ↓ mortality; ↓ morbidity
AIRE, 1993 ²⁴⁰	2006	MI	Ramipril	3-10 days	15 mo	27% ↓ mortality; ↓ morbidity
GISSI-3 (6-wk effects), 1994 ¹⁹⁷	19,394	MI	Lisinopril	≤24 hr	6 wk	11% ↓ mortality; ↓ morbidity
ISIS-4, 1995 ¹⁹⁸	58,050	MI	Captopril	≤24 hr	35 days	7% ↓ mortality; ↓ morbidity
TRACE, 1995 ²⁵¹	6676	MI	Trandolapril	3-7 days	24 mo	34.7% ↓ mortality; ↓ morbidity
CCS-1, 1995 ²⁵²	13,634	MI	Captopril	≤36 hr	1 mo	6% ↓ mortality; ↓ morbidity
SMILE, 1995 ²⁵³	1556	MI	Zofenopril	≤24 hr	6 wk	29% ↓ mortality; ↓ morbidity
GISSI-3 (6-mo effects), 1996 ²⁵⁴	19,394	MI	Lisinopril	≤24 hr	6 wk	6.2% ↓ mortality and LV dysfunction combined
HEART, 1997 ²⁵⁵	352	MI	Ramipril	≤24 hr	1-14 days	↓ LV remodeling

HF, heart failure; LV, left ventricular; MI, myocardial infarction; NS, nonsignificant.

Adapted from Jugdutt BI: Valsartan in the treatment of heart attack survivors. *Vasc Health Risk Management* 2006;2:125-138.

In GISSI-3,¹⁹⁷ patients given lisinopril within 24 hours showed early benefit, with 21 fewer deaths on days 0 to 1, 42 fewer deaths on days 2 to 7, and 12 fewer deaths later.²⁶² In the SMILE trial,²⁵³ with anterior MI patients without fibrinolytic therapy, there was a trend toward mortality benefit in the first 6 weeks. In CCS-1,²⁵³ there was a 0.5% absolute mortality benefit.

A meta-analysis of all the trials, comprising more than 100,000 patients, showed a benefit of 4.6 fewer deaths for every 1000 patients treated with ACE inhibitor therapy.²⁶³ Patients with anterior MI, age 55 to 74 years, and a heart rate greater than 80 beats/min tended to benefit more.²⁶³ Benefit occurred early, with approximately 40% of prevented deaths in the first 7 days.

Based on the ISIS-4 and GISSI-3 data, where the maximum dose of ACE inhibitor was achieved within 48 hours, the dose of ACE inhibitor should be rapidly titrated upward to achieve the full dose by 24 to 48 hours.¹⁰ Besides reperfusion and aspirin, ACE inhibitor therapy is the only other therapy shown to reduce 30-day mortality when CHF complicates STEMI.¹⁰ The survival benefit of ACE inhibitor therapy seems to be a class effect.¹⁰

The CONSENSUS II trial²⁶⁴ was stopped early by the Safety Committee because of concerns that there was an adverse effect in elderly patients who experienced early hypotension with enalapril. At the end of 6 months, there was a trend (not statistically

significant) toward harm in patients given intravenous enalapril. For this reason, intravenous enalapril should not be used in the management of STEMI.¹⁰ Nevertheless, the potentially harmful effect at 6 months in elderly patients is noteworthy. Additional clinical studies are needed to evaluate fully the safety of ACE inhibitor therapy during healing after large STEMI in elderly patients.

The optimal length of ACE inhibitor therapy has not been determined, especially in patients who are asymptomatic, normotensive, or nondiabetic with normal left ventricular function. In STEMI patients, the general consensus is that ACE inhibitor therapy should be continued indefinitely.¹⁰ In the PEACE trial,²⁶⁵ there was no benefit after a mean follow-up of 4.8 years in patients who were medically managed with aspirin, β -blocker, and a statin, and had an ejection fraction 40% or greater and stable coronary artery disease with prior revascularization in 72%. There was a reduction in blood pressure, but no reduction in mortality, infarction, or coronary revascularization rate.²⁶⁵

In view of extensive experience with ACE inhibitors in STEMI, ACE inhibitors remain the preferred RAAS inhibitor, and ARBs are used in ACE inhibitor-intolerant patients.¹⁰ Several trials investigated the benefits of ARBs in patients with MI and CHF, using an ACE inhibitor as comparator and on top of

Table 13-4. Major Trials of Angiotensin Receptor Blockers in Heart Failure and Myocardial Infarction

Trial, Year	N	Disease	Angiotensin Receptor Blocker	Comparator	Outcome
ELITE, 1997 ²⁶⁶	722	HF	Losartan	Captopril	Unexpected 46% ↓ in mortality (secondary end point)
RESOLVD, 1999 ²⁶⁷	768	HF	Candesartan	Enalapril	Early trend in ↑ mortality and HF (secondary end point)
ELITE II, 2000 ²⁶⁸	3152	HF	Losartan	Captopril	Not superior
Val-HeFT, 2001 ²⁶⁹	5010	HF	Valsartan	ACE inhibitor	Not superior; ↓ composite end point
OPTIMAAL, 2002 ²⁷⁰	5477	MI	Losartan	Captopril	Not superior (noninferiority criteria not met)
CHARM-Overall, 2003 ²⁷¹	7601	HF	Candesartan	ACE inhibitor	Improved primary outcome (mortality and morbidity)
CHARM-Added, 2003 ²⁷²	2548	HF	Candesartan	ACE inhibitor	Improved primary outcome (clinical, morbidity)
CHARM-Alternative, 2003 ²⁷³	2028	HF	Candesartan	ACE inhibitor	Improved primary outcome (mortality and morbidity)
CHARM-Preserved, 2003 ²⁷⁴	3023	HF	Candesartan	ACE inhibitor	Similar primary outcome (improved secondary outcome)
VALIANT, 2003 ²⁷⁵	14,703	MI	Valsartan	Captopril	Not superior, noninferior

ACE, angiotensin-converting enzyme; HF, heart failure; MI, myocardial infarction.

Adapted from Jugdutt BI: Valsartan in the treatment of heart attack survivors. *Vasc Health Risk Management* 2006;2:125-138.

background therapy (Table 13-4).²⁶⁶⁻²⁷⁵ In ELITE,²⁶⁶ losartan showed an unexpected reduction in the secondary end point of all-cause mortality by 46% relative to captopril. Although the study was small and not designed to assess mortality, this effect was thought to be due primarily to a reduction in sudden cardiac death. ELITE II,²⁶⁸ which was designed to assess superiority of losartan over captopril in reducing mortality, showed similar survival rates.

In the large CHARM trials,²⁷¹⁻²⁷⁴ candesartan improved cardiovascular death or heart failure hospitalization in patients taking ACE inhibitors and patients intolerant to ACE inhibitors. Compared with placebo in patients not receiving ACE inhibitors, candesartan reduced the composite primary end point of cardiovascular death or admission for heart failure, although overall mortality did not improve. In a substudy of patients with low ejection fraction ($\leq 40\%$) in the CHARM trial, candesartan reduced all-cause mortality, cardiovascular death, and heart failure hospitalizations.²⁷⁶ In RESOLVD,²⁶⁷ candesartan was compared with enalapril and the combination of candesartan and enalapril; this study was prematurely terminated because of an early trend in increased mortality and heart failure hospitalization (secondary end point) in the candesartan and combined therapy groups, although combined therapy more effectively prevented left ventricular remodeling than monotherapy. In OPTIMAAL,²⁷⁰ which was designed to test for superiority of an ARB on survival and other major cardiovascular outcomes in high-risk post-MI heart failure patients with captopril as comparator, losartan did not show superiority over captopril, but noninferiority criteria were also not met.

In VALIANT,²⁷⁵ which was designed to assess superiority of valsartan over captopril, and the efficacy and safety of long-term treatment with valsartan, captopril, and the combination

of valsartan and captopril in 14,703 high-risk patients with MI and left ventricular systolic dysfunction (ejection fraction $<40\%$) or heart failure or both, patients were randomly assigned 0.5 to 10 days after acute MI and followed for a median period of 24.7 months. There was no difference in the primary end point of all-cause mortality. Although valsartan was noninferior to captopril, adverse events were greater with the combination of valsartan and captopril; valsartan monotherapy was associated with more hypotension and renal dysfunction, and captopril monotherapy was associated with cough, rash, and taste disturbance.

This study established conclusively that valsartan was as effective as captopril in reducing mortality in high-risk patients after MI. The authors also performed a statistical comparison of the VALIANT results with the results of SAVE, AIRE, and TRACE using an imputed placebo, and showed that the 25% risk reduction in all-cause mortality in VALIANT was comparable to reductions in the ACE inhibitor trials. The finding that the valsartan plus captopril combination increased adverse events including hypotension underscores the need for careful monitoring of blood pressure when combining RAAS inhibitors after MI, and supports the caveat regarding vasodilator-induced hypotension in acute MI.

In a substudy of VALIANT,²⁷⁷ 21.5% of the 14,703 patients were elderly (≥ 75 years old), and their outcomes remained poor. With increasing age, mortality, composite end points, and heart failure admissions all increased. Adverse events from captopril and valsartan or both were also more common in elderly patients.

In Val-HeFT,²⁶⁹ which randomly assigned 5010 patients with heart failure to treatment with valsartan or placebo in addition to standard therapy, valsartan did not reduce the primary end point of all-cause mortality, but treatment reduced the composite end

point of mortality and morbidity, improved clinical signs and symptoms of heart failure, and decreased heart failure hospitalizations. A post-hoc analysis of the combined end point revealed that valsartan had a favorable effect in patients who did not receive ACE inhibitors or β -blockers, but an adverse effect in the 30% of patients who received the combination of valsartan, ACE inhibitor, and β -blocker.²⁷⁸ In a substudy of Val-HeFT,²⁷⁹ valsartan improved left ventricular size and ejection fraction in all groups except those taking valsartan together with an ACE inhibitor and a β -blocker. The finding that valsartan decreased mortality by 33% ($P = .017$) and the combined end point by 44% ($P < .001$) in patients not taking ACE inhibitors²⁷⁹ supports the use of valsartan as an alternative in ACE inhibitor-intolerant patients.

Valsartan is recommended in STEMI as an alternative to an ACE inhibitor and in ACE inhibitor-intolerant patients, with a target dose of 160 mg twice daily.¹⁰ Candesartan is also recommended for the same indication, with a target dose of 32 mg daily.¹⁰

Two large trials showed that aldosterone blockade reduces total mortality and hospitalization for heart failure in post-MI patients with left ventricular systolic dysfunction.²⁸⁰⁻²⁸³ In RALES,²⁸⁰ 1663 patients with severe CHF (left ventricular ejection fraction $\leq 35\%$) of ischemic origin in 55% received the aldosterone blocker spironolactone (target dose 50 mg daily if the patient did not develop hyperkalemia) or placebo in addition to background therapy with an ACE inhibitor, diuretic, digoxin, and β -blocker. The trial was prematurely terminated because of the finding of a 30% reduction in all-cause mortality over the 24 months of follow-up. Potassium-sparing diuretics were excluded. Although there were no significant differences in rates of hyperkalemia in the spironolactone group, the rates of breast pain and gynecomastia were higher. In a substudy of RALES,²⁸¹ spironolactone was associated with increased levels of markers of cardiac fibrosis or collagen synthesis, suggesting that limitation of excessive extracellular matrix turnover may have contributed to the benefits.

In the EPHEsus study,²⁸² 6642 patients with acute MI, left ventricular ejection fraction 40% or less, and heart failure were randomly assigned to receive the selective aldosterone blocker eplerenone (target dose of 50 mg daily) or placebo in addition to optimal background therapy. Eplerenone reduced all-cause mortality by 15% and cardiovascular mortality by 17%. Although serious hyperkalemia increased by 1% and 1.6% in these studies, this did not result in deaths. Potassium-sparing diuretics were excluded from this trial. In a substudy of EPHEsus,²⁸³ eplerenone begun at a mean of 7.3 days after acute MI was shown to reduce the 30-day all-cause mortality, supporting the initiation of eplerenone in the hospital. RALES and EPHEsus support long-term aldosterone blocker therapy in patients with heart failure and ejection fraction less than 40%, preserved renal function, and normokalemia.

Several post-MI trials showed that RAAS inhibition limited left ventricular remodeling with progressive left ventricular dilation after MI and improved outcome. These include SAVE with captopril^{237,241}; HEART with ramipril^{255,284}; VALIANT with valsartan, captopril, or both.²⁸⁵ Several heart failure trials also showed beneficial effects of RAAS inhibition on left ventricular remodeling, including V-HeFT I and II^{286,287} and RESOLVD.²⁶⁷

ACE inhibitor therapy also has proven benefits in unstable angina/NSTEMI patients with left ventricular dysfunction or

ejection fraction less than 40%,^{12,263,288,289} diabetics with post-MI left ventricular dysfunction,²⁹⁰ and high-risk patients for coronary events without left ventricular dysfunction.²⁸⁹ Long-term benefit of ACE inhibitor therapy was also shown in the TRACE trial, which followed patients with post-MI left ventricular dysfunction for 10 to 12 years.²⁹⁰

The ACC/AHA heart failure guidelines provide recommendations for initial and target doses of ACE inhibitors, ARBs, and aldosterone blockers (Table 13-5).²⁹¹

Adverse Effects

The side effects of ACE inhibitors include hypotension, acute renal failure, hyperkalemia, increased cough, angioedema, and anaphylactic reactions. ACE inhibitors are contraindicated during pregnancy because of the risk of renal toxicity in the fetus. ARBs have a similar side-effect profile except for minimal cough and lower rates of angioedema. The side effects of aldosterone receptor blockers include hyperkalemia and hypotension. Spironolactone can result in painful gynecomastia in men or menstrual irregularities in women. Eplerenone, being a selective mineralocorticoid blocker, does not have those side effects.

Before starting ACE inhibitor or ARB therapy, one should ensure that the patient is volume replete and begin with a low dose because hypovolemic patients have elevated renin levels, and ACE inhibitors and ARBs may cause a precipitous decrease in blood pressure. In patients with bilateral renal artery stenosis, chronic renal failure, hypertensive nephrosclerosis, CHF, and polycystic kidney disease, in whom the glomerular filtration rate (GFR) is maintained by an increased resistance at the efferent arteriole, ACE inhibitors lower this resistance and decrease GFR and renal function. Typically, creatinine begins to increase a few days after initiating therapy so that a patient's renal function should be checked after initiating ACE inhibitor therapy and followed for the first 3 months.²⁹² Some decrease in GFR may occur, especially in patients with pre-existing renal disease. With a GFR decline greater than 30%, ACE inhibitor or ARB therapy should be stopped and the GFR allowed to return to normal.²⁹²

Hyperkalemia (potassium concentration >5.1 mEq/L) is a common side effect that can be ruled out by measuring potassium levels. It is more common in diabetic patients taking NSAIDs, patients taking potassium-sparing diuretics, and elderly patients.²⁹²⁻²⁹⁴ The risk of hyperkalemia is much higher in patients taking multiple drugs that act on the RAAS, such as ACE inhibitors, ARBs, and aldosterone receptor blockers.²⁹⁵

Cough as a side effect ranges from 10% to 20% with ACE inhibitors, but is much less common with ARBs.^{292,296} It typically begins within the first 1 to 2 weeks, but may take 6 months to manifest. The cough is thought to be due to increased levels of kinins, substance P, and potentially other mediators such as prostaglandins and thromboxane.^{296,297} ACE metabolizes kinins and substance P, and ACE inhibitor therapy increases levels of these substances in the bloodstream. Kinins increase production of prostaglandin that stimulates the C-fibers in the airway and triggers coughing.²⁹⁶

ARB therapy does not have the same effect because it mainly targets AT_1 receptors that are not involved in the cough pathway; the rate of cough as a side effect is the same as with placebo (3%).²⁹⁸ Women are more commonly affected than men.²⁹⁶ Chinese patients have a nearly 50% risk of developing cough with ACE inhibitor therapy.²⁹⁹ Typically, the cough resolves when ACE inhibitor therapy is stopped, within 1 to 4 days, but may

Table 13-5. Initial and Target Doses for Renin-Angiotensin-Aldosterone System Inhibitors

Drug	Initial Dose	Target Dose
ACE Inhibitors		
Captopril	6.25 mg three times daily	50 mg three times daily
Enalapril	2.5 mg twice daily	10-20 mg twice daily
Fosinopril	5-10 mg daily	40 mg daily
Lisinopril	2.5-5 mg daily	20-40 mg daily
Perindopril	2 mg daily	8-16 mg daily
Quinapril	5 mg twice daily	20 mg twice daily
Ramipril	1.25-2.5 mg daily	10 mg daily
Trandolapril	1 mg daily	4 mg daily
Angiotensin Receptor Blockers		
Aldosterone		
Antagonists		
Candesartan	4-8 mg daily	32 mg daily
Eplerenone	25 mg daily	50 mg daily
Losartan	25-50 mg daily	50-100 mg daily
Spironolactone	12.5-25 mg daily	25 mg daily or twice daily
Valsartan	20-40 mg daily	160 mg daily

Note: Drugs are listed alphabetically and not in order of preference.

take 4 weeks.^{296,300} Asthmatic patients are not more susceptible to the cough side effect, but bronchospasm has been reported.³⁰¹ Patients who develop cough as a side effect on ACE inhibitor therapy should be switched to ARB therapy because of the high rate of recurrence with the same or another ACE inhibitor.²⁹²

Angioedema is a life-threatening complication of ACE inhibitor and ARB therapy. Angioedema is caused by two different mechanisms. One involves mast-cell degranulation that increases vascular permeability, and the other involves kinin-related causes, which are triggered by increased bradykinin levels and complement-related mediators that also increase vascular permeability. The angioedema caused by ACE inhibitor and ARB therapy is thought to be related to the kinin pathway rather than mast-cell degranulation. Urticaria and pruritus are usually not present in angioedema caused by the kinin pathway.

Angioedema typically occurs in 0.1% to 0.7% of patients treated with ACE inhibitors.^{296,302,303} Risk factors for angioedema include African-American race, a history of prior drug rash, age older than 65, and history of seasonal allergies.³⁰³ It starts within the first week of therapy, but delayed reactions several years later have been reported.^{302,304,305} When angioedema develops, there is a high risk of recurrence if ACE inhibitor therapy is continued.³⁰⁵ Angioedema has also been associated

with ARB therapy despite the belief that ARBs do not affect kinin metabolism,³⁰⁶⁻³⁰⁸ but its rate is lower than with ACE inhibitors. Patients started on ARB therapy after ACE inhibitor–induced angioedema have a higher risk of angioedema than the general population,^{304,309,310} but no large trials have been done to quantify this risk. A small retrospective review showed that 2 of 26 patients who were thought to have angioedema from ACE inhibitor therapy and switched to ARB therapy developed recurrent angioedema.³¹⁰ A careful risk-benefit assessment should be done before starting a patient who had angioedema from ACE inhibitor therapy on ARB therapy.^{304,309} Hereditary or acquired defects in complement 1-esterase inactivator, a component of the kinin pathway that regulates bradykinin, can be unmasked by ACE inhibitor or ARB therapy.^{296,309,311,312}

There have been concerns in various trials regarding ACE inhibitor and aspirin interactions. The CONSENSUS II, GUSTO-1, and EPILOG trials showed an association, with significantly lesser benefits in patients who were treated with aspirin and an ACE inhibitor.^{313,314} Other reviews did not find the same association, however.^{198,315-318} One review using non-randomized data of nearly 100,000 patients showed that 89% of patients taking an ACE inhibitor and aspirin had a similar benefit as patients taking an ACE inhibitor and no aspirin.³¹⁶ The consensus is that although there may be an interaction between ACE inhibitors and aspirin, it is of small magnitude, and the benefits of ACE inhibitor and aspirin outweigh this potential adverse drug reaction.¹⁰ Using smaller doses of aspirin seems to mitigate this interaction.³¹⁸

Summary of ACC/AHA Task Force Recommendations for Angiotensin-Converting Enzyme Inhibitors and Other Renin-Angiotensin-Aldosterone System Inhibitors in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for ACE and other RAAS inhibitors in STEMI are summarized as follows.^{10,11}

Early Phase

- Patients with anterior STEMI, pulmonary congestion, and left ventricular ejection fraction less than 40%, without hypotension (systolic blood pressure <100 mm Hg or 30 mm Hg below baseline) or contraindications (i.e., ACE inhibitor intolerance), should be started on an oral ACE inhibitor within the first 24 hours (class I, evidence level A).
- An ARB, such as valsartan and candesartan, should be used in patients who are intolerant to ACE inhibitor therapy (class I, evidence level C).
- An oral ACE inhibitor in the first 24 hours of STEMI can also be used for patients with normal left ventricular ejection fraction in the absence of hypotension or contraindications and without anterior STEMI, pulmonary congestion, or ejection fraction less than 40% (class IIa, evidence level B).
- STEMI patients should not be given an intravenous ACE inhibitor in the first 24 hours because of the risk of hypotension (class III, evidence level B), with the possible exception of refractory hypertension.
- STEMI patients with pulmonary congestion should be given a short-acting ACE inhibitor, starting with a low dose (e.g., 1 to 6.25 mg of captopril), provided that there is no hypotension (systolic blood pressure <100 mm Hg or >30 mm Hg below baseline) (class I, evidence level A).

Convalescent Phase

- STEMI patients who tolerate an ACE inhibitor should be continued on it over the long-term (class I, evidence level A).
- An ARB, such as valsartan or candesartan, should be used in ACE inhibitor–intolerant STEMI patients with evidence of CHF or left ventricular dysfunction (ejection fraction <40%) (class I, evidence level B).¹¹
- An aldosterone antagonist should be added in patients without significant renal dysfunction (creatinine should be ≤ 2.5 mg/dL in men and ≤ 2 mg/dL in women) or hyperkalemia (potassium should be ≤ 5 mEq/L) who are already receiving an ACE inhibitor in therapeutic doses but have a left ventricular ejection fraction less than 40% and symptomatic heart failure or diabetes (class I, evidence level B).
- An ARB, such as valsartan or candesartan, can be useful as an alternative in STEMI patients who tolerate an ACE inhibitor, provided that there is evidence of heart failure or a left ventricular ejection fraction less than 40% (class IIa, evidence level B).

Postdischarge

- STEMI patients without contraindications at discharge should be prescribed a long-term ACE inhibitor (class I, evidence level A). A long-term aldosterone blocker should be prescribed for patients without renal dysfunction or hyperkalemia, who are receiving an ACE inhibitor and have an ejection fraction less than 40% and heart failure or diabetes (class I, evidence level A). A long-term ARB should be prescribed in ACE inhibitor–intolerant patients who have evidence of heart failure and ejection fraction less than 40% (class I, evidence level B). An ARB can be used as an alternative to an ACE inhibitor for the same indications (class IIa, evidence level B). An ACE inhibitor may be combined in the long-term if there is persistent heart failure and left ventricular dysfunction (class IIb, evidence level B).
- STEMI patients who are not at lower risk (i.e., normal left ventricular ejection fraction, well-controlled cardiovascular risk factors, and revascularization performed) should be started and continued indefinitely on ACE inhibitors unless contraindicated (class I, evidence level B).¹¹
- STEMI patients who are at lower risk can be given ACE inhibitors (class I, evidence level B).¹¹
- STEMI patients who are ACE inhibitor intolerant and have hypertension can be given an ARB (class I, evidence level B).¹¹
- STEMI patients who have heart failure secondary to systolic dysfunction can be given an ARB in combination with an ACE inhibitor (class IIb, evidence level B).¹¹

Calcium Channel Blockers

Calcium channel blockers (CCBs) are not helpful as adjunctive therapy in acute STEMI. Despite experimental and clinical evidence of anti-ischemic, cardioprotective, and antiremodeling effects, systematic overviews raise concern about an increased mortality risk with routine use of CCBs. Routine use of CCBs in patients with acute MI is not recommended.

Mode of Action

CCBs block the entry of calcium into cells or transmembrane calcium flux through voltage-dependent L-type and T-type calcium channels. The major sites of action are the vascular smooth

muscle cells, cardiomyocytes, and sinoatrial and AV node cells. The voltage-gated L-type calcium channel is long-acting, slow-activating, and blocked by all CCBs. The channel normally allows calcium entry for initiating contraction by calcium-induced calcium release from the sarcoplasmic reticulum. The T-type (transient) channel plays a role in depolarization of the sinoatrial and AV nodes. CCBs inhibit the slow inward calcium current, exert a negative inotropic effect on myocardium, and dilate vascular smooth muscle. As vasodilators, CCBs reduce myocardial oxygen demand and increase supply and are effective anti-ischemic and spasmolytic agents. They also reduce myocardial oxygen demand by decreasing heart rate and contractility.

CCBs were used in acute MI for limiting infarct size and limiting coronary vasospasm.³¹⁹⁻³²² They prevent calcium overload in ischemic cells. They are effective in postinfarction angina. CCBs have been classified into the dihydropyridines, such as nifedipine, and the nondihydropyridines, such as verapamil and diltiazem. Dihydropyridines cause more inhibition of vascular smooth muscle, and nondihydropyridines cause more inhibition of myocardial contractility.

Dose, Timing, and Benefits

Several studies evaluated the effect of CCBs in acute MI. A meta-analysis of the trials indicated that their routine use for treating acute MI did not reduce mortality or morbidity.³²³ The lack of benefit was probably attributable to reflex tachycardia, coronary steal from ischemic myocardium, negative inotropism, and decreased conduction.

Although nifedipine was thought to reduce infarct expansion in one study,³²⁴ its use is contraindicated in acute MI because of the lack of effect on infarct size and the potentially deleterious effects on survival. Nifedipine, a first-generation dihydropyridine CCB, has been studied in acute MI acutely and long-term.^{323,325-333} Data from trials such as TRENT and SPRINT I found no evidence of harm.^{325,326} Other trials such as SPRINT II,³²⁷ a trial by Muller and colleagues,³²⁸ and results from the Augsburg Myocardial Infarction Follow-up Study 1985-1993,³²⁹ found evidence of harm, however, with increased mortality rates when patients with MI were treated with nifedipine.³²⁷⁻³²⁹ There are other data showing harm with nifedipine.^{333,334} HINT was stopped early because of concern that nifedipine caused harm, but subset analysis showed that with the addition of metoprolol, nifedipine did have some benefit.^{334,335} Short-acting, immediate-release nifedipine may cause harm in STEMI by reducing coronary artery perfusion pressure, inducing coronary steal, and increasing reflex sympathetic activity, leading to increased myocardial oxygen demand, and does not reduce reinfarction or mortality. The unstable angina/NSTEMI and STEMI guidelines caution against using nifedipine.^{10,12}

DAVIT II showed that STEMI patients with normal ejection fraction started on immediate-release verapamil in the second week after admission had reduced mortality.³³⁶ Patients with depressed ejection fraction did not have the same mortality benefit, however, if they had evidence of CHF or depressed ejection fraction.³³⁶ CRIS, with verapamil in post-MI patients with normal ejection fraction and no CHF, showed no difference in mortality, but a nonsignificant reduction in reinfarction and a significant reduction in angina.³³⁷ The collective evidence indicates that verapamil is not beneficial in post-MI patients with CHF or depressed ejection fraction and may be harmful.^{323,338-340} Verapamil was detrimental in patients with

heart failure or bradycardia during the first 24 to 48 hours after STEMI.^{323,336,338,339} All trials used oral verapamil, and none showed a mortality benefit after STEMI.

Diltiazem was shown to reduce early reinfarction and recurrent angina in patients with non-Q wave MI (NSTEMI).³⁴¹ There is some evidence that early diltiazem is beneficial in MI.³⁴² A small pilot study of 69 patients presenting with STEMI and given thrombolytic therapy and intravenous diltiazem followed by oral diltiazem or placebo showed a benefit in early postinfarction ischemia and reinfarction at 35 days.³⁴³ Older trial data from MDPIT and DRS suggested a benefit of oral diltiazem in STEMI (Q wave MI) and NSTEMI (non-Q wave MI) patients with preserved ejection fraction and no signs of heart failure.^{323,338,341,344-346} The MDPIT patients with impaired ventricular function (ejection fraction <40%) did worse, however, in terms of mortality than patients with normal ventricular function. There were some potentially confounding factors with MDPIT because about 50% of the patients in the diltiazem and placebo groups were also treated with β -blockers. Also, diltiazem therapy was started 3 to 15 days after MI in MDPIT and 24 to 72 hours after MI in DRS.

Data from MDPIT and DRS showed, however, that there may be more benefit with diltiazem in NSTEMI and a harmful mortality effect in patients with left ventricular dysfunction. The INTERCEPT trial evaluated patients with STEMI and normal ejection fraction treated with thrombolytic therapy and placebo or oral diltiazem³⁴⁷ and showed no significant difference in the primary end point of death, reinfarction, or ischemia at 6-month follow-up. There have been no trials with diltiazem and primary PCI.

The 2004 ACC/AHA guidelines for STEMI¹⁰ and the 2007 guidelines for unstable angina/NSTEMI¹² support the use of nondihydropyridine CCBs such as verapamil and diltiazem (but not the dihydropyridine CCB nifedipine) for heart rate control when β -blocker therapy is contraindicated. Verapamil and diltiazem can also be used for refractory angina in addition to β -blocker therapy and nitrates.¹² Diltiazem, verapamil, and nifedipine all are contraindicated in patients with heart failure, poor ejection fraction, and AV block. None of the CCBs studied has been shown to reduce mortality in acute MI, and they may be harmful in patients with heart failure.

Adverse Effects

The main side effects of CCBs include hypotension, bradycardia, AV block, and worsening of CHF. Potential risk to the fetus during pregnancy indicates the need for caution.

Summary of ACC/AHA Recommendations for Calcium Channel Blockers in ST Segment Elevation Myocardial Infarction

ACC/AHA recommendations for CCBs in STEMI are summarized as follows.¹⁰

Early Phase

- For STEMI patients in whom β -blockers are ineffective or contraindicated (as for bronchospasm allergy to β -blockers), it is reasonable to give verapamil or diltiazem for the relief of ongoing ischemia, controlling rapid ventricular response in atrial fibrillation or flutter as long as there is no CHF, left ventricular dysfunction, or AV block (class IIa, evidence level C). Intravenous or oral short-acting or long-acting forms may be used.

- STEMI patients with left ventricular systolic dysfunction and CHF should *not* be given verapamil or diltiazem (class III, evidence level A). Immediate-release nifedipine should *not* be given because it causes reflex sympathetic activation, tachycardia, and hypotension (class III, evidence level B).

Convalescent Phase and Postdischarge

- No advice is provided in the 2004 guidelines.¹⁰ CCBs are effective in angina (equal in efficacy to β -blockers), coronary vasospasm, cold-induced angina, and supraventricular tachycardias. Verapamil is used in Scandinavian countries for post-MI protection on the basis of a modest benefit in the Danish DAVIT-1 and DAVIT-2 trials.³³⁶ Short-term diltiazem also reduced recurrent ischemia and infarction.³⁴¹ New-generation CCBs continue to be evaluated for their potential value for stunned myocardium, cardioprotection during CABG surgery, and antiremodeling therapy. Second-generation dihydropyridine CCBs (e.g., amlodipine and felodipine) relax smooth muscle, reduce blood pressure, and have little effect on inotropism or heart rate. They have not been studied in acute MI. Evidence from multiple CHF and stable angina trials shows that these agents cause no harm even in patients with low ejection fraction and do not worsen ejection fraction.³⁴⁸⁻³⁵⁴

Magnesium

Experimental and clinical studies suggested that early magnesium in MI might limit infarct size, prevent serious arrhythmias, and reduce mortality. Meta-analyses of seven trials from 1984-1991 suggested the efficacy of magnesium therapy for reducing mortality in acute MI (4.4% absolute risk reduction).^{355,356} The ISIS-4 trial, mounted in part to test the hypothesis that 24 hours of intravenous magnesium sulfate (8 mmol initial bolus, followed by 72 mmol) might improve survival, indicated no significant reduction in 5-week mortality and perhaps a slight increase (7.64% versus 7.24%).¹⁹⁸ There was an excess of heart failure and cardiogenic shock during or after the infusion, an increase in hypotension requiring termination of treatment, and cutaneous flushing, but no net effect on early 0- to 1-day mortality.¹⁹⁸ The subsequent LIMIT-2 showed a mortality benefit (2.5% absolute risk reduction).³⁵⁷ The MAGIC trial using early intravenous magnesium in high-risk STEMI patients showed no mortality benefit at 30 days (15.3% versus 15.2%).³⁵⁸

Evidence from 68,684 patients in 14 trials from 1980-2002 does not support routine use of magnesium for treating STEMI patients.^{10,358-372} Magnesium should be used, however, for treating hypomagnesemia and ventricular arrhythmias such as torsades de pointes.¹⁰ Serum magnesium (and potassium) levels should be checked on admission because electrolyte deficits increase the risk of arrhythmias after MI. A magnesium deficit may develop in STEMI patients because of diet, aging, and prior diuretic use. It is often difficult to correct a potassium deficit when a concurrent magnesium deficit is present.

Summary of ACC/AHA Task Force Recommendations for Magnesium in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for magnesium in STEMI are summarized as follows.¹⁰

Early Phase

- It is reasonable to correct magnesium deficits, especially in patients receiving diuretics before STEMI (class IIa, evidence level C), and to treat torsades de pointes with magnesium (1- to 2-g intravenous bolus over 5 minutes) (class IIa, evidence level C). Otherwise, routine intravenous magnesium should *not* be used in STEMI (class III, evidence level A). There is no definite advice on subsequent use of magnesium.

Lidocaine

Cardiac arrhythmias are common after STEMI and after reperfusion. Most episodes of ventricular fibrillation and ventricular tachycardia occur in the first 48 hours. The pharmacologic management of ventricular fibrillation and ventricular tachycardia after STEMI has been reviewed.¹⁰ The prophylactic use of lidocaine in early MI was controversial before.⁹ Its use in patients at high risk for developing ventricular fibrillation is declining in the era of reperfusion, β -blockers, and antiarrhythmic agents such as amiodarone and procainamide.¹⁰

A meta-analysis of 14 trials with lidocaine indicated a 33% reduction in the risk for developing primary ventricular fibrillation, but no mortality benefit and an increased risk of bradycardia and fatal asystole.³⁷³ Lidocaine was recommended for the control of ventricular premature beats that are more frequent than six per minute, are closely coupled (R-on-T), are multiform, or occur in bursts of three or more, and for ventricular tachycardia or ventricular fibrillation resistant to defibrillation.⁹ In GUSTO-I and GUSTO-IIb, the prophylactic use of lidocaine in STEMI patients showed no mortality benefit, however.³⁷⁴ Evidence that intravenous β -blockers decrease early ventricular fibrillation in patients without contraindications³⁷⁵ supports the use of metoprolol (5 mg intravenously every 2 minutes for three doses, followed by 50 mg orally twice daily for 24 hours, and 100 mg twice daily subsequently) or atenolol (5 to 10 mg intravenously followed by 100 mg daily) for early ventricular fibrillation.¹⁰ In CAST, patients receiving class I antiarrhythmic drugs for suppression of ventricular premature beats fared poorly compared with patients given placebo,³⁷⁶ so this goal is no longer pursued after STEMI.¹⁰ No prophylactic antiarrhythmic therapy should be used when fibrinolytics are used (class III, evidence level B).¹⁰

Free Radical Scavengers

Although thrombolytic therapy is highly effective for myocardial salvage and in limiting ventricular remodeling,^{377,378} reperfusion injury and damage induced by oxygen free radicals are serious problems.^{7,8,379} Superoxide dismutase therapy has been shown to reduce infarct size in late reperfusion models.³⁸⁰ Experimental and clinical studies continue to evaluate new agents aimed at reducing reperfusion injury and improving ventricular function, such as iloprost, human recombinant superoxide dismutase, Fluosol, and others. None of these agents are currently recommended as adjunctive therapy for patients with acute STEMI.

Morphine

Morphine sulfate is the analgesic of choice for managing pain in patients with STEMI. Typically, the pain control algorithm involves a combination of opiate analgesics, nitrates, β -blockers, and oxygen.

Mode of Action, Dosage, and Benefits

Morphine binds to central nervous system receptors, preventing them from transmitting pain signals to the brain. In acute MI, morphine has analgesic, anxiolytic, and hemodynamic properties. It relieves pain that contributes to the hyperadrenergic state, decreases blood pressure via arterial dilation and venodilation, decreases heart rate via increased vagal tone and withdrawal of sympathetic tone, decreases myocardial oxygen demand, and relieves pulmonary edema. There have been no randomized controlled trials describing dosing. A dose of 2 to 4 mg intravenously, with increments of 2 to 8 mg intravenously repeated at 5- to 15-minute intervals, is commonly used.¹⁰⁻¹²

The most common side effects of morphine are nausea and vomiting, with 20% of patients affected.¹² Adverse effects include hypotension, especially prominent in patients who are volume depleted or have been given vasodilator therapy. Treatment of morphine-induced hypotension includes placing the patient in a supine or Trendelenburg position and administering intravenous saline boluses, with the addition of atropine (0.5 to 1.5 mg intravenously) for concomitant bradycardia.^{10,12} Rarely, the narcotic antidote naloxone (0.1 to 0.2 mg intravenously) or an inotropic agent is required. Respiratory compromise from morphine overdose can be treated with naloxone (0.4 to 2 mg intravenous boluses) and very rarely may require intubation for respiratory support. Other narcotics should be considered in patients with severe side effects or allergic reactions to morphine.

Evidence from an observational study reporting increased mortality (odds ratio of 1.41; 95% confidence interval 1.26 to 1.71) in unstable angina/NSTEMI patients treated with morphine³⁸¹ led the ACC/AHA guideline panel to downgrade its recommendation for patients from class I to class IIb.¹² Its use remains as a class I recommendation, however, for the relief of continuing pain in STEMI patients.¹¹

Summary of ACC/AHA Task Force Recommendations for Morphine in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for morphine in STEMI are summarized as follows.¹⁰

- Morphine should be used to manage pain associated with STEMI (class I, evidence level C) along with other anti-ischemic therapy.

Glycemic Control and Insulin

Acute STEMI is associated with low insulin and increased catecholamines, cortisol, glucagon, and free fatty acids, which lead to increased blood glucose. Elevated glucose levels in the post-MI period correlate with increased mortality.³⁸² The first DIGAMI study showed that controlling elevated glucose reduces mortality in the acute post-MI period and up to 1 year.^{383,384} Intensive and standard therapies in DIGAMI 2 showed similar glycemic control and no difference in mortality, however.³⁸⁵ The American Diabetes Association emphasizes glucose control in the post-MI period.³⁸⁶ The target should be less than 180 mg/dL (<10 mmol/L)³⁸³ or less than 140 mg/dL (<7.8 mmol/L).^{387,388} The data are especially strong for critically ill patients.^{387,389,390} There is evidence, however, for a U-shaped curve for the relationship between mortality and blood glucose in patients with acute MI.^{391,392}

Glucose-insulin-potassium infusions in STEMI were evaluated, mostly in the era preceding reperfusion, and suggested benefit. A subsequent trial in 20,201 STEMI patients did not show a mortality benefit, however.³⁹³

Besides the need for tight glycemic control in diabetics and nondiabetics in the early phase of acute STEMI, diabetic patients need glycemic control during the convalescent and postdischarge phases. Long-term management may require insulin or oral hypoglycemic agents or both.^{394,395}

Summary of ACC/AHA Task Force Recommendations for Glycemic Control in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for glycemic control in STEMI are summarized as follows.¹⁰

Acute Phase

- Insulin infusion should be given to normalize blood glucose in STEMI patients with complicated courses (class I, evidence level B). Insulin infusion during the first 24 to 48 hours is reasonable for managing STEMI patients with hyperglycemia even in patients with an uncomplicated course (class IIa, evidence level B).
- Glucose control should be targeted at less than 180 mg/dL (<10 mmol/L) for all post-MI patients. Critically ill cardiac patients (cardiogenic shock) may benefit from even further aggressive control of glucose to less than 140 mg/dL (<7.8 mmol/L).

Convalescence

- It is reasonable to individualize treatment of diabetics after the acute phase of STEMI with insulin, insulin analogues, and oral hypoglycemic agents for the best glycemic control (class IIa, evidence level C).

3-Hydroxy-3-methylglutaryl Coenzyme A Reductase Inhibitors or Statins

Statins are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which is a rate-limiting step in cholesterol synthesis. All statins reduce low-density lipoprotein (LDL) cholesterol, and some also increase high-density lipoprotein (HDL) (e.g., simvastatin, rosuvastatin) and reduce triglycerides (e.g., atorvastatin, rosuvastatin). Evidence shows secondary prevention and mortality benefits with lowering of cholesterol in patients with hypercholesterolemia after MI³⁹⁶ and even patients with mild cholesterol elevation.^{397,398} Lowering cholesterol in patients with normal LDL level is also beneficial.³⁹⁹⁻⁴⁰¹ The REVERSAL trial showed that aggressive lipid lowering prevented progression of atheroma in patients with known coronary artery disease.⁴⁰² ASTEROID showed that very high intensity statin therapy was effective for regression of coronary atherosclerosis.⁴⁰³ Aggressive lipid lowering has been shown to decrease atheroma burden⁴⁰³ and is beneficial in all patients with coronary artery disease.

Early studies on the use of statin therapy for STEMI patients excluded the acute phase and began statin therapy months later.¹⁰ Studies such as PROVE-IT⁴⁰¹ and MIRACL⁴⁰⁴ showed, however, that aggressive lipid lowering in patients with acute coronary syndromes including STEMI is beneficial in the acute setting.

Patients after STEMI should be started on statins for secondary prevention. Starting therapy while the patient is in the hospital improves adherence, with no noted adverse effects,^{405,406} and adherence improves survival.⁴⁰⁷ The National Cholesterol Education Program (NCEP) guidelines recommend the in-hospital initiation of statin therapy.⁴⁰⁸ The target LDL level in the NCEP guidelines is 100 mg/dL or less,⁴⁰⁹ although reducing LDL to less than 70 mg/dL should be considered in very-high-risk patients.⁴⁰⁸ It is recommended that post-STEMI cholesterol be aggressively lowered with high-dose statins (e.g., atorvastatin, 80 mg daily); the dose should be titrated down if the patient develops side effects.

Side effects include elevated aminotransferases, myopathies, and drug interactions. Aminotransferase elevations can occur in 3% of patients taking statins; however, a meta-analysis of 35 trials found that the risk difference between patients taking statins and patients receiving placebo was 4.2 patients per 1000.⁴¹⁰ The FDA guidelines ask that liver enzyme testing be done before the initiation of statin therapy and repeated 12 weeks after that, at any dose elevation, and periodically. Statin therapy should be changed if aminotransferases remain elevated to three times normal. Statin-induced myopathies range from benign myalgias to rhabdomyolysis. Creatine kinase levels should be measured before the initiation of therapy. Clinically significant myopathy is defined as muscle symptoms with creatine kinase elevation 10 times normal. It occurs in less than 1% of patients treated with statins.⁴¹¹⁻⁴¹⁴ If the creatine kinase elevation is thought to be due to statin therapy, the statin should be discontinued.

Drug interactions are common because statins are metabolized by the cytochrome P450 enzyme system, specifically CYP3A4. The metabolism of clopidogrel is inhibited by atorvastatin.⁴¹⁵ The only exceptions are pravastatin or rosuvastatin. Although a listing of all interactions is impossible here, the clinician should be aware of them. A common interaction is between gemfibrozil and a statin other than pravastatin, which can lead to increased risk of rhabdomyolysis. Fenofibrate is safer than gemfibrozil in this respect. Other interactions include interactions with cyclosporine, macrolide antibiotics, and human immunodeficiency virus protease inhibitors.

Summary of ACC/AHA Task Force Recommendations for Lipid Management in ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for lipid management in STEMI are summarized as follows.¹⁰

- On discharge, all STEMI patients should be started on dietary therapy low in saturated fat and cholesterol, with increased consumption of omega-3 fatty acids, fruits, vegetables, soluble fiber and grains, and a balanced calorie intake.
- In the hospital, a fasting lipid profile should be done or obtained within 24 hours of symptom onset (class I, evidence level C), and the target LDL cholesterol should be maintained at less than 100 mg/dL (class I, evidence level A), prescribing drug therapy on discharge, preferably a statin, in patients with LDL cholesterol 100 mg/dL or greater (class I, evidence level A). Patients with LDL cholesterol less than 100 mg/dL or unknown should also be prescribed statin therapy (class I, evidence level B). In addition, patients with non-HDL cholesterol less than 130 mg/dL and HDL cholesterol less than 40 mg/dL should be placed on nonpharmacologic therapy (lifestyle management) to increase HDL (class I, evidence level B).

- It is reasonable to prescribe drug therapy (preferably statins) on discharge in patients with non-HDL cholesterol of 130 mg/dL or greater and LDL cholesterol less than 100 mg/dL or patients with unknown LDL cholesterol levels, with the goal of reducing non-HDL cholesterol to much less than 130 mg/dL (class IIa, evidence level B). It is also reasonable to prescribe drugs such as niacin or fibrate on discharge to increase HDL cholesterol to 130 mg/dL or greater in patients with LDL cholesterol less than 100 mg/dL or non-HDL cholesterol less than 130 mg/dL but HDL cholesterol less than 40 mg/dL (class IIa, evidence level B). It is also reasonable to add drug therapy (niacin or fibrate) to the diet regardless of LDL and HDL levels when triglyceride levels are greater than 500 mg/dL (class IIa, evidence level B).

Anticoagulants

Anticoagulants are useful as adjunctive therapy during convalescence and for secondary prevention after discharge following STEMI (Table 13-6). They can be used to prevent formation or progression of coronary thrombi, limit the formation of mural left ventricular thrombi and systemic embolization, and limit venous thrombosis and pulmonary embolism. Anticoagulants include heparin, unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), synthetic heparins such as fondaparinux and bivalirudin, and warfarin (Coumadin) (see Table 13-6; see also Chapters 9 and 13). A useful algorithm for adjunctive antithrombotic therapy after discharge includes warfarin and antiplatelet agents such as aspirin and clopidogrel (Fig. 13-8).¹⁰

Modes of Action

Thrombin is a key protease of the coagulation system. Thrombin inhibitors (e.g., heparin, UFH, and LMWH) prevent the formation of thrombin and inhibit the activity of already formed thrombin. Heparin is a mixture that consists of 66% high-molecular-weight (average mass 20 kD) and 33% low-molecular-weight (average mass 7 kD) fractions. The low-molecular-weight fraction has 85% of the total anticoagulant activity and causes little platelet activation, whereas the high-molecular-weight fraction has weak anticoagulant activity and can activate platelets. The two fractions consist of subspecies with varying antithrombin III affinity, and the low-molecular-weight fraction has high affinity for antithrombin III.

UFH is a mixture of glycosaminoglycan chains (molecular weights 5 to 3 kD) that produces its anticoagulant effect by binding to antithrombin III, which inactivates factor IIa (thrombin), factor IXa, factor Ia, and factor Xa (see Fig. 13-4). UFH prevents growth of existing thrombus, but does not lyse it.⁴¹⁶ LMWH (molecular weights 2 to 9 kD) produces more potent inactivation of factor Xa than thrombin, whereas UFH produces equal inhibition of factor Xa and thrombin. Fondaparinux is a synthetic heparin polysaccharide that binds to antithrombin with higher affinity than either UFH or LMWH and causes a conformational change that results in preferential increase in the ability of the antithrombin-fondaparinux complex to inactivate factor Xa. Direct thrombin inhibitors such as hirudin bind and inactivate thrombin⁴¹⁷ without need for a cofactor, but have little effect on generation of thrombin. Bivalirudin is a synthetic analogue of hirudin that binds reversibly to thrombin and inhibits clot-bound thrombin.

Table 13-6. Duration of Antiplatelet and Anticoagulant Therapy

Duration of Therapy	
Oral Antiplatelet Therapy	
Aspirin	Lifelong
Clopidogrel/ticlopidine	If patient had bare metal stent, minimum 1 mo
	If patient had drug-eluting stent, minimum 1 yr
	If patient has not been revascularized, can continue clopidogrel or ticlopidine for up to 1 yr
Anticoagulant Therapy	
Unfractionated heparin (intravenous)	Up to 48 hours, provided no other contraindications to discontinuation
	Can discontinue when patient has been revascularized by stenting
Low-molecular-weight heparin	Up to 8 days or duration of hospitalization, provided no other contraindications to discontinuation
	Can discontinue when patient has been revascularized by stenting
Fondaparinux	Up to 8 days or duration of hospitalization, provided no other contraindications to discontinuation
	Can discontinue when patient has been revascularized by stenting
Bivalirudin	Up to 3 days, provided no other contraindications to discontinuation
	Can discontinue when patient has been revascularized by stenting
Warfarin	If patient has left ventricular thrombus or aneurysm, 3 mo to lifelong therapy

Thrombin amplifies the generation of factor VIIIa and factor Va, enhancing thrombus formation. Thrombin also promotes platelet activation by binding to platelet thrombin receptors. Cross-linked fibrin polymer formation, via fibrinogen (factor I) and platelet GP IIb/IIIa receptors, leads to platelet aggregation (see Fig. 13-4). Thrombin also activates factor XIII (fibrin stabilizing factor) to factor XIIIa, which cross-links covalently with fibrin polymer and stabilizes clot.

The endogenous fibrinolytic system is activated to dispose of fibrin. Plasmin, the key protease of this system, is formed from plasminogen via cleavage by plasminogen activators such as tissue-type plasminogen activator and urokinase-type plasminogen activator. This conversion is modulated by plasminogen activator inhibitors PAI-1 and PAI-2. Plasmin cleaves fibrin to fibrin degradation products that have potent anticoagulant and antiplatelet actions (see Fig. 13-4). This conversion is modulated by α_2 -antiplasmin. The regulation of physiologic fibrinolysis involves plasminogen activator inhibitors and α_2 -antiplasmin and thrombin-activatable fibrinolysis inhibitor (TAFI), which is

Figure 13-8. Algorithm for antithrombotic therapy at hospital discharge after ST segment elevation myocardial infarction (STEMI).

*Clopidogrel is preferred over warfarin because of increased risk of bleeding and low patient compliance in warfarin trials. †For 12 months.

‡Discontinue clopidogrel 1 month after implantation of a bare metal stent or several months after implantation of a drug-eluting stent

(3 months after sirolimus, 6 months after paclitaxel) because of potential increased risk of bleeding with warfarin and two antiplatelet agents. Continue aspirin (ASA) and warfarin long-term if warfarin is indicated for other reasons, such as atrial fibrillation, left ventricular thrombus, cerebral emboli, or extensive regional wall-motion abnormality. §An international normalized ratio (INR) of 2.0 to 3.0 is acceptable with tight control, but the lower end of this range is preferable. The combination of antiplatelet therapy and warfarin may be considered in patients younger than 75 years with low bleeding risk who can be monitored reliably. (Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction—executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation* 2004;110:588-636.)

activated by thrombin. Elevated TAF1 and TAF1 polymorphism may increase the risk of venous thrombosis and thromboembolism in patients with high factor VIII, factor IX, or factor XI levels. GP IIb/IIIa inhibitors (e.g., abciximab, eptifibatide, tirofiban) exert their effect at the final step of platelet aggregation (see Fig. 13-4).

Warfarin and coumarin derivatives inhibit the synthesis of vitamin K-dependent coagulation factors (e.g., II, VII, IX, and X) and other anticoagulant factors such as proteins C, S and Z. Because of a narrow therapeutic index; the need for stringent dose management; and interactions with drugs, foods, and comorbid conditions, warfarin may be replaced by orally active direct thrombin inhibitors.

Dosing, Timing, Benefits, and Adverse Effects

Evidence from the prethrombolytic era suggested that heparin produced a small (about 17%) decrease in mortality, so heparin was recommended as a prophylactic anticoagulant for preventing rethrombosis in all patients with acute MI.⁶⁰ Heparin is highly effective in preventing recurrent or new thrombus formation.^{49,60} It is started early, with or after thrombolytic therapy and continued over several days. In the United States, it is given intravenously, as a bolus followed by an infusion to maintain the activated partial thromboplastin time between 1.5 and 2 times control values (i.e., between 60 and 85 seconds). It is safely given together with low-dose aspirin.⁶⁰ Heparin is an adequate adjunctive agent in patients receiving the fibrin-specific recombinant

tissue plasminogen activator.⁴¹⁸ The risk of intracerebral bleed is considered minor (<3 per 1000).

In GUSTO-1,⁴¹⁹ in which intravenous and subcutaneous heparin and systemic activator streptokinase were used, an optimal activated partial thromboplastin time of between 60 and 70 seconds was associated with the lowest mortality, least bleeding complications, least reinfarction rate, and lowest frequency of hemorrhagic shock. Intravenous heparin should be given cautiously or not at all, however, when streptokinase is used, unless it is specifically indicated, as for intracavitary thrombus. Prolonged heparin is effective in preventing left ventricular thrombus after acute MI, and the response is proportional to the dose.⁴²⁰

An advantage of LMWH over UFH is that it does not require blood monitoring for titrating dose to a therapeutic activated partial thromboplastin time. Use of LMWH in patients with renal failure requires frequent monitoring of anti-factor Xa,⁴²¹ however, because it increases when creatinine clearance is less than 30 mL/min.⁴²² Side effects with both types of heparin include bleeding, thrombocytopenia, and osteoporosis. Patients at high risk for bleeding include women; elderly patients (>65 years old); and patients with comorbid states such as peptic ulcer, liver disease, and malignancy.⁴²³⁻⁴²⁵ Intravenous protamine can be used to reverse UFH.

Heparin-induced thrombocytopenia (HIT) is a well-known complication of UFH and LMWH therapy. Two types of HIT are recognized.⁴²⁶ HIT type I occurs in the first 4 days with a platelet nadir of 100,000/mm³, resolves even with continued therapy, and is thought to be non-immune related.⁴²⁷ HIT type II occurs within 5 to 10 days in 1% to 3% of patients and is immune-mediated.⁴²⁸ It should be suspected when the platelet count decreases more than 50%, or if there is evidence of venous or arterial thrombosis or evidence of necrosis at heparin injection sites.⁴²⁹ LMWH is associated with lower rates of HIT than UFH.⁴³⁰

Monitoring of platelet counts is recommended for patients on heparin therapy. Patients exposed to heparin during the previous 3 months can develop early HIT type II owing to circulating antibodies.^{428,431} Management of HIT type II includes immediate discontinuation of LMWH or UFH, with careful attention to routine heparin flushes and heparin-bonded catheters.⁴³² Patients who have a history of HIT type II should not be re-exposed to either type of heparin because a recurrence can be expected 2 to 3 days after re-exposure. A HIT assay can be done to ensure that antibodies are no longer detectable before restarting heparin. STEMI patients who still require anticoagulation with heparin can be given bivalirudin.¹⁰ Because of its long half-life, LMWH should not be used.

Heparin therapy in conjunction with thrombolytic therapy or primary PCI is addressed elsewhere. There have been no randomized controlled studies or new data to guide the management of STEMI patients who do not undergo reperfusion therapy. As part of the trial design, ISIS-2 patients were treated with aspirin and subcutaneous or intravenous UFH and did not show a survival advantage in the intravenous heparin group.³ Other trials showed that heparins induce less overall systemic anticoagulant effect and less breakdown of fibrinogen or depletion of coagulation factors.⁴³³ Although postlytic intravenous UFH increased bleeding in other trials, a statistically nonsignificant 18% decrease in mortality was also found.⁴³⁴ The LATE trial, designed to test alteplase versus placebo, showed lower

mortality in the group that received off-protocol intravenous heparin.⁴³⁵

It is recommended that STEMI patients who require heparin be given UFH as an intravenous infusion, with a bolus of 60 U/kg (maximum 4000 U) followed by infusion of 12 U/kg/hr (maximum 1000 U/hr). Weight-based initial dosing for intravenous heparin is preferred⁴³⁶ because of evidence that the effects of heparin are primarily mediated by weight.⁴³⁷ A useful target is an activated partial thromboplastin time range of 50 to 70 seconds, or 1.5 to 2 times control values, based on data showing that ranges above this have increased risks of bleeding, stroke, and mortality, whereas ranges below this have increased mortality.^{437,438} Anticoagulation can be continued beyond 48 hours after thrombolytic therapy in patients at high risk for thromboembolism, such as anterior STEMI, severe left ventricular dysfunction, CHF, history of systemic or pulmonary embolization, atrial fibrillation, or echocardiographic evidence of thrombus.^{10,439,440}

LMWH for the management of STEMI has also been studied. CREATE⁴⁴¹ randomly assigned 15,570 patients in India and China presenting with STEMI or new left bundle branch block, who had reperfusion therapy with either primary PCI or thrombolytic therapy, to LMWH (reviparin) or placebo. Subgroup analysis showed benefits in the patients who did not receive reperfusion therapy. Overall, LMWH prolonged survival regardless of whether the patient had primary PCI, lytic therapy, or no reperfusion therapy.⁴⁴¹ TETAMI compared UFH and LMWH in patients who did not receive reperfusion therapy.⁴⁴² The patients who were ineligible for acute reperfusion therapy were randomly assigned to UFH or enoxaparin and to placebo or tirofiban. The groups treated with UFH and placebo versus enoxaparin and placebo showed no difference in overall mortality.

The effect of the factor Xa inhibitor fondaparinux (2.5 mg/day) was studied in the OASIS-6 trial of 12,092 STEMI patients.⁴⁴³ The patients were divided into two strata. The first stratum, consisting of 5658 patients with no indication for heparin, was assigned to fondaparinux, 2.5 mg daily, early and for up to 8 days, or placebo; the second stratum, consisting of 6434 patients with an indication for heparin (e.g., fibrin-specific thrombolytic, primary PCI, or no reperfusion), was assigned to fondaparinux for up to 8 days or UFH for 48 hours. The results showed a reduction in 30-day mortality or reinfarction with fondaparinux compared with control (from 11.2% to 9.7%), with benefits apparent at 9 days and driven primarily by reductions in stratum 1. In stratum 2 patients who were not managed with primary PCI, fondaparinux was superior to UFH in preventing death or reinfarction at 30 days. The overall findings indicated that in STEMI patients who are not managed with primary PCI, fondaparinux reduces mortality and reinfarction without increasing bleeding and strokes.⁴⁴³

There are some theoretical advantages in using a direct thrombin inhibitor over heparin. After thrombolytic therapy, a procoagulant state is induced by thrombin bound to soluble fibrin derivatives.⁴⁴⁴ In contrast to direct thrombin inhibitors, a heparin-antithrombin III complex is unable to inactivate a thrombin-bound clot because it cannot penetrate the clot.⁴⁴⁵ Activated platelets have been documented to release heparin inhibitory factors that neutralize heparin but have no effect on the thrombin inhibitor hirudin.⁴⁴⁶ The direct thrombin inhibitor bivalirudin has also been studied in patients undergoing

thrombolytic therapy.^{447,448} Bivalirudin can be used as an alternative to heparin in patients with HIT.¹⁰ A useful dose regimen is to give an initial bolus of 0.25 mg/kg intravenously followed by an infusion at 0.5 mg/kg/hr for 12 hours, and 0.25 mg/kg/hr for the next 36 hours for a total of 48 hours.⁴⁴⁸

Several pathways are involved in platelet activation besides TXA₂ stimulation (blocked by aspirin) and ADP-mediated platelet activation (blocked by clopidogrel). Vascular injury exposes subendothelial von Willebrand factor or collagen to blood. Platelets adhere, and the GP IIb/IIIa receptors on activated platelets (see Fig. 13-4) help to bind platelets to fibrinogen or von Willebrand factor. Cross-linking occurs between other platelets as the final step in platelet activation, with the help of fibrinogen and the GP IIb/IIIa receptors.⁴⁴⁹ Side effects of GP IIb/IIIa inhibitors include increased risk of bleeding and thrombocytopenia. The risk of bleeding is increased by the concurrent use of other anticoagulants (e.g., aspirin, clopidogrel, heparin) in typical STEMI patients.

A careful risk-benefit analysis is needed before starting GP IIb/IIIa inhibitors. Two types of thrombocytopenia may develop with their use⁴⁵⁰ and must be distinguished. Pseudothrombocytopenia is benign and is due to platelet clumping induced by anticoagulant in the tube used for taking blood. True thrombocytopenia can also occur, and is more likely with abciximab than with tirofiban or eptifibatide. Thrombocytopenia with abciximab occurs within the first 24 hours, and even in the first 30 minutes of the infusion,⁴⁵¹ but occurs much later with other drugs.⁴⁵² A meta-analysis of patients treated with GP IIb/IIIa inhibitors showed higher rates of thrombocytopenia.⁴⁵³ Significant clinical events have been reported, including higher death rates and MI, and need for revascularization and blood transfusions.⁴⁵⁴ Platelet counts and hemoglobin should be monitored during GP IIb/IIIa inhibitor therapy. Re-exposure to the drug should be avoided because the risk of developing thrombocytopenia again is increased.⁴⁵⁵ The use of GP IIb/IIIa inhibitors in STEMI depends on whether the patient proceeds to have primary PCI, primary thrombolysis, or no reperfusion. Patients who do not receive reperfusion therapy do not show any benefit from adjuvant GP IIb/IIIa therapy and should not receive it.⁴⁴²

The ACC/AHA guidelines do not recommend GP IIb/IIIa inhibitors for achieving reperfusion in STEMI.^{10,11,456} The evidence for the combination of GP IIb/IIIa inhibitors and thrombolytics is weak; this treatment is associated with little mortality benefit and increased bleeding risk.¹⁰ There are recommendations for use of GP IIb/IIIa inhibitors, such as abciximab (class IIa, evidence level B) and tirofiban and eptifibatide (class IIb, evidence level C), in conjunction with primary PCI for STEMI.⁵⁷

Warfarin dosing is highly dependent on the individual and dietary vitamin K intake, and should be titrated by measuring the patient's response through the INR. The antithrombotic properties of warfarin do not occur until 72 to 96 hours. Its major side effect is related to its anticoagulant effect, which may be reversed with vitamin K or fresh frozen plasma. After MI, thrombotic risk is augmented because of culprit lesion progression and elevation of thrombin,^{457,458} so long-term warfarin therapy may reduce cardiac events. An uncommon but serious side effect of warfarin therapy, typically following large loading doses, is skin necrosis, which occurs in the first few days of therapy,⁴⁵⁹ and may be related to protein C deficiency.⁴⁶⁰ Treatment

of warfarin-induced skin necrosis includes stopping warfarin, administering protein C,⁴⁶¹ giving vitamin K to reverse warfarin, and switching to intravenous heparin for anticoagulation. In patients who still require oral anticoagulation, warfarin has been started at low doses together with protein C to ensure there is no deficiency.^{462,463}

Several trials and meta-analyses have assessed the effectiveness of long-term anticoagulation with varying levels of target INRs from low level to high intensity (<1.5, 1.5 to 2.5, >2.5).⁴⁶⁴⁻⁴⁷⁶ A large meta-analysis showed that warfarin therapy reduced stroke and MI rates, but did not reduce mortality and almost doubled bleeding rates.⁴⁶⁵ The trials included in that meta-analysis looked at patients on warfarin and aspirin, but not clopidogrel. Current management practices with early revascularization imply that patients will be receiving clopidogrel for some time. There have been no trials on the safety or efficacy of the combination of aspirin, clopidogrel, and warfarin. STEMI patients should be considered for long-term warfarin therapy for secondary prevention, provided that they have no risk factors for bleeding, and their INRs can be reliably monitored.¹⁰ This recommendation has been challenged,⁴⁷⁷ however, and warfarin is recommended only if there are established indications for patients with unstable angina/NSTEMI.¹²

Indications for long-term warfarin use after STEMI include atrial fibrillation and evidence of left ventricular thrombus or aneurysm or both. There have been no randomized controlled studies of warfarin for left ventricular thrombus, but such patients have been studied in multiple observational trials.⁴⁷⁸⁻⁴⁸³ A meta-analysis showed that anticoagulated patients had an 86% reduction in embolization rate.⁴⁴⁰ Most embolic events occur within 4 months.^{478,484,485} Anticoagulation with warfarin for at least 3 to 6 months is recommended for STEMI patients with a left ventricular thrombus, and indefinitely in patients with low risk of bleeding.¹⁰ The AHA/American Stroke Association guidelines recommend that warfarin therapy be continued for at least 3 months to a maximum of 1 year in patients with prior embolic events.⁴⁸⁶ Warfarin is thought to delay the resolution of a left ventricular thrombus,⁴⁸⁵ and serial echocardiograms to follow the resolution of left ventricular thrombus is a reasonable approach.^{484,485}

Left ventricular aneurysm is a common complication of STEMI, especially if reperfusion has not been performed. Approximately 50% of left ventricular aneurysms have a thrombus.⁴⁸⁰ Patients with a left ventricular aneurysm and thrombus after recent MI are at high risk of emboli—13% over a 6- to 15-month follow-up period⁴⁸²—and should be anticoagulated. Chronic left ventricular aneurysms have a lower risk of embolization—0.35% over a 5-year follow-up period—and the thrombus may be organized or endothelialized.^{487,488} Warfarin is not warranted in these patients unless other indications are present.

The benefits of warfarin therapy are less clear in STEMI patients with severe left ventricular dysfunction. The SAVE⁴⁸⁹ and SOLVD⁴⁹⁰ trials showed that patients with poor left ventricular ejection fraction tended to have increased rates of stroke that increased as ejection fraction decreased. Potentially, warfarin could reduce this risk. Cochrane analyses have shown that anticoagulation may not be helpful, however.^{491,492} Anticoagulation may be considered in individual STEMI patients with severe left ventricular dysfunction, but is not recommended routinely.¹⁰

Summary of ACC/AHA Task Force Recommendations for Anticoagulation in ST Segment Elevation

Myocardial Infarction

ACC/AHA Task Force recommendations for anticoagulation in STEMI are summarized as follows.¹⁰

Unfractionated Heparin and Low-Molecular-Weight Heparin

- The 2004 ACC/AHA guidelines,¹⁰ which did not consider the more recent studies,^{441,443} recommend UFH or LMWH for 48 hours in STEMI patients who did not receive reperfusion therapy and substitution as the clinical scenario demands.
- The 2007 ACC/AHA guideline update¹¹ recommends that STEMI patients who do not undergo reperfusion therapy be given anticoagulant therapy, ideally a non-UFH heparin regimen, for the duration of hospitalization up to 8 days (class IIa, evidence level B), or LMWH (class IIa, evidence level C), or fondaparinux (class IIa, evidence level B).
- LMWH should not be used in STEMI patients older than 75 years or with renal dysfunction (creatinine >2.5 mg/dL [$>221 \mu\text{mol/L}$] in men or >2 mg/dL [$>177 \mu\text{mol/L}$] in women).

Fondaparinux

- The 2004 ACC/AHA guidelines¹⁰ do not address fondaparinux. On the basis of OASIS-6,⁴⁴³ STEMI patients who do not undergo primary PCI should receive fondaparinux. The 2007 ACC/AHA guideline update¹¹ does not recommend fondaparinux as the sole anticoagulant in primary PCI patients (class III, evidence level C). In patients who do not undergo reperfusion therapy, fondaparinux is superior to control therapy (placebo/UFH).

Bivalirudin

- Bivalirudin can be used in STEMI patients with HIT. Evidence does not support its use for conservative management of STEMI. It can be used for bridging anticoagulation for left ventricular thrombus or poor left ventricular function (also see warfarin for long-term anticoagulation).

Warfarin

- STEMI patients with aspirin allergy should be given warfarin (class I, evidence level B), with INRs dependent on whether or not they have stents and clopidogrel is used.¹⁰
- STEMI patients with left ventricular anterior akinesis, aneurysm, or thrombus should be started on warfarin therapy for target INR 2.0 to 3.0 for 3 months (class I, evidence level B) and indefinitely in patients without risk of bleeding (class I, evidence level C) or reassessed thereafter.
- For secondary prevention, STEMI patients younger than 75 years without specific indications and who can be monitored can be given warfarin alone or together with aspirin (class IIa, evidence level B).
- Warfarin is reasonable for post-STEMI patients with left ventricular dysfunction and extensive regional wall motion abnormalities (class IIb, evidence level A), and may be considered in patients with severe left ventricular dysfunction with or without CHF (class IIb, evidence level C).

- Patients receiving warfarin along with aspirin or clopidogrel or both after STEMI are at increased risk of bleeding and should be monitored closely (class I, evidence level B).¹¹
- STEMI patients requiring aspirin, clopidogrel, and warfarin for clinical indications (i.e., atrial fibrillation, left ventricular thrombus) should have low-dose aspirin (81 mg daily) and clopidogrel (75 mg daily) with a target INR of 2.0 to 3.0 (class I, evidence level A).¹¹

Antioxidants, Vitamins, and Natural Supplements

Vitamin supplementation to reduce homocysteine levels, a marker of inflammation, has no proven benefit.⁴⁹³ The HOPE and NORVIT trials failed to show that using folate to reduce homocysteine reduced cardiac events.^{494,495} Antioxidant vitamins (i.e., vitamins A, C, and E; selenium; and beta-carotene) were found to have no benefit in reducing cardiovascular risk.^{496,497} Populations with large intake of omega-3 polyunsaturated fats were found to have lower rates of heart disease,⁴⁹⁸ and dietary supplementation with fish oil and other omega-3 polyunsaturated fatty acids was associated with a reduction in cardiovascular risk and nonfatal reinfarction within 3 months of an MI.⁴⁹⁹

A large study that examined whether or not omega-3 supplementation can reduce cardiovascular risk is the GISSI Prevenzione study, which randomly assigned 11,324 patients with recent MI in a 2 × 2 design to vitamin E (300 mg) or omega-3 supplementation with fish oil (1 g).⁵⁰⁰ This study found a reduction in the primary end point of death, nonfatal MI, and nonfatal stroke at 42 months with fish oil supplementation.⁵⁰⁰ Vitamin E (300 mg/day) had no benefit.⁵⁰⁰ The benefit of fish oil supplementation was driven by a 30% reduction in cardiovascular death and 45% reduction in sudden cardiac death. The benefits occurred quickly after randomization, with the reduction in sudden cardiac death becoming statistically significant after 4 months, and the reduction in cardiovascular, cardiac, and coronary death becoming statistically significant at 6 to 8 months.⁵⁰¹ The reduction in sudden cardiac death supports an antiarrhythmic effect of fish oil supplementation.

The unstable angina/NSTEMI guidelines recommend encouraging patients to increase their consumption of omega-3 fats through either increasing fish consumption or capsule supplementation.¹² At least two servings of fish a week are thought to be the minimum for a benefit in reducing cardiovascular risk.⁵⁰²

Summary of ACC/AHA Task Force Recommendations for Secondary Prevention Using Vitamin and Dietary Supplements after ST Segment Elevation Myocardial Infarction

ACC/AHA Task Force recommendations for secondary prevention using vitamin and dietary supplements after STEMI are summarized as follows.¹⁰

- For secondary prevention after STEMI, patients can increase fish consumption or add fish oil supplementation to reduce cardiovascular risk. Available evidence does not support the use of antioxidant vitamin supplementation (i.e., vitamins A, C, and E; selenium; and beta carotene) or folate (with or without vitamin B₆ or B₁₂ supplementation) for secondary prevention.

Conclusion

Adjunctive pharmacologic therapy should be considered for all STEMI patients whether or not they are treated with reperfusion therapy. This therapy is necessary to minimize infarct size, ventricular remodeling, reinfarction, recurrent angina, and mortality, and to maximize ventricular function. The agents can be used to widen the time frame for reperfusion therapy and to minimize reperfusion injury and ventricular dysfunction. Agents of proven benefit that are underused include low-dose aspirin, β -blockers, and ACE inhibitors; they should be prescribed more readily. The continued use of low-dose intravenous nitroglycerin in early acute STEMI is justified for control of ischemic pain and remodeling benefits. Long-term administration of nitrates should be used for recurrent angina, but eccentric dosing should be used to limit development of tolerance. Lidocaine, magnesium, and current calcium blockers have no proven benefit as routine therapy.

Medical Management of Unstable Angina and Non-ST Segment Elevation Myocardial Infarction

David M. Leder, Duane S. Pinto

CHAPTER 14

Anti-ischemic Therapies
Antiplatelet Therapy
Antithrombotic Therapies

Statin Therapy
Postdischarge Therapy
Conclusion

IN THE SPECTRUM of acute coronary syndromes (ACS), unstable angina (UA) and non-ST segment elevation myocardial infarction (NSTEMI) are caused by atherosclerotic plaque rupture and thrombosis, resulting in nonocclusive or transiently occlusive blockage. This chapter describes the initial medical management of UA/NSTEMI, which focuses on relief of ischemic pain and antithrombotic therapy to prevent further thrombosis and embolism of an ulcerated plaque, and early, intensive statin therapy.

Anti-ischemic Therapies

Anti-ischemic therapy is routine for all patients with ACS and has not changed significantly in the last several decades. It generally consists of nitrates (either sublingual or intravenous) and intravenous followed by oral administration of β blockade. In patients who cannot tolerate β blockade because of severe bronchospastic lung disease, the addition of a nondihydropyridine calcium antagonist can be considered (Table 14-1).

Nitrates

Despite their routine use in patients with ACS, data showing that nitroglycerin reduces mortality or reinfarction are sparse.^{1,2} Nitroglycerin mainly provides symptom relief. Relief of symptoms is achieved by several mechanisms, including arterial vasodilation, reduction in coronary vasospasm, reduced myocardial oxygen demand (by decreasing preload and afterload), augmentation of collateral blood flow, and inhibition of platelet aggregation. There is no optimal intensity of nitroglycerin therapy, but a loading dose should be administered using sublingual nitroglycerin followed by either a topical or an intravenous agent. The dose is generally titrated until symptoms abate or side effects occur, most notably headache and hypotension. Caution should be exercised in patients who are volume depleted or relatively hypotensive or both because these patients may be sensitive to the preload reduction, and the beneficial effects of the nitrates may be outweighed by severe reduction in the mean arterial pressure.

β Blockers

In the absence of contraindications, all patients with ACS should be treated with intravenous β blockade as soon as possible to minimize the risk of arrhythmia or reinfarction.³⁻⁵ The cardioprotective effects of β blockers occur by reducing sympathetic activation and myocardial ischemia, attenuating the toxicity associated with high circulating catecholamines. β blockers decrease myocardial oxygen demand by reducing heart rate, contractility, and systolic blood pressure, and by prolonging diastolic filling, which may allow for increased coronary perfusion time. The antiarrhythmic effects of β blockers result from direct cardiac electrophysiologic activity with decreased spontaneous firing of ectopic pacemakers, slowed conduction, and increased refractory period of the atrioventricular node. Contraindications include β blocker allergy, bradycardia (heart rate <60 beats/min), heart failure, shock, and second-degree or third-degree atrioventricular block.

A meta-regression analysis of randomized controlled trials after myocardial infarction (MI) showed that β blockers reduce the odds of death in long-term trials by 23% and in short-term trials by 4%.⁶ In addition to the immediate administration of intravenous β blockade, patients who survive MI should be continued on oral agents indefinitely. A study in nearly 70,000 patients prescribed a β blocker (atenolol, metoprolol, or propranolol) after acute MI showed that these agents were associated with a 40% improvement in survival at 2 years, and suggested that the specific β blocker chosen has little influence on mortality.⁷

COMMIT has called into question the practice of routinely using intravenous β blockade in patients with ST segment elevation MI. Although benefits in reduction of reinfarction and ventricular fibrillation were noted, an excess of early shock was associated with use of intravenous β blockers.⁸ In UA/NSTEMI patients, the beneficial anti-ischemic and antiarrhythmic effects of intravenous β blockers may be counterbalanced by adverse effects in hemodynamic stability if administered rapidly and at high doses in patients with even mild heart failure or hypotension. In such patients, withholding β blockade 12 to 24 hours until hemodynamic stabilization has been confirmed may be prudent.

Table 14-1. Recommendations for Anti-Ischemic Therapy: Continuing Ischemia or Other Clinical High-Risk Features Present*

Bed/chair rest with continuous ECG monitoring
Supplemental oxygen with arterial saturation <90%, respiratory distress, or other high-risk features for hypoxemia. Pulse oximetry can be useful for continuous measurement of SaO_2
NTG 0.4 mg sublingually every 5 min for a total of 3 doses; afterward, assess need for intravenous NTG
Intravenous NTG for first 48 hr after UA/NSTEMI for treatment of persistent ischemia, HF, or hypertension
Decision to administer intravenous NTG and dose should not preclude therapy with other mortality-reducing interventions such as β blockers or ACE inhibitors
β blockers (via oral route) within 24 hr without a contraindication (e.g., HF) regardless of concomitant performance of PCI
When β blockers are contraindicated, a nondihydropyridine calcium channel blocker (e.g., verapamil or diltiazem) should be given as initial therapy in the absence of severe left ventricular dysfunction or other contraindications
ACE inhibitor (via oral route) within first 24 hr with pulmonary congestion, or LVEF ≤ 0.40 , in the absence of hypotension (systolic blood pressure <100 mm Hg or <30 mm Hg below baseline) or known contraindications to that class of medications
ARB should be administered to UA/NSTEMI patients who are intolerant of ACE inhibitors and have either clinical or radiologic signs of HF or LVEF ≤ 0.40

*Recurrent angina or ischemia-related ECG changes (≥ 0.05 mV ST segment depression or bundle branch block), or both, at rest or with low-level activity; or ischemia associated with HF symptoms, S_3 gallop, or new or worsening mitral regurgitation; or hemodynamic instability or depressed left ventricular function (LVEF <0.40 on noninvasive study); or serious ventricular arrhythmia. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; HF, heart failure; LVEF, left ventricular ejection fraction; NTG, nitroglycerin; PCI, percutaneous coronary intervention; UA/NSTEMI, unstable angina/non-ST segment elevation myocardial infarction.

Adapted from Anderson JL, Adams CD, Antman EM, et al: ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients with Unstable Angina/Non-ST-Elevation Myocardial Infarction) Developed in Collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons Endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol* 2007;50:e1-e157.

Calcium Antagonists

For patients in whom β blockade is contraindicated, calcium antagonists can be considered to alleviate anginal symptoms. The antianginal effects of calcium channel blockers are mediated through a reduction of myocardial oxygen demand secondary to decreased afterload and myocardial contractility. Dihydropyridines (nifedipine and amlodipine) and nondihydropyridines (verapamil and diltiazem) have antianginal properties, but dihydropyridines can result in reflex tachycardia, so these are generally avoided unless a β blocker can be administered

concurrently. Nondihydropyridines, especially verapamil, can cause bradycardia and significant depression of myocardial contractility, and should be used cautiously when added to β blocker therapy. Similar to β blockers, nondihydropyridines are generally avoided completely in patients with congestive heart failure and significant atrioventricular dysfunction.

Apart from severe bronchospastic lung disease, allergy, and possibly cocaine ingestion, the contraindications for β blockers are the same as the contraindications for calcium antagonists. No definitive data exist to suggest that there are substantial reductions in ischemic complications of MI with these agents. A meta-analysis of trials of patients with acute MI or UA who were treated with calcium antagonists found that these agents do not reduce the risk of initial or recurrent infarction or death,⁹ reinforcing the fact that β blockers are the preferred initial therapy, and calcium channel blockers should not be routinely used as first-line therapy for ACS.

Antiplatelet Therapy

Circulating platelets play a crucial role in normal hemostatic function; however, platelet aggregation and thrombosis are maladaptive processes in ACS. Atherosclerotic plaque rupture during ACS exposes thrombogenic subendothelial components, leading to platelet deposition and activation.¹⁰ Platelet activation is associated with surface expression of greater numbers of glycoprotein (GP) IIb/IIIa receptors that are available for binding fibrin strands and platelet cross-linking. In addition to cross-linking as part of the aggregation process, activated platelets also release local mediators that can induce further platelet accumulation and activation, vasoconstriction, thrombosis, and mitogenesis. Platelet activation leads not only to thrombus formation in the epicardial artery, but also distal embolization and occlusion of the microcirculation, which have been associated with poor outcomes.^{11,12} Because of the significant contribution of platelets to the pathophysiology of ACS, one of the cornerstones of medical therapy is directed at inhibiting their deleterious effects.

Aspirin

Numerous trials consistently show the benefits of aspirin in patients with ACS,¹³⁻¹⁸ and its use has become the foundation of medical management for UA/NSTEMI. Aspirin acts by inhibiting cyclooxygenase-1 within platelets, which interferes with the biosynthesis of thromboxane A_2 , prostacyclin, and other prostaglandins. These prostanoids are the main determinants of platelet aggregation in this pathway.

Acute treatment with aspirin is recommended for all patient with suspected ACS, unless contraindicated, and should be continued indefinitely. Current American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend an initial dose of aspirin of 162 to 325 mg.² In clinical practice, most physicians in the United States use initial doses of aspirin of 325 mg during the initial phase of ACS. After stent implementation, a maintenance dose of 325 mg is recommended for 1 month with bare metal stents and for 6 to 12 months with drug-eluting stents. Thereafter, or in the absence of percutaneous coronary intervention (PCI), the optimal maintenance dose of aspirin is 75 to 162 mg daily.² Ibuprofen interferes with the cardioprotective effects of aspirin¹⁹; an alternative nonsteroidal anti-inflammatory drug ideally should be prescribed to patients requiring indefinite aspirin therapy. If ibuprofen use cannot be

avoided, it should be taken at least 30 minutes after or at least 8 hours before aspirin.²

There is growing evidence that many individuals may exhibit aspirin resistance.²⁰ Whether the term *aspirin resistance* represents a clinical failure of aspirin therapy (i.e., stroke, MI) or some level of residual platelet aggregation despite therapy remains a matter of debate. Nevertheless, this syndrome has been variously described as relative failure to inhibit platelet aggregation or failure to prolong bleeding time, or the development of a clinical event while on aspirin therapy. Presently, no test of platelet function is currently preferred to assess the antiplatelet effect of aspirin in the individual patient because it is difficult to assess the clinical significance of in vitro platelet function studies. In patients with contraindications or intolerance to aspirin or patients who experience a cardiac event while taking aspirin (e.g., aspirin failures), clopidogrel, 75 mg daily, is a suitable alternative.

Thienopyridine Agents

Thienopyridine agents block the adenosine diphosphate receptor P2Y₁₂ on the platelet surface, inhibiting platelet activation. The currently approved agents, clopidogrel and ticlopidine, have been widely used. Because of the adverse potential of ticlopidine (i.e., neutropenia and rarely thrombotic thrombocytopenic purpura), clopidogrel has emerged as the preferred thienopyridine.

The widespread use of clopidogrel in the treatment of ACS is based primarily on the CURE and CREDO trials.^{21,22} The CURE trial compared the benefit of aspirin plus clopidogrel (300 mg loading dose, then 75 mg/day) treatment versus aspirin alone in 12,562 patients with UA/NSTEMI for 3 to 12 months. The use of clopidogrel reduced the risk of cardiovascular death, recurrent MI, or stroke significantly by 20%, from 11.5% in the placebo group to 9.3% in the clopidogrel group. A reduction of death, nonfatal MI, stroke, or refractory or severe ischemia was already present within 24 hours of randomization.²¹ The beneficial effects of clopidogrel were noted across all subgroups regardless of whether high-risk features were present, such as electrocardiogram (ECG) changes or elevated cardiac biomarkers, suggesting broad use for this agent as adjunctive therapy in all UA/NSTEMI patients if no contraindications exist.

In PCI-CURE, an observational substudy of the CURE trial, 2658 patients underwent PCI a median of 10 days after randomization.²³ All patients received an open-label thienopyridine after PCI for approximately 30 days, after which the original blinded study drug was restarted for an additional 8 months. Pretreatment with clopidogrel was associated with a 30% reduction in risk of cardiovascular death, recurrent MI, or target vessel revascularization at 30 days (6.4% versus 4.5%). The benefit of pretreatment and long-term therapy with clopidogrel before PCI was also observed in the CREDO trial.²² CREDO comprised 2116 patients, 55% of whom had UA/NSTEMI and were to undergo PCI, and compared pretreatment with clopidogrel, 300 mg, followed by maintenance therapy, 75 mg, versus placebo with 1-year follow-up. Patients allocated to placebo received 75 mg of clopidogrel at the time of PCI, followed by 75 mg daily for 1 month and placebo thereafter. The benefit of pretreatment with 300 mg of clopidogrel was primarily observed among patients who had received pretreatment 15 hours or more before PCI.²⁴

Taken together, the PCI-CURE and CREDO trials suggest that ACS patients should be treated early with clopidogrel before PCI, and treatment should be continued for 9 to 12 months.

A suggested algorithm for antiplatelet therapy after an episode of UA is outlined in Figure 14-1.

More recent investigation in this area has focused on the optimal timing and loading dose of clopidogrel before PCI. ARMYDA-2 randomly assigned patients to receive either a 300-mg or 600-mg loading dose of clopidogrel 4 to 8 hours before PCI, and found that the 600-mg loading dose significantly reduced periprocedural MI.²⁵ Most patients in ARMYDA-2 underwent PCI for stable angina (75%). Cuisset and colleagues²⁶ randomly assigned 292 consecutive patients with non-ST segment elevation ACS undergoing stenting to receive a 300-mg or 600-mg loading dose of clopidogrel at least 12 hours before PCI. During the 1-month follow-up, 18 (12%) cardiovascular events occurred in the 300-mg group compared with 7 (5%) events in the 600-mg group. Based on the current available evidence, all patients without contraindications who present with ACS should be given a 300-mg loading dose of clopidogrel, and in situations in which longer durations of pretreatment are impossible, 600 mg may be used when given at least 2 hours before PCI.²

Several new thienopyridine agents are currently being investigated. Prasugrel is a thienopyridine that has been shown in pre-clinical studies to be more potent and to have a more rapid onset of action than clopidogrel.²⁷ It was evaluated in the TRITON-TIMI 38 study, in which 13,608 ACS patients undergoing PCI were randomly assigned to prasugrel or clopidogrel. Although prasugrel therapy was associated with significantly reduced rates of ischemic events, this benefit came at a cost of more major bleeding events.²⁸ AZD-6140, another newer thienopyridine with greater potency than clopidogrel, is currently being evaluated. Cangrelor, an intravenous agent with an extremely short half-life and rapid onset of action,²⁹ is the subject of the ongoing CHAMPION-PLATFORM and CHAMPION-PCI trials.

Glycoprotein IIb/IIIa Receptor Inhibitors

Platelet activation is associated with surface expression of greater numbers of GP IIb/IIIa receptors available for binding fibrin strands and platelet cross-linking. Several large, randomized clinical trials have shown improved clinical outcomes with the administration of GP IIb/IIIa receptor inhibitors (GPIs) in patients presenting with ACS and after PCI to inhibit platelet aggregation.³⁰ Although intravenous agents seem to be beneficial, the oral GPI, in contrast, has been ineffective and may increase mortality.³¹ Three intravenous GPIs are currently available for clinical use: abciximab, tirofiban, and eptifibatide. Abciximab is a GPI that comprises Fab fragment of the chimeric human-murine monoclonal antibody 7E3. Tirofiban is a non-peptide inhibitor of the platelet GP IIb/IIIa receptor, interfering with aggregation by mimicking the geometric, stereotactic, and charge characteristics of the platelet integrin-binding domain sequence. Eptifibatide is a nonimmunogenic, cyclic heptapeptide with an active pharmacophore that is derived from the structure of barbourin, a platelet GPI from the venom of the Southeastern pigmy rattlesnake.³² Table 14-2 summarizes the clinical indications for GPI administration.

The TIMI risk score for UA/NSTEMI³³ (Fig. 14-2) and GRACE prediction score³⁴ (Fig. 14-3) have been validated for UA/NSTEMI patients to predict patients at increased risk of adverse clinical outcomes. The decision whether to initiate therapy with a GPI and which agent to use should be determined based on an assessment of the patient's risk, and whether an early invasive versus selective treatment strategy is anticipated.³⁵ Among high-risk, troponin-positive UA/NSTEMI patients treated with medical

Figure 14-1. Suggested algorithm for antiplatelet therapy in follow-up after unstable angina and non-ST segment elevation myocardial infarction (UA/NSTEMI). ASA, aspirin. (Adapted from Anderson JL, Adams CD, Antman EM, et al: ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients with Unstable Angina/Non-ST-Elevation Myocardial Infarction) developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol* 2007;50:e1-e157.)

*For aspirin (ASA) allergic patients, use clopidogrel alone (indefinitely), or try aspirin desensitization.

†For clopidogrel allergic patients, use ticlopidine, 250 mg by mouth twice daily.

‡Continue ASA indefinitely and warfarin longer term as indicated for specific conditions such as atrial fibrillation; LV thrombus; cerebral, venous, or pulmonary emboli.

§When warfarin is added to aspirin plus clopidogrel, an INR of 2.0 to 2.5 is recommended. INR = international normalized ratio; LOE = Level of Evidence; LV = left ventricular; UA/NSTEMI = unstable angina/non-ST-elevated myocardial infarction.

therapy alone, benefits have been shown with eptifibatide (PUR-SUIT)³⁶ and tirofiban (PRISM, PRISM-PLUS, and RESTORE).³⁷⁻³⁹ In contrast, mortality was higher among medically treated patients who received abciximab in the GUSTO 4 ACS trial.⁴⁰

Antman and colleagues⁴¹ conducted a meta-analysis of GPIs in six large trials involving 31,402 UA/NSTEMI patients who were not scheduled to undergo PCI. Significant reduction in the odds for the combined end point of death or MI was observed in the GPI group at 5 days (5.7% versus 6.9% for placebo/control; odds ratio [OR] 0.84, 95% confidence interval [CI] 0.77 to 0.93) and at 30 days (10.8% versus 11.8%; OR 0.91, 95% CI 0.85 to 0.98). Bleeding rates were significantly higher (2.4% versus 1.4%; $P < .0001$), but there was no increase in intracranial bleeding (0.09% versus 0.06%).

The observed benefit of GPI was largely confined to patients who went on to have PCI or coronary artery bypass graft surgery within 30 days (OR for death or MI 0.89, 95% CI 0.80 to 0.98). Patients with positive cardiac biomarkers were identified as a high-risk cohort, and much of the benefit seemed to be among the patients with a positive troponin T or I concentration (0.1 ng/mL) (OR 0.85, 95% CI 0.71 to 1.03). For the patients who did *not* undergo early revascularization (25,555 [81%] in this analysis), there was no significant reduction in death or MI (OR 0.95, 95% CI 0.86 to 1.05). Among low-risk, troponin-negative patients in

whom a selective invasive strategy is selected, there is less benefit of adding a GPI, and it is generally not recommended.

For patients in whom an early invasive strategy is selected, all three GPIs have been shown to reduce the incidence of death or MI in patients with UA/NSTEMI undergoing PCI.^{36,39,42-44} An analysis of data from 12,296 patients in CAPTURE, PUR-SUIT, and PRISM-PLUS using abciximab, eptifibatide, and tirofiban showed that intravenous GPI added to heparin and aspirin significantly reduced the rate of death or nonfatal MI during drug infusion (2.5% versus 3.8%) and during the first 48 hours after PCI (4.9% versus 8%).⁴⁵ The benefit from GPI was primarily observed among troponin-positive patients.^{46,47} Data from more than 60,000 patients in the National Registry of Myocardial Infarction show a 5.5% absolute reduction in mortality when a GPI is initiated within the first 24 hours. In a multivariate model and after adjustment for the propensity to be treated with such agents, there was a significant 12% relative risk reduction.⁴⁸

The challenge in delivering the optimal medical therapy to patients with UA/NSTEMI is incorporating the evidence from the above-mentioned GPI studies, which were performed in the 1990s, with the more recent studies involving clopidogrel loading before PCI and newer anticoagulants. The current ACC/AHA guidelines for UA/NSTEMI patients in whom an initial

invasive strategy is selected is to add either an intravenous GPI or clopidogrel to aspirin and anticoagulant therapy before diagnostic angiography (upstream) for lower risk, troponin-negative patients.² High-risk, troponin-positive patients should receive a GPI and clopidogrel before angiography (class I recommendations). The evidence for benefit in patients in whom a selective invasive strategy is selected is less clear. In that situation, the addition of eptifibatide or tirofiban to anticoagulant and oral

antiplatelet therapy may be reasonable for high-risk patients (class IIb recommendation).² Antiplatelet therapies for UA/NSTEMI are summarized in Table 14-3.

Regarding the decision of whether an early invasive or conservative approach should be chosen, current ACC/AHA guidelines support an early invasive strategy. Many of the initial data supporting this decision were derived from TACTICS TIMI-18,³³ in which 2220 patients with UA/NSTEMI were treated with an initial medical regimen of aspirin, heparin, and tirofiban, and then randomly assigned to either an early invasive strategy (cardiac catheterization within 4 to 48 hours) or an early conservative approach. The early invasive strategy was associated with a 3.5% absolute reduction in the composite end point of death, recurrent MI, or rehospitalization for ACS at 6 months (OR 0.78, 95% CI 0.62 to 0.97, $P = .025$), but most of this benefit was driven by a reduction in recurrent MI and rehospitalization.

In a meta-analysis of clinical trials using contemporary therapies (GPI or thienopyridine or both, and coronary stents for PCI), an early invasive strategy was found to improve individual outcomes of mortality.³⁴ Seven trials with 8375 patients were analyzed with a primary end point of all-cause mortality. At a mean follow-up of 23.7 months, the mortality incidence in patients assigned to early invasive therapy was 4.9% compared with 6.5% among the patients treated conservatively (relative risk 0.75, 95% CI 0.63 to 0.90, $P = .001$). Similar to TACTICS-TIMI 18, the early invasive strategy was also associated with a reduction in recurrent MI (7.6% versus 9.1%; $R = 0.83$, 95% CI 0.72 to 0.96, $P = .012$) and rehospitalization for ACS (19.9% versus 28.7%; $R = 0.69$, 95% CI 0.65 to 0.74, $P < .0001$).

The weight of available evidence shows that for patients presenting with UA/NSTEMI, an early invasive strategy of cardiac catheterization within 48 hours results in fewer ischemic complications, which is primarily driven by reductions in recurrent MI. Although these individual trials were not powered to detect a mortality benefit, a more recent meta-analysis suggests that an early invasive strategy may also confer an improved survival advantage. The benefits of an early invasive strategy were limited

TIMI RISK SCORE FOR UA/NSTEMI

to moderate-risk and high-risk patients (see Figs. 14-2 and 14-3); low-risk patients are unlikely to derive benefit and may potentially experience adverse outcomes from early cardiac catheterization.

Antithrombotic Therapies

Because ACS are precipitated by the rupture of vulnerable atherosclerotic plaques with resultant formation of intracoronary thrombus, agents directed against the generation of thrombin are a hallmark of management. Unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), direct thrombin inhibitors, and factor Xa inhibitors all target this crucial step.

Heparin

UFH works to accelerate the action of circulating antithrombin, inactivating factors IIa, IXa, and Xa. Although UFH prevents thrombus propagation, it does not result in lysis of existing thrombi.^{2,35} Its benefits when combined with aspirin have been shown in numerous clinical trials, establishing UFH as a cornerstone of ACS management for more than 15 years. In the RISC trial, patients receiving heparin and aspirin had the fewest events during the first 5 days.³⁶ A meta-analysis of six UA trials showed a 33% ($P = .06$) reduction in the risk of death or MI at 2 to 12 weeks in patients treated with UFH and aspirin versus aspirin alone.³⁷

(Continued)

Note: Additional considerations include the possibility that a patient who has been conservatively managed may develop a need for PCI, in which case an IV bolus of 50 to 60 U/kg is recommended if fondaparinux was given for initial medical treatment; the safety of this drug combination is not well established. For conservatively managed patients in whom enoxaparin was the initial medical treatment, as noted in the table, additional IV enoxaparin is an acceptable option.

*This list is in alphabetical order and is not meant to indicate a particular therapy preference.

†In patients in whom the physician is concerned about the risk of bleeding, a lower initial American Society of Anesthesiologists dose after PCI of 75 to 162 mg/day is reasonable (class IIa, Level of Evidence: C).

‡Dalteparin was evaluated for management of patients with non-ST segment elevation myocardial infarction in an era before the widespread use of important therapies such as stents, clopidogrel, and GP IIb/IIIa inhibitors. Its relative efficacy and safety in the contemporary management era is not well established.

§Some operators use <60 U/kg of UFH with GP IIb/IIIa blockade, although no clinical trial data exist to show the efficacy of doses <60 U/kg in this setting.

¶For patients managed by an initial conservative strategy, agents such as enoxaparin and fondaparinux offer the convenience advantage of SC administration compared with an IV infusion of UFH. They are also less likely to provoke heparin-induced thrombocytopenia than UFH.

¶Available data suggest fondaparinux is associated with less bleeding than enoxaparin in conservatively managed patients using the regimens listed.

***This regimen has not been rigorously tested in prospective randomized trials.

ACT, activated clotting time; aPTT, activated partial thromboplastin time; BMS, bare metal stent; GP, glycoprotein; IU, international unit; IV, intravenous; LD, loading dose; MD, maintenance dose; NA, not applicable; PCI, percutaneous coronary intervention; PES, paclitaxel-eluting stent; SC, subcutaneous; SES, sirolimus-eluting stent; UFH, unfractionated heparin.

From Anderson JL, Adams CD, Antman EM, et al: ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients with Unstable Angina/Non-ST-Elevation Myocardial Infarction) Developed in Collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons Endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol* 2007;50:e1-e157.

Much of the benefit from the administration of UFH combined with aspirin is thought to be driven by a reduction in recurrent MI. The duration of UFH in most UA/NSTEMI trials has been 2 to 5 days; the optimal duration of therapy is uncertain and likely varies by strategy. There is an important risk of rebound ischemia when the drug is stopped prematurely.^{38,39} Other disadvantages of UFH include its poor bioavailability related to its binding to many plasma proteins. Consequently, there is marked variability in the anticoagulant response and a need for frequent monitoring of the activated partial thromboplastin time, which is not standardized among laboratories. Typically, higher doses are required for diabetics, smokers, and patients weighing more than 100 kg, whereas lower doses are often required for elderly women. Rarely, autoimmune heparin-induced thrombocytopenia (heparin-induced thrombocytopenia type II) may result with serious prothrombotic complications, and should be investigated when the platelet count declines by more than 50% or to values less than 100,000/ μ L.

Low-Molecular-Weight Heparins

The limitations of UFH have led to significant attention directed to alternative antithrombotic agents, such as LMWHs. LMWHs are prepared by depolymerization of the polysaccharide chains of heparin into shorter peptides of lower weight.² LMWHs are more potent inhibitors of factor Xa than UFH. Advantages over UFH include decreased binding to plasma proteins, dose-independent clearance, and a longer half-life resulting in a more predictable anticoagulant response that does not typically require laboratory monitoring.

The ESSENCE and TIMI 11B trials, which comprised more than 7000 patients, showed a 20% reduction in major adverse cardiovascular events with enoxaparin compared with UFH.^{40,41} More recently, the efficacy and safety of enoxaparin versus UFH were evaluated when given in combination with GPIs. In INTERACT, the primary safety outcome of major bleeding not associated with coronary artery bypass graft surgery was significantly lower in the enoxaparin group (1.8% versus 4.6%). Additionally, the rate of death or nonfatal MI at 30 days was reduced by almost half (relative risk 0.55, 95% CI 0.30 to 0.96).⁴² An important caveat is that the median time to revascularization was relatively slow in this trial at 101 hours. SYNERGY, a

trial of an early invasive strategy, showed that enoxaparin was noninferior with respect to UFH for death or MI at 30 days, but was associated with an increased rate of TIMI major bleeding (9.1% versus 7.6%; $P = .008$).⁴³ Post-hoc analysis of the trial suggested that some of this excess bleeding could be attributed to crossover to UFH at the time of PCI.

Taken together, these two trials suggest that in patients receiving GPIs, enoxaparin is safest and beneficial in patients in whom a conservative or delayed invasive approach is planned, whereas UFH is preferable for patients managed with an early invasive strategy. Additionally, if patients initially treated with LMWH undergo early PCI, it is preferable to maintain a consistent anticoagulation strategy rather than crossover at the time of PCI. For patients in whom coronary artery bypass graft surgery is planned, UFH is preferable to LMWH. Finally, LMWH should be avoided in patients older than 75 years or with significant renal dysfunction (glomerular filtration rate <30 mL/min).

Direct Thrombin Inhibitors

Direct thrombin inhibitors, such as hirudin and bivalirudin, have theoretical advantages compared with UFH because they (1) bind directly and tightly with thrombin without the need for cofactors such as antithrombin III, (2) are more effective in inhibiting fluid-phase and clot-bound thrombin, (3) do not cause or aggravate heparin-induced thrombocytopenia, and (4) achieve more stable levels of anticoagulation.

In TIMI-9B and OASIS-2, hirudin showed mixed efficacy compared with UFH and excess bleeding at higher doses.^{44,45} Bivalirudin, a synthetic analogue of hirudin, was investigated in more than 13,000 patients with UA/NSTEMI in the ACUTY trial. Patients undergoing cardiac catheterization within 72 hours of presentation were assigned to one of three treatment regimens: (1) UFH or enoxaparin with or without upstream GPI, (2) bivalirudin with or without upstream GPI, or (3) bivalirudin alone. Patients assigned to the first two groups were randomly assigned further in a 2×2 factorial design, whereby if they did not receive upstream GPI it was given at the time of PCI. When used with a GPI, bivalirudin was shown to be noninferior to heparin with respect to a 30-day rate of the net clinical outcome of composite ischemia or major bleeding or both (11.8% versus 11.7%), with no significant difference in major bleeding (5.3% versus 5.7%).

When used alone, bivalirudin was superior to heparin plus GPI with respect to the rate of major bleeding (3% versus 5.7%).⁴⁶

Subgroup analysis showed that bivalirudin was comparable to heparin plus a GPI with regard to ischemic complications when clopidogrel pretreatment was administered (7% versus 7.3%), but was inferior in patients who did not receive thienopyridine pretreatment (9.1% versus 7.1). Whether this finding is due to the limitations inherent in retrospective analyses or truly represents the adverse consequences of inadequate platelet inhibition in patients not pretreated is uncertain. Nevertheless, to optimize outcomes in ACS patients receiving bivalirudin who have not had pretreatment with a thienopyridine, it is prudent to consider a concomitant GPI.

Factor Xa Inhibitors

Synthetic pentasaccharides, such as fondaparinux, act proximally in the coagulation cascade by binding to antithrombin and providing specific inhibition of factor Xa. This action results in suppression of thrombin generation without interfering with the other clotting factors. Similar to LMWHs, fondaparinux is advantageous compared with UFH because it has decreased binding to plasma proteins, has dose-independent clearance with a longer half-life, has more predictable and sustained anticoagulation, and allows once-daily administration without the need for laboratory monitoring.

OASIS-5 evaluated the safety and efficacy of fondaparinux in 20,078 patients with UA/NSTEMI.⁴⁷ After standard treatment with aspirin, clopidogrel, and a GPI (according to local practice), patients were randomly assigned to either once-daily fondaparinux or twice-daily enoxaparin. The rates of the primary composite end point of death, MI, or refractory ischemia at 9 days were similar in the two groups (5.8% versus 5.7%). A 47% reduction in major bleeding was seen in the fondaparinux group (2.2% versus 4.1%; $P < .001$). At 6 months, fondaparinux was associated with a significant reduction in mortality (5.8% versus 6.5%) and the combined end point of death, MI, and stroke (11.3% versus 12.5%).⁴⁷

These favorable results for fondaparinux were tempered by an excess of catheter-associated thrombus in patients undergoing PCI. It would be reasonable to recommend fondaparinux as the preferred anticoagulant strategy in patients managed with a non-invasive strategy, especially if they are at high risk of bleeding.

Statin Therapy

Numerous trials have shown that 3-hydroxy-3-methylglutaryl coenzyme-A reductase inhibitors, or “statins,” are safe and effective in reducing cardiovascular events in patients with or at risk for coronary artery disease.⁴⁸ Two more recent trials sought to determine whether more intensive therapy and earlier initiation after ACS would result in a greater benefit.

In the PROVE IT-TIMI 22 trial,⁴⁹ 4126 patients who had been hospitalized with UA/NSTEMI in the preceding 10 days were randomly assigned to intensive (atorvastatin, 80 mg) or standard (pravastatin, 40 mg) therapy. The primary end point was a composite of all-cause mortality, MI, readmission for UA, revascularization (>30 days after randomization), and stroke.⁴⁹ Although the study was designed to show noninferiority of the standard dose statin regimen, there was a 4% absolute decline in the rate of the primary end point in the intensive therapy group (22.4% versus 26.3%; $P = .005$). Similarly, the A to Z Trial evaluated 4497

patients hospitalized with ACS within the preceding 5 days and randomly assigned them to either 40 mg of simvastatin for 1 month followed by 80 mg thereafter (early, intensive strategy) or placebo for 4 months followed by 20 mg of simvastatin thereafter (delayed, conservative strategy).⁵⁰ The primary end point was a composite of cardiovascular death, nonfatal MI, readmission for ACS, and stroke. Although there was a trend toward a reduction in the primary end point in the intensive group, it did not reach statistical significance (14.4% versus 16.7%).

When the two trials are compared, it seems that the difference in results can be explained almost entirely by an early benefit (first 4 months) seen in PROVE IT, but not A to Z Trial. One significant factor that may have contributed to this finding is the increased rate of revascularization for the index presentation in PROVE IT compared with A to Z Trial (69% versus 44%; $P < .001$). Other factors include differences in the baseline risk factors, rates of early revascularization, intensity of early therapy, timing and magnitude of low-density lipoprotein and C-reactive protein lowering, and chance. The rates of events and event reduction during the late phase (>4 months) were very similar.⁵¹ When these two trials were pooled, a patient level analysis showed that all-cause mortality was significantly reduced in the patients with intensive statin therapy compared with the patients receiving moderate therapy (3.6% versus 4.9%; $P = .015$).⁵²

Postdischarge Therapy

Although the benefits of acute and long-term therapy with aspirin, clopidogrel, β blockers, and statins have been discussed previously, specific discussion is needed regarding UA/NSTEMI patients who sustain impairment of left ventricular systolic function. Left ventricular systolic dysfunction is the most potent predictor of sudden arrhythmic death in post-MI survivors.^{53,54} Numerous large-scale clinical trials have shown that pharmacologic therapy can dramatically reduce the risk of recurrent cardiovascular events and death in patients who survive MI with left ventricular systolic dysfunction.

Angiotensin-Converting Enzyme Inhibitors

The SAVE trial was the first study to report a benefit with angiotensin-converting enzyme (ACE) inhibitors in post-MI patients with left ventricular systolic dysfunction. At 42 months, treatment with captopril reduced cardiovascular mortality by 21% and reinfarction by 25% (mean left ventricular ejection fraction 31%).⁵⁵ Similar risk reduction was shown in the TRACE,^{56,57} SMILE,⁵⁸ and SMILE-2 trials.⁵⁹

The utility of ACE inhibition in patients without heart failure resulting from left ventricular systolic dysfunction is less clear. A systematic review⁶⁰ of three major trials (HOPE,⁶¹ EUROPA,⁶² and PEACE⁶³) showed that the absolute benefit of ACE inhibition is directly proportional to patient risk, with patients at the highest risk benefiting the most.

Angiotensin II Receptor Blockers

VALIANT evaluated the effects of captopril, valsartan, or both in patients with MI and clinical heart failure or left ventricular systolic dysfunction (mean left ventricular ejection fraction 35%).⁶⁴ This study found no significant difference between the three treatment groups with respect to cardiovascular death, recurrent MI, or rates of hospitalization for heart failure.

Table 14-4. Medications Used for Stabilized Unstable Angina/Non-ST Segment Elevation Myocardial Infarction Patients

Anti-ischemic and Antithrombotic/ Antiplatelet Agents	Drug Action	Class/Level of Evidence
Aspirin	Antiplatelet	I/A
Clopidogrel* or ticlopidine	Antiplatelet when aspirin is contraindicated	I/A
β blockers	Anti-ischemic	I/B
ACE inhibitor	EF <0.40 or CHF EF >0.40	I/A, IIa/A
Nitrates	Antianginal	I/C for ischemic symptoms
Calcium channel blockers (short-acting dihydropyridine antagonists should be avoided)	Antianginal	I for ischemic symptoms; when β blockers are unsuccessful (B) or contraindicated, or cause unacceptable side effects (C)
Dipyridamole	Antiplatelet	III/A
<i>Agents for Secondary Prevention and Other Indications</i>	<i>Risk Factor</i>	
HMG-CoA reductase inhibitors	LDL cholesterol >70 mg/dL	Ia
Fibrates	HDL cholesterol <40 mg/dL	IIa/B
Niacin	HDL cholesterol <40 mg/dL	IIa/B
Niacin or fibrate	Triglycerides 200 mg/dL	IIa/B
Antidepressant	Treatment of depression	IIb/B
Treatment of hypertension	Blood pressure >140/90 mm Hg or >130/80 mm Hg if kidney disease or diabetes present	I/A
Treatment of diabetes	Hemoglobin A _{1c} >7%	I/B
Hormone therapy (initiation) [†]	Postmenopausal state	III/A
Hormone therapy (continuation) [†]	Postmenopausal state	III/B
COX-2 inhibitor or NSAID	Chronic pain	IIa/C, IIb/C, III/C
Vitamin C, vitamin E, beta carotene, folic acid, vitamin B ₆ , vitamin B ₁₂	Antioxidant effect; homocysteine lowering	III/A

*Preferred to ticlopidine.

J Am Coll Cardiol 2007;50:e1-e157.

The combination of an ACE inhibitor and angiotensin receptor blocker was associated with greater intolerance because of hypotension.

β Blockers

The CAPRICORN trial⁶⁵ is the only post-MI trial to investigate the effects of β blockade exclusively in patients with left ventricular systolic dysfunction (left ventricular ejection fraction $\leq 40\%$). The trial randomly assigned 1959 patients to receive either carvedilol or placebo within 3 weeks after admission for MI and had a mean follow-up of 1.3 years. Treatment with carvedilol was associated with a 23% reduction in all-cause mortality ($P = .031$) and a 40% reduction in fatal or nonfatal reinfarction ($P = .01$).

Conclusion

UA/NSTEMI result from atherosclerotic plaque rupture and thrombus formation and the subsequent reduction in myocardial blood flow and oxygen delivery. The initial care of these patients is directed at reducing ischemia and preventing further thrombosis and embolization (Table 14-4). When medical stabilization has been achieved, it is important to estimate the individual patient's risk for adverse events because patients at high risk are more likely to benefit from the addition of antiplatelet inhibition with GPIs and an early invasive strategy with regard to cardiac catheterization. Postdischarge care should focus on risk factor modification, such as aggressive statin therapy, tight blood pressure and glucose control, and tobacco

cessation, and the addition of an ACE inhibitor or angiotensin receptor blocker for patients who sustain impairment of left ventricular function.

Biochemistry and Assays of Troponins
Troponin and Myocardial Damage
Nonthrombotic Mechanisms of Troponin Elevation

Prognostic Significance of Troponin Elevation in
Thrombotic and Nonthrombotic Mechanisms and
Potential Treatment Strategies
Conclusion

PATIENTS PRESENTING to the emergency department with acute chest pain are often difficult to assess and triage because the etiology of their chest pain may range from benign processes to life-threatening diseases. Even patients with acute myocardial infarction (MI) may have symptoms atypical for coronary artery disease, and electrocardiogram (ECG) abnormalities diagnostic for acute coronary syndromes (ACS) may be absent. Because of these limitations, the measurement of serum biomarkers, particularly cardiac troponin, has been used to identify high-risk patients for admission to coronary care units for rapid therapeutic interventions.

Diagnostic criteria used for defining MI have changed significantly in recent years. The previously used World Health Organization definition required the presence of at least two criteria (typical clinical presentation, ischemic changes on ECG, and elevated total creatine kinase (CK) or its MB isoenzyme [CK-MB]) to diagnose an MI properly.¹ An individual with absent biomarker elevation could have been diagnosed with an MI in the appropriate clinical setting and if ECG changes existed. With the advent of more sensitive myocardial biomarkers—the cardiac troponins—new definitions have since been proposed. In 2000, a joint committee of the European Society of Cardiology/American College of Cardiology (ESC/ACC) emphasized the presence of troponin elevation and proposed a new definition for acute MI, stating that “any amount of myocardial damage” (as evidenced by the troponin level) regardless of the magnitude, “implies an impaired clinical outcome,” and should be characterized as an MI.² The 2002 American College of Cardiology/American Heart Association practice guidelines for the management of patients with unstable angina and non–ST segment elevation MI also reflected this view.³

Execution of these new guidelines into clinical practice has significantly increased the frequency of MI diagnoses. Kontos and colleagues⁴ reported that among 2181 patients presenting to the emergency department with chest pain, MI diagnoses based on cardiac troponin level increased 195% compared with diagnoses made according to CK-MB criteria. Troponin testing is now also being used as a screening tool in patients with

a low pretest probability of thrombotic coronary artery disease. Because of its high sensitivity for detecting even minimal myocardial cell necrosis, troponin may become “positive” even in the absence of thrombotic obstruction of a coronary artery. In many instances, these troponin elevations may occur due to demand ischemia, with minor epicardial coronary obstruction (or even without significant coronary artery disease), rather than an acute thrombotic coronary occlusion.⁵ One retrospective study comprising 166 patients presenting to the emergency department with elevated troponin showed that only 61% of the patients had significant coronary stenosis as per coronary angiography.⁶ Ng and colleagues⁷ showed that of 112 patients presenting to the emergency department with increased troponin I levels, 45% had a final diagnosis other than ACS.

Because of the high sensitivity but low specificity in patients with a low pretest probability of thrombotic coronary disease, the detection of even minimal troponin elevation is often immediately associated with ACS, and may divert attention from the true underlying clinical problem, leading to inappropriate admissions to coronary care units and unnecessary diagnostic and therapeutic measures, including coronary angiography. This chapter reviews potential causes of troponin elevations that are unrelated to coronary thrombosis and provides guidance on the evaluation and management of patients with nonthrombotic troponin elevations.

Biochemistry and Assays of Troponins

Cardiac troponins are regulatory proteins found on the contractile apparatus of striated muscle that control the calcium-mediated interaction of actin and myosin.^{8,9} They form complexes with actin and tropomyosin on the thin filament of the contractile apparatus and regulate contraction by initiating or inhibiting the sliding of thin filaments over thick filaments. The troponin complex consists of three subunits (Fig. 15-1): troponin C, which binds to calcium ions and regulates activation of the thin filaments during contraction; troponin T, which binds to tropomyosin and facilitates contraction; and troponin I,

Figure 15-1. Structure of troponin.

which binds to actin and inhibits actin-myosin interactions in the absence of calcium.^{8,10,11}

The amino acid sequences of the skeletal and cardiac isoforms of cardiac troponin T and troponin I are dissimilar. Monoclonal antibodies to both of these cardiac troponins have been developed with no cross-reactivity with troponins from skeletal muscle.³ In contrast, cardiac and skeletal muscle share troponin C isoforms; no clinical assay has been developed to test for this protein because of its lack of cardiac specificity.

Current troponin assays are very sensitive, detecting even small amounts of myocardial necrosis. The ESC/ACC Committee defined MI as a troponin level greater than the upper reference limit of the healthy population—that is, greater than the 99th percentile of the reference control group with a coefficient of variation of 10% or less. Because very few assays being used meet this standard, it has been proposed that a troponin elevation greater than the 10% coefficient of variation be indicative of myocardial injury.¹² Although this reference limit may slightly reduce the sensitivity for MI according to the biochemical diagnostic criterion, it allows providers to avoid being faced with minor troponin elevations that may simply be secondary to analytic noise. With a wide variety of commercial assays being used, each institution's laboratory must first confirm the reference range in their particular population before defining their cutoff for a "significant" troponin elevation.

Troponin and Myocardial Damage

Approximately 7% of troponin T and 3% to 5% of troponin I is normally found free in the myocyte cytoplasm, whereas most is structurally bound in the contractile apparatus of the muscle fiber.¹³ The release of troponin from the myocyte to the blood can be due to reversible or irreversible cell damage.⁸ A biphasic increase in serum troponin occurs during myocardial ischemia, corresponding to the early release of free cytoplasmic proteins, followed by a gradual release of myofibril-bound cytosolic complexes as the myocytes are irreversibly damaged, and the cell membrane degrades.⁸

Speculations have been made regarding the mechanism of this early troponin release. Observations of patients with unstable angina have shown only transient troponin elevations, with values returning to baseline within a few hours.¹⁴ This pattern of early troponin increase may not necessarily be associated with irreversible myocardial necrosis. It is conceivable that myocardial troponin can also be released in the setting of increased membrane permeability. It is thought that myocardial depressive factors (released in the setting of sepsis and other inflammatory states) cause degradation of free troponin in situ to

lower molecular weight fragments.¹⁵ With increased membrane permeability, the smaller troponin fragments could be released into the systemic circulation. In this setting, myocyte damage may not be permanent, and cell necrosis does not occur. This notion is also supported by the clinical observation that myocardial depression during sepsis is a fully reversible process in most surviving patients.¹⁶

Nonthrombotic Mechanisms of Troponin Elevation

Troponin elevation can occur in the absence of ACS. Frequent conditions causing troponin elevation include hypovolemia, sepsis, heart failure, atrial fibrillation, myocarditis, myocardial contusion, pulmonary embolus, and renal failure (Table 15-1).

Demand Ischemia

The term *demand ischemia* refers to inadequate myocardial oxygen supply in the setting of increased demand and in the absence of a thrombotic coronary artery occlusion. Myocardial oxygen demand increases in several clinical conditions, including sepsis or the systemic inflammatory response syndrome,¹⁷⁻¹⁹ hypotension or hypovolemia,²⁰ and atrial fibrillation or other tachyarrhythmias.^{21,22} These disease states can predispose to tachycardia and various loading conditions on the heart. Tachycardia can augment myocardial oxygen demand while decreasing myocardial oxygen supply predominantly by reducing the time of diastole, the time period in which much of myocardial perfusion occurs. Also, systemic inflammatory processes, including sepsis, can result in higher oxygen consumption, decreased perfusion pressure, myocardial depression, and reduced delivery of oxygen to the heart, resulting in release of troponin into the systemic circulation.¹⁸

Elevated troponin is a common finding in critically ill patients and is associated with a significant increase in mortality.¹⁷ Ammann and colleagues¹⁸ reported that in 20 intensive care unit (ICU) patients with sepsis, 85% had elevated troponin levels, 59% of which had no evidence of significant coronary artery disease. A more recent study evaluating 58 ICU patients without ACS found that of the 55% that had elevated troponins, significant coronary artery disease was excluded in 72% of these patients. Levels of C-reactive protein, tumor necrosis factor- α , and interleukin-6 were markedly higher among troponin-positive patients.¹⁹ Mortality was also fourfold higher in this group. Troponin elevation is common in ICU patients without thrombotic ACS. No definitive causal relationship has yet been shown; however, it has been proposed that the inflammatory mediators involved in systemic inflammatory states may contribute to the myocardial oxygen demand-supply mismatch. In addition, whether any cardiovascular work-up or intervention could improve the mortality risk of these patients remains unclear.

Tachycardia and several tachyarrhythmias are other potential causes of demand ischemia in the absence of thrombotic coronary artery disease. Bakshi and colleagues²¹ showed that among 21 patients with elevated troponin levels but a normal coronary angiogram, tachycardia was the cause in 28%, strenuous exercise was the cause in 10%, pericarditis was the cause in 10%, and congestive heart failure was the cause in 5%; 47% of patients had no identifiable trigger.²¹ Similarly, Zellweger and associates²²

Table 15-1. Nonthrombotic Causes and Presumed Mechanism for Elevated Cardiac Troponin Level

Diagnosis	Mechanism
Demand Ischemia	
Sepsis/systemic inflammatory response syndrome	Myocardial depression/supply-demand mismatch
Hypotension	Decreased perfusion pressure
Hypovolemia	Decreased filling pressure/output
Supraventricular tachycardia/atrial fibrillation	Supply-demand mismatch
Left ventricular hypertrophy	Subendocardial ischemia
Myocardial Ischemia	
Coronary vasospasm	Prolonged ischemia with myonecrosis
Intracranial hemorrhage or stroke	Imbalance of autonomic nervous system
Ingestion of sympathomimetic agents	Direct adrenergic effects
Direct Myocardial Damage	
Cardiac contusion	Traumatic
Direct current cardioversion	Traumatic
Cardiac infiltrative disorders	Myocyte compression
Chemotherapy	Cardiotoxicity
Myocarditis	Inflammatory
Pericarditis	Inflammatory
Cardiac transplantation	Inflammatory/immune-mediated
Myocardial Strain	
Congestive heart failure	Myocardial wall stretch
Pulmonary embolism	Right ventricular stretch
Pulmonary hypertension or emphysema	Right ventricular stretch
Strenuous exercise	Ventricular stretch
Chronic renal insufficiency	Unknown

From Jeremias A, Gibson CM: Narrative review: alternative causes for elevated cardiac troponin levels when acute coronary syndromes are excluded. *Ann Intern Med* 2005;142:787.

described four patients with supraventricular tachycardia with increased levels of troponin but no evidence of epicardial coronary stenoses. It is evident from these reports that troponin release can be a result of tachycardia alone, and can be released in the absence of coronary artery disease, inflammatory mediators, and myocardial depressive factors.

Elevated cardiac troponin has also been noted in the setting of left ventricular hypertrophy. Hamwi and colleagues²³ reported that in 74 patients without any clinical evidence of active myocardial ischemia, patients in the upper tertile of left ventricular mass had increased troponin levels compared with patients in

the lowest tertile. The increased left ventricular mass necessitates a greater myocardial oxygen demand and may induce occult subendocardial ischemia. Also, flow reserve is decreased secondary to the remodeling of coronary microcirculation. Similarly, elevated troponins in the setting of aortic valve disease are thought to be associated with greater left ventricular mass and higher pulmonary artery systolic pressures.²⁴

Myocardial Ischemia with Dynamic Coronary Artery Obstruction

Myocardial ischemia, in the absence of obstructive ACS, can also be caused by vasospasm, also termed *Prinzmetal angina*. Wang and coworkers²⁵ evaluated 93 patients with suspected myocardial ischemia and a final diagnosis of nonobstructive coronary artery disease, and found that 25% of these patients had increased troponins. Ergonovine provocation testing subsequently revealed vasoconstriction in 74% of these patients, suggesting that prolonged ischemia can be induced by coronary vasospasm.

Patients with intracranial hemorrhage or acute stroke are frequently found to have elevated troponins alongside ischemic changes on the ECG. Studies have reported approximately 20% of patients with subarachnoid hemorrhages,²⁶ and 27% with acute stroke symptoms²⁷ have increased levels of troponin. It has been proposed that the subsequent imbalance of the autonomic nervous system results in excessive sympathetic activity, and ultimately an increased catecholamine effect on the myocardium.²⁸ This is comparable to the effects seen after consumption of sympathomimetic agents, which have also been associated with myocardial damage and troponin elevation. Substantial elevation of troponin I in the setting of subarachnoid hemorrhage carries an ominous prognosis.²⁹ Ramappa and colleagues²⁹ showed that mortality in patients with subarachnoid hemorrhage was significantly higher in patients with elevated troponin I levels (55% versus 27%; $p=0.01$).

Direct Myocardial Damage

Myocardial injury can also predispose to increased troponin levels secondary to cell injury via inflammation or trauma. One study of 333 patients with significant blunt thoracic trauma showed that the positive and negative predictive values of elevated troponin level predicting cardiac contusion were 21% and 94% respectively,³⁰ emphasizing the utility of troponin in ruling out any traumatic myocardial injury. Blunt cardiac trauma may also include cardiopulmonary resuscitation measures and implantable cardioverter-defibrillator shocks.³¹ Troponin elevation may also be present in infiltrative disorders, such as amyloidosis, and has been shown to have prognostic value within this population.^{32,33} Extracellular amyloid deposition may produce myocyte compression injury, inducing myocardial damage and subsequent troponin release. Troponin testing may also be used in evaluating the cardiotoxicity of anthracycline-based chemotherapeutic agents to help predict future development of a drug-induced cardiomyopathy.³⁴

Inflammatory diseases, including myocarditis, acute pericarditis, and an immune response after heart transplantation, have also been associated with an increase in troponin. Myocarditis may involve inflammatory-mediated myocyte damage, causing the release of cardiac troponins and sometimes, the production of regional wall motion abnormalities on echocardiogram.³⁵ The level of troponin I elevation has been shown to correlate directly

with the size of myocardial inflammation.³⁵ Acute pericarditis can be associated with epicardial myocyte damage. Troponin I has been reportedly elevated in an estimated one third of patients with acute pericarditis, but, as opposed to many other conditions, has not been shown to be a poor prognostic indicator in this patient population.^{36,37} Chronically elevated troponin levels after cardiac transplantation may be a poor prognostic indicator. Labarrere and associates³⁸ performed a prospective cohort study involving 110 patients who had undergone cardiac transplantation and showed that troponin levels, which remained elevated in 51% of these transplant patients, were associated with more fibrin deposition in the microvasculature and myocardium, and a higher risk for graft failure and coronary artery disease.

Heart Failure

Heart failure can lead to troponin release via myocardial strain and myocyte death. Myocardial strain is produced by volume and pressure overload of the right and the left ventricle, causing excessive wall tension with resulting myofibrillary damage. Myocardial strain may be defined as the percentage change of a structure compared with its initial length with the application of stress.²⁴ Support for the "strain" theory comes from multiple studies that show a close positive correlation between troponin and B-type natriuretic peptide (BNP),³⁹ a marker of right and left ventricular wall strain. Troponin degradation has also been shown to be a result of increased preload independent of myocardial ischemia in isolated rat hearts.⁴⁰ It has also been hypothesized that increased myocardial wall stress may lead to decreased subendocardial perfusion, with resulting troponin elevation and decline in left ventricular systolic function.⁴¹

Many reports have described troponin elevation in normal individuals after ultraendurance exercise.^{42,43} This troponin elevation may be related to an increase in myocardial strain during exercise, although catecholamine-induced vasospasm has also been suggested as an explanation.⁸

Progressive myocyte loss is now thought to play a prominent role in the progression of cardiac dysfunction; it may explain the ominous prognosis of patients with congestive heart failure and elevated troponin levels. In vitro experiments with myocytes established a link between myocardial wall stretch and programmed cell death,⁴⁴ which may also represent a cause of increased troponin in this setting. In the setting of acute or chronic congestive heart failure, additional factors, including the activation of the renin-angiotensin system, sympathetic stimulation, and inflammatory mediators, may be partially responsible for myocyte injury and cell death.

Several small studies documented troponin elevation in the presence of congestive heart failure without evidence of ACS. These studies have also established a relationship between troponin elevation and increased mortality during follow-up. Of 238 patients with advanced heart failure who were referred for cardiac transplantation evaluation, 49% were found to have elevated cardiac troponin levels.⁴¹ Patients with detectable troponin had significantly higher BNP levels, type natriuretic peptide levels, higher pulmonary wedge pressures, lower cardiac indices, and a twofold increase in mortality.

Pulmonary Disease

Troponin elevations have also been observed in pulmonary embolism, pulmonary hypertension, and chronic obstructive pulmonary disease (COPD), usually secondary to right heart

strain. Acute pulmonary embolism is characterized by increased right ventricular oxygen demand and intramural pressures and decreased cardiac output, possible features contributing to the right ventricular ischemia or injury that may result.⁴⁵ The reported incidence of troponin elevation in patients with acute pulmonary embolism ranges from 16% to 50%, and elevated levels are associated with a significant increase in mortality.⁴⁶⁻⁴⁸ In contrast to acute myocardial injury, troponin elevation in pulmonary embolus usually resolves within 40 hours. Hsu and colleagues⁴⁹ found that the combination of right ventricular enlargement and elevated troponin I significantly increased 100-day mortality (31.4%) compared with patients with right ventricular dilation alone (17%), elevated troponin I alone (3.7%), or neither (16%). As a result, several authors have advocated the utility of measuring troponin in patients with acute pulmonary embolism to help identify high-risk patients and help determine whether embolectomy or thrombolysis is clinically indicated.^{45,50-52}

Of patients with chronic pulmonary hypertension, troponin was detectable in 14% and was associated with higher heart rates, lower mixed venous oxygen saturation, higher levels of BNP-type natriuretic peptide, and significantly worse cumulative survival at 2 years (81% versus 29%).⁵³ Exacerbations of COPD can also increase troponin levels.⁵⁴ During a COPD exacerbation, the increase in the work of breathing, worsening of pulmonary hypertension, and more negative intrathoracic pressure along with the increase in left ventricular afterload all are possible factors contributing to myocardial injury. Elevated troponin I levels in critically ill COPD patients have been reported to be an important predictor of in-hospital mortality.^{54,55}

Chronic Renal Insufficiency and End-Stage Renal Disease

Persistently elevated cardiac troponin is frequently observed in patients with end-stage renal disease (ESRD).⁵⁶⁻⁵⁸ The prevalence of increased troponin in asymptomatic ESRD patients may be as high as 53%.⁵⁸ This increased troponin may be the result of small areas of clinically silent myocardial necrosis,^{59,60} but other causes, such as increased left ventricular mass and impaired renal troponin excretion, have also been proposed.⁶¹⁻⁶³ There is often a reluctance to use troponin in hemodialysis patients as a diagnostic tool because of the assumption that renal failure per se leads to increased troponin levels and to a false diagnosis of ACS.

Brunet and colleagues⁶² measured the mean basal troponin levels in hemodialysis patients without evidence of ACS (e.g., asymptomatic, no ECG changes) and showed that 2% to 3% of these patients had abnormal troponin I, and 27% had abnormal troponin T. These results suggest that elevated troponin T levels can lead to false-positive diagnoses of ACS, whereas increased troponin I levels should not be neglected in these patients because they are more diagnostic for acute MI. Sharma and coworkers⁶³ showed that in 121 ESRD patients selected for renal transplantation, although elevated troponin T levels did not predict the presence of coronary artery disease, they were often associated with global left ventricular dysfunction as seen on dobutamine stress echocardiogram.

Although the exact mechanism of troponin elimination is unknown, troponin is believed to be cleared by the reticulo-endothelial system because of the relatively large molecular size of troponin.⁵⁸ More recent evidence shows, however, that

troponin T is fragmented into molecules small enough to be renally excreted; this may explain the high prevalence of troponin elevation in patients with severe renal failure.⁶¹ In addition, although it is well known that uremia increases the free serum concentration and clearance of protein-bound drugs, the effect of uremia on the clearance of different troponin subunits is unclear.

Regardless of the cause, detectable troponin in stable patients with ESRD seems to be a powerful predictor of increased long-term, all-cause, and cardiovascular mortality,^{56-59,64-71} and may be an even stronger risk factor in conjunction with elevated C-reactive protein levels.^{56,72} In the GUSTO IV trial, troponin was found to be an independent predictor of death or MI across the entire spectrum of renal function in 7033 patients with ACS.⁷³

Prognostic Significance of Troponin Elevation in Thrombotic and Nonthrombotic Mechanisms and Potential Treatment Strategies

In patients with a high clinical suspicion for thrombotic coronary artery disease, troponin elevation has been associated with a worse prognosis.⁷⁴ The mortality risk seems to correlate with the level of troponin increase. With increasing levels of troponin, a statistically significant increase in mortality exists, with a relative risk for death of 7.8 among the group with the highest level of troponin.⁷⁵ Although impaired epicardial blood flow and the presence of thrombus are associated with increases in troponin,^{76,77} poor myocardial perfusion is an independent predictor of troponin elevation in patients with ACS.⁷⁸

Similarly, troponin elevation in the setting of nonthrombotic disease states, including congestive heart failure, sepsis, pulmonary disease, and renal insufficiency, have also been associated with higher short-term and long-term mortality risks. The reasons for this impaired survival are unclear, but possibly may be secondary to underlying quiescent coronary artery disease or myocardial necrosis with loss of myocytes. Because of the worse prognosis associated with this biomarker, patients with nonthrombotic conditions and an increase in troponins generally should receive a proper diagnostic evaluation, and management should be geared toward treating the underlying disorder.

Discerning the etiology of an elevated troponin (i.e., whether it is secondary to a thrombotic or nonthrombotic mechanism) can be difficult. The presence of chest pain, atherosclerotic risk factors, ischemic changes on the ECG, and regional wall motion abnormalities on echocardiography can help to identify a thrombotic origin for the elevated troponin, and further cardiovascular evaluation, including early cardiac risk stratification, may be implemented.³ In patients with a low pretest probability of coronary artery disease, the underlying cause of the troponin elevation can usually be discerned from a thorough history and physical examination, especially in conditions such as congestive heart failure, sepsis, pulmonary embolism, cardiac contusion, myocarditis, and pericarditis. Data examining the efficacy and outcomes of various therapies in patients with troponin elevation in the absence of ACS are sparse. Patients with a nonthrombotic condition are unlikely to derive benefit from anti-thrombotic, antiplatelet, or invasive revascularization therapies

that are commonly used in thrombotic ACS. Rather, management should be targeted toward treating the underlying cause.

Although an elevated troponin level may be associated with increased risk of morbidity and mortality, a normal troponin level does *not* mean that the patient is not at risk. Heesch and colleagues⁷⁹ reported that patients presenting with ACS in the absence of troponin elevation still had an estimated 4% incidence of MI and death at 30 days.

Conclusion

Troponin is an exceptionally sensitive biomarker that is used to detect myocardial damage.⁸⁰ Its measurement in clinical practice, however, has been referred to by some authors as a double-edged sword,⁸¹ because the detection of even minor troponin increases may be associated with ACS and divert focus from other possible clinical problems. When patients with suspected ACS “make troponins,” guidelines for management exist, and treatments, including antithrombotic, antiplatelet, and interventional therapies, may be implemented. No data support the role of these therapies, however, in the management of patients with a nonthrombotic syndrome causing a troponin increase. Instead, treatment should be aimed at the underlying disorder.

Finally, although the high sensitivity of troponin may be used to help “rule out” a non-ST segment elevation MI, its low specificity for ACS makes it difficult to “rule in” an event. Consequently, when tested indiscriminantly in populations with low cardiac risk profiles, the positive predictive value of troponin becomes significantly reduced. In the absence of thrombotic ACS, an elevated troponin can aid with determining prognosis, and screening may still be justified on this basis.

Complications of Acute Myocardial Infarction

Recurrent Ischemia after Reperfusion Therapy for Acute Myocardial Infarction

Eduardo I. de Oliveira, Stephen G. Ellis

CHAPTER 16

Predictors
Incidence
Consequences

Prevention
Recognition
Treatment

RECURRENT ISCHEMIA after acute myocardial infarction (MI) is a heterogeneous process. It is most often caused by reocclusion of the infarct-affected artery by thrombosis, but also may occur as a result of spasm, extension of subintimal hemorrhage (usually after angioplasty at that site), inadequate collaterals to the same territory in the face of increased myocardial oxygen demand, or “ischemia at a distance”¹ unrelated to the initial culprit site. Recurrent ischemia also may result in processes as disparate as recurrent MI or occult reocclusion without any symptoms.

Predictors

Symptomatic recurrent ischemia after presentation with MI is more likely in patients treated with thrombolysis rather than primary percutaneous coronary intervention (PCI) (see later), patients with recurrent electrocardiogram (ECG) changes, patients with substantial myocardial salvage, patients with high-grade residual stenoses, and patients with augmented platelet and thrombin activation. Demographic and clinical variables have not proved to be helpful in predicting which patients will develop reocclusion.^{2,3} One large series found, however, that clinical predictors of reinfarction included advanced age, shorter time to thrombolysis, nonsmoking status, prior MI or angina, female sex, anterior infarction, and lower systolic blood pressure.⁴ Other authors have reported that right coronary artery infarcts and infarcts associated with bradycardia on admission are more prone to reocclusion.⁵

The TIMI-4 trial attempted to identify angiographic predictors of reocclusion after thrombolysis.⁶ TIMI grade 2 flow, lesion ulceration, presence of collaterals, and eccentric lesions were associated with a significantly higher rate of infarct-related artery reocclusion (Fig. 16-1). In contrast to these findings, other studies, such as GUSTO and TAMI, did not find angiographic

Figure 16-1. Infarct-related artery reocclusion.

features at a 90-minute baseline study to be helpful for predicting reocclusion.^{7,8} There were, however, important differences among these trials that could explain the different findings.⁶ Other authors have associated the following characteristics with persistent symptoms, adverse in-hospital outcomes, or reocclusion: lesion ulceration,⁹⁻¹² high-grade residual stenosis and reduced lumen area,¹³⁻¹⁷ and lack of restoration of normal coronary flow (TIMI flow <3).¹⁸⁻²²

Incidence

In the era before reperfusion, recurrent angina with or without ECG changes occurred in 19% to 37% of patients, but reinfarction was far less common. Recurrent ischemia was more frequently seen in patients who had not initially developed a Q wave MI,²³⁻²⁶ although this classic teaching has not been a uniform finding.²⁶ After coronary reperfusion, within the first few hours of infarction, the risk of recurrent ischemia is higher than without reperfusion, presumably because the risk is higher with an open

infarcted artery and salvaged myocardium. In a meta-analysis of nearly 50,000 patients from six large, placebo-controlled thrombolytic trials of patients usually treated less than 6 hours from the onset of symptoms, reinfarction occurred in 3.6% of patients treated with thrombolytic agents compared with 3% of patients who did not undergo thrombolysis ($P < .001$).²⁷⁻³² In the two placebo-controlled thrombolytic trials in which all patients had symptoms for at least 6 hours before treatment (i.e., EMERAS³³ and LATE³⁴), there was no difference in the incidence of reinfarction between patients treated with or without thrombolysis (2.4% versus 2.9%; $P = .10$), presumably because MIs treated later had less salvaged myocardium.

After apparently successful fibrinolysis by clinical criteria, and despite adjunctive pharmacologic therapy, early recurrence of ischemia or ST segment shifts (threatened reocclusion) have been observed in 20% to 30% of patients,^{35,36} thrombotic coronary reocclusion has been observed in 5% to 15% before hospital discharge and in 25% by 3 months,^{2,3,37-39} and early reinfarction has been observed in 3% to 5%.^{4,39-43} When symptomatic reocclusion occurs after thrombolytic therapy, it generally occurs (80% of the time) within the first 2 days after treatment. Only a few reocclusions occur during the initial hospitalization, however. Reocclusion is clinically silent in more than 50% of cases and tends to occur later.³ In the APRICOT study,³⁸ 300 patients treated with recombinant tissue plasminogen activator (rt-PA) with patent infarct-affected arteries, documented by angiography 24 to 48 hours after treatment, underwent protocol-required repeat cardiac catheterization 3 months later. The patients were further randomly assigned to treatment with aspirin, warfarin, or neither drug. At follow-up, 25%, 30%, and 32% in the three groups had reocclusions, only 25% of which were associated with a recurrent MI. Because reocclusion can be clinically silent, late angiography remains the gold standard in assessing the frequency of reocclusion.

In an overview by Granger and colleagues⁴⁴ of 1183 patients with paired angiograms, 14% of patients receiving rt-PA versus 8% of patients treated with non-fibrin-specific agents had reocclusion ($P = .002$). This finding was not confirmed, however, in the similarly sized angiographic arm of the GUSTO-I study, possibly because of the more vigorous treatment of patients receiving rt-PA with heparin in the latter study. Also, patients treated with accelerated or weight-adjusted rt-PA regimens consistently had lower rates of reocclusion than patients treated with the original U.S. Food and Drug Administration–approved 3-hour dosing regimen.^{5,45} In two reviews of almost 76,000 patients from GUSTO-I, GUSTO-III, TIMI, and InTIME II trials, reinfarction occurred in 4.3% of patients at a median of 2 to 4 days after fibrinolytic therapy, and was independent of the fibrinolytic agent used.^{4,39}

Reinfarction might occur in a new territory, rather than reflecting failed fibrinolysis in the index territory. This issue was addressed in a report from the HERO-2 trial of bivalirudin versus unfractionated heparin before streptokinase administration. Confirmed reinfarction occurred in 552 patients (3.2%). Among these patients, 4% (0.15% of all patients) had ST segment elevation in a new territory at a mean of 46 hours.⁴⁶

Multiple randomized trials have been done to compare PCI with thrombolytic therapy. PCI enhances survival with a lower rate of intracranial hemorrhage and recurrent MI. In a review of 23 trials, primary PCI was better than thrombolytic therapy at reducing death (7% versus 9%; $P = .0002$) and nonfatal

reinfarction (3% versus 7%; $P < .0001$). The review included 7739 patients; streptokinase was used in 8 trials ($n = 1837$), and fibrin-specific agents were used in 15 trials ($n = 5902$). Stents were used in 12 trials, and platelet glycoprotein (GP) IIb/IIIa inhibitors were used in 8 trials. The results seen with primary PCI remained better than the results seen with thrombolytic therapy during long-term follow-up, and were independent of the type of thrombolytic agent used, and whether or not the patient was transferred for primary PCI.⁴⁷

Several randomized trials (DANAMI-2, STAT, STOPAMI-1, and STOPAMI-2) have shown a better outcome with primary stenting compared with thrombolysis.⁴⁸⁻⁵¹ The largest is the DANAMI-2 trial, which was discontinued prematurely because of a significant reduction in the primary end point of mortality, reinfarction, or stroke at 30 days with PCI (8% versus 13.7%). The benefit was primarily due to less reinfarction.⁴⁸

The clinical efficacy of primary balloon angioplasty in acute ST segment elevation myocardial infarction (STEMI) and other settings is limited by the risks of early reocclusion and late restenosis, providing the rationale for the use of intracoronary stents. Initial nonrandomized studies suggesting that primary stenting was more effective than primary balloon angioplasty⁵²⁻⁵⁴ were followed by randomized trials.⁵⁵⁻⁵⁸ A 2005 meta-analysis evaluated nine randomized trials comprising 4433 patients.⁵⁹ Stenting was associated with significant reductions in reinfarction (odds ratio [OR] 0.52 at 30 days, OR 0.67 at 1 year) and target vessel revascularization (OR 0.45 at 30 days, OR 0.47 at 1 year). There was no significant difference in mortality (OR 1.06 at 1 year). Finally, in a 2007 meta-analysis of eight randomized trials of drug-eluting stents versus bare metal stents involving 2786 patients, reinfarction was less common with drug-eluting stents (OR 0.72), whereas there was no difference in stent thrombosis (OR 0.86) or mortality (OR 0.76).⁶⁰

Consequences

The consequences of reocclusion depend partly on the amount of newly ischemic myocardium, the capacity of the remaining myocardium to compensate, and whether adequate coronary flow is promptly re-established. Whether symptomatic or silent, reocclusion is associated with significant morbidity and mortality in the short-term and the long-term. In the report by Ohman and coworkers³ from the TAMI study, reocclusion was associated with about a threefold risk of worsened ventricular function, heart failure, and conduction abnormalities, and a higher in-hospital mortality ($P = .01$) than maintained coronary patency (Table 16-1).

In the University of Michigan 1984-1990 experience,⁶¹ of 405 patients with paired baseline and prehospital discharge angiography, the mortality rate for patients with sustained reperfusion was 2%, but it was 15% after reperfusion and reocclusion. Risk factors for death after recurrent ischemia were advanced age, hemodynamic instability at the time of initial presentation, multivessel disease, and failure to obtain successful reperfusion within 90 minutes of recurrent ischemia (all $P < .05$).⁶¹

In two reviews of almost 76,000 patients from GUSTO-I, GUSTO-III, TIMI, and InTIME II,^{4,39} patients with reinfarction had a higher overall mortality rate at 30 days (11.3% to 16.4% versus 3.5% to 6.2% without reinfarction), which could be markedly reduced with PCI during index hospitalization.^{4,39} The data were conflicting as to whether 30-day survivors of reinfarction

Table 16-1. Consequences of Coronary Reocclusion after Thrombolytic Therapy for Acute Myocardial Infarction*

Clinical Event	Infarct Artery Patent (% of Patients)	Infarct Artery Reoccluded (% of Patients)
Improvement in LVEF, baseline to day 7	+3	-1
Pulmonary edema	4	19
Sustained hypotension	17	25
Second-degree or third-degree AV block	13	25
In-hospital death	5	11

*TAMI trial (N = 810 patients).

AV, atrioventricular; LVEF, left ventricular ejection fraction.

do^{4,39} or do not^{4,39} have a modest increase in risk from 30 days to 1 year. In the TIMI and InTIME II trials, most deaths occurred early, and the risk of additional deaths between the index hospital period and 2 years was not significantly increased in patients with recurrent MI.³⁹

Prevention

The thrombus associated with reocclusion after thrombolytic therapy or stenting is typically platelet-rich⁶² and resistant to further thrombolysis. The effect of thrombolytic agents on platelet function is complex, involving thrombin activation and perturbation of the GP IIb/IIIa and the GP Ib receptors, but in aggregate, platelet activation is often demonstrable.^{63,64}

The effect of aspirin, a weak platelet antagonist, has been studied in several trials, most notably ISIS-2.^{29,65} Reinfarction was essentially halved with aspirin usage in ISIS-2 (1.8% versus 3.3%; $P < .0001$), and an overview suggested that reocclusion was similarly reduced (11% versus 25%; $P < .001$).

Thienopyridines were initially considered as an alternative to aspirin in patients with STEMI. The benefit of this approach was suggested by results from the CAPRIE trial, which was not limited to STEMI, and the STAMI trial, which showed that clopidogrel and ticlopidine are at least as effective as aspirin.⁶⁶⁻⁶⁸ The role of clopidogrel in addition to aspirin must be considered in the context of the form of reperfusion therapy (primary PCI, thrombolysis, or no reperfusion). In the setting of STEMI treated with thrombolytic therapy, two randomized trials (CLARITY-TIMI 28 and COMMIT/CCS-2) showed clear evidence of benefit from early administration of clopidogrel in addition to aspirin.^{69,70}

No randomized trials have specifically evaluated the efficacy of clopidogrel in addition to aspirin in patients with STEMI who are not reperfused. Half of patients in COMMIT/CCS-2, which showed benefit from clopidogrel therapy, were not reperfused, however.⁶⁹ Most physicians also extrapolate from the benefit seen with clopidogrel in patients with non-ST segment elevation acute coronary syndromes who were not revascularized in the CURE trial.⁷¹ No randomized trials have evaluated the efficacy of clopidogrel in addition to aspirin in patients with STEMI who are treated with primary PCI. Most clinicians give clopidogrel based on extrapolation from randomized trials (PCI-CURE

and CREDO) in patients with non-ST segment elevation acute coronary syndromes. These trials showed that clopidogrel improves short-term and long-term cardiovascular outcomes—reduction of acute thrombotic complications—when given in addition to aspirin in patients treated with PCI.^{72,73}

Along with aspirin, heparin has also been a standard treatment after thrombolytic therapy. GUSTO-I results suggest that heparin is unnecessary when streptokinase is the thrombolytic agent used, but several studies have suggested that heparin improves short-term patency after rt-PA use.^{74,75} Hsia and colleagues⁷⁶ observed that the degree of elevation of activated partial thromboplastin time (aPTT), not the use of heparin, was crucial in determining patency after rt-PA use. In the HART study, if the aPTT in the first 12 hours after rt-PA use was less than 45 seconds, only 45% of infarct-affected arteries were patent at follow-up, but if the aPTT was longer than 60 seconds, 95% of vessels were open. Higher aPTT values are associated with a greater risk of bleeding. Data from the much larger GUSTO-I study suggest that the optimal compromise in reducing both risks is to have the aPTT between 63 and 72 seconds.⁷⁷

Two randomized studies addressed the issue of how long heparin should be continued in this setting.^{78,79} Both studies concluded that heparin could be safely discontinued in most patients after 24 hours. American College of Cardiology (ACC)/American Heart Association (AHA) 2004 STEMI guidelines recommended infusions of heparin routinely for 48 hours, and for a longer period only in patients with an ongoing indication for anticoagulation.⁸⁰⁻⁸²

Although no new trials specifically focusing on heparin in STEMI have been reported, numerous studies have compared alternative anticoagulant regimens (reviparin, fondaparinux, or enoxaparin) with heparin or placebo. In these studies, the new regimen was administered for the duration of the index hospitalization. The CREATE (reviparin versus placebo),⁸³ OASIS-6 (fondaparinux versus placebo or heparin),⁸⁴ and ExTRACT-TIMI-25 (enoxaparin versus heparin)⁸⁵ trials provided a rationale for a new recommendation of anticoagulation therapy for a minimum of 48 hours, preferably extended to the duration of the index hospitalization (up to 8 days) for patients undergoing reperfusion with fibrinolytics.⁸⁶ In the reperfused cohort of the CREATE trial, reviparin was associated with fewer deaths, reinfarctions, and strokes (11% versus 12.3% at 30 days). Reviparin was associated, however, with higher rates of life-threatening bleeding (1.1% versus 0.4% at 30 days).^{83,86} In the subset of OASIS-6 trial patients submitted to thrombolysis, fondaparinux was superior to control therapy (placebo or unfractionated heparin) with lower rates of death, reinfarction and severe hemorrhage at 30 days.^{86,89} This benefit was not observed in the cohort submitted to primary PCI, with a trend toward worse outcome.^{84,86}

In the ExTRACT-TIMI 25 trial, enoxaparin compared with unfractionated heparin was associated with lower rates of death and reinfarction (9.9% versus 12% at 30 days), but with higher rates of severe hemorrhage (2.1% versus 1.4% at 30 days). Findings were consistent among subgroups, regardless of thrombolytic agent type, age (dose was adjusted for patients >75 years old), or postlysis PCI.^{85,86} In the 2007 update ACC/AHA STEMI guidelines, unfractionated heparin, enoxaparin, and fondaparinux were considered as anticoagulation regimens with established efficacy as ancillary therapy to thrombolysis.⁸⁶ Anticoagulation regimens with unfractionated heparin or low-molecular-weight

heparins should be maintained if patients proceed to PCI, without crossover to other agents.⁸⁶ Fondaparinux is associated, however, with catheter thrombosis, and additional anticoagulation with anti-factor IIa activity, such as unfractionated heparin or bivalirudin, is recommended.⁸⁶

The search for better agents led to direct thrombin inhibitors and to antagonists of the final common pathway of platelet aggregation, the GP IIb/IIIa receptor. Direct thrombin inhibitors have the putative advantages over heparin of accessing clot-bound thrombin, having no reliance on antithrombin III (in which some patients are deficient), having no natural inhibitors, and being easier to regulate therapeutic levels.⁸⁸ The phase II TIMI-5 study suggested that these characteristics would translate into clinical benefits, with greater coronary patency after rt-PA use with hirudin than heparin (98% versus 89%; $P = .01$) and with a reduction in in-hospital death or reinfarction (7% versus 17%; $P = .02$).⁸⁹ These results were not confirmed by the larger GUSTO-IIa and TIMI-9a studies,^{87,90} however, both of which were stopped prematurely because of an excess of bleeding and strokes with hirudin.

Clinical experience with bivalirudin in the setting of acute MI has shown some benefit.^{91,92} In a pilot trial (HERO) of 412 patients receiving streptokinase and aspirin, a dose-related improvement in TIMI grade 3 flow was observed with bivalirudin in 48% of patients in the high-dose bivalirudin group, 46% of patients in the low-dose bivalirudin group, and 35% of patients in the heparin group. There were no differences in reocclusion or clinical end point event rates, and major bleeding seemed to be less frequent with bivalirudin. Based on these favorable findings, bivalirudin was compared with unfractionated heparin in the HERO-2 mortality trial in 17,073 patients receiving streptokinase.⁹¹ At 30 days, there was no difference in mortality rates (10.5% versus 10.9% with heparin); there was a small but significant reduction in reinfarction at 96 hours with bivalirudin (1.6% versus 2.3%); there was a nonsignificant trend toward more episodes of severe bleeding (0.7% versus 0.5%; $P = .07$) and intracerebral bleeding (0.6% versus 0.4%; $P = .09$) with bivalirudin; and there was a significant increase in moderate and mild bleeding with bivalirudin.

In the HORIZON AMI trial, patients treated with primary PCI (stenting) were randomly assigned to unfractionated heparin plus a GP IIb/IIIa inhibitor (abciximab or eptifibatide), or to bivalirudin monotherapy stopped at the end of the procedure plus provisional GP IIb/IIIa inhibitors for large thrombus or refractory no-flow. Only 7.2% of patients in the bivalirudin-treated group also received GP IIb/IIIa inhibitors in the catheterization laboratory. At 30 days, investigators saw a 24% reduction in net adverse clinical events and a 40% reduction in major bleeding—the primary end points of the study. Major adverse cardiac events, defined as all-cause death, reinfarction, ischemic target vessel revascularization, or stroke, were not different between the two groups. There were no significant differences between any of the individual event rates that made up the major adverse cardiac events end point, with the exception of cardiac mortality, which was significantly reduced in patients in the bivalirudin arm of the study.⁹³

Combination therapy using a half-dose of a thrombolytic agent with a GP IIb/IIIa inhibitor may be more likely to restore coronary perfusion; promote ST segment resolution at 90 minutes; and reduce the incidence of recurrent ischemia, nonfatal reinfarction, and rescue PCI. Despite these benefits, two large

trials, GUSTO V^{94,95} and ASSENT-3,^{96,97} and a meta-analysis found no improvement in survival compared with conventional thrombolytic therapy, and bleeding was increased, particularly in patients older than 75 years.⁹⁸ Presently, the use of GP IIb/IIIa inhibitors with thrombolysis is not recommended.^{80-82,99}

Adjunctive abciximab therapy during primary PCI for STEMI was evaluated after angioplasty alone in RAPPORT and CADILLAC and with stenting in ISAR-2, ADMIRAL, CADILLAC, and ACE. In a meta-analysis that included all five trials, abciximab therapy in patients undergoing primary PCI was associated with significant reductions in mortality at 30 days (2.4% versus 3.4% with placebo) and 6 to 12 months (4.4% versus 6.2%), and in reinfarction at 30 days (1% versus 1.9%); there was no increase in bleeding.⁹⁸ This analysis provides strong support for the concept that abciximab is beneficial in reducing acute ischemic events during primary PCI with stenting. Several trials tested the (upstream) abciximab hypotheses. The more recent, large FINESSE trial showed no benefit of “upstream” abciximab compared with abciximab given in the catheterization laboratory.¹⁰⁰

The pharmacologic approach may not be the only effective one for the prevention of recurrent ischemia. Improvement in coronary flow by PCI seems to reduce recurrent adverse events compared with thrombolytic use alone. Among the 20,101 patients enrolled in the TIMI trials, PCI during the index hospitalization was associated with a lower rate of in-hospital reinfarction (1.6% versus 4.5%) and a lower 2-year mortality rate (5.6% versus 11.6%). Performance of coronary artery bypass graft (CABG) surgery was also associated with a lower recurrent rate of infarction (0.7% versus 4.3%) and lower 2-year mortality rate (7.95% versus 10.6%).³⁹

Two early studies suggested less recurrent ischemia in association with intra-aortic balloon pump use than without it.¹⁰⁰⁻¹⁰² This finding was challenged by the PAMI 2 study,¹⁰³ where prophylactic intra-aortic balloon pump strategy after primary PCI in hemodynamically stable high-risk patients did not decrease the rates of infarct-related artery reocclusion or reinfarction, promote myocardial recovery, or improve overall clinical outcome. We recommend the use of intra-aortic balloon pump for hemodynamic support and in the rare instance that PCI cannot provide a satisfactory angiographic luminal (<50% stenosis) and flow (TIMI 3) result.

Lastly, considering late and very late stent thrombosis to be a form of reinfarction, the benefit and optimal duration of clopidogrel need be considered. In the only randomized trial to address early dosing, Han and colleagues¹⁰⁴ found 150 mg to be superior to 75 mg daily in reducing the risk of reinfarction after drug-eluting stenting (few of these patients were initially treated for acute MI, however).^{105,106} Consensus calls for at least 12-month dosing of clopidogrel after drug-eluting stenting. Beyond that, data are conflicting regarding the benefit of more protected dosing.^{105,106}

Recognition

Many reocclusions are silent. Because of the lack of sensitivity and specificity of single-lead ECG systems to detect changes that might be seen on a 12-lead ECG, some cardiologists have advocated routine 12-lead continuous monitoring for 48 hours. Not all studies have found re-elevation of ST segments to be associated with worsened outcome, but most have.^{107,108}

Recurrent chest pain with any ECG changes, silent ST segment elevation, a 30% to 50% increase of creatine kinase after it has reached its early peak, new heart failure, high-grade atrioventricular block, or ventricular tachycardia (the last with considerably less specificity) should alert the clinician to the possibility of coronary reocclusion. Because reocclusion can be clinically silent, late angiography remains the gold standard in assessing the frequency of reocclusion.

The 2004 ACC/AHA Task Force recommended some specific guidelines for the diagnosis of reinfarction after acute STEMI.^{81,82} Within the first 18 hours of the initial MI, a recurrent elevation in cardiac biomarkers alone should not be relied on to diagnose reinfarction, but should be accompanied by recurrent ST segment elevation on ECG and at least one other supporting criterion (e.g., recurrent chest pain or hemodynamic decompensation). For patients more than 18 hours from the initial MI, a biomarker increase of at least 50% and at least one additional criterion are sufficient for the diagnosis.^{81,82} The joint ESC/ACCF/AHA/WHF (European Society of Cardiology/American College of Cardiology/American Heart Association/World Health Federation) Task Force for the redefinition of MI established the following as criteria for diagnosing reinfarction: recurrent ischemic symptoms or ECG changes or both after the initial MI together with an increase 20% or greater of biomarkers (preferably troponin) measured after the recurrent event with at least one value above the 99th percentile of the reference range.¹⁰⁹⁻¹¹²

Treatment

PCI is the treatment of choice for patients with recurrent MI. The magnitude of the benefit was illustrated in a retrospective review of 20,100 patients from the TIMI and InTIME-II trials of fibrinolytic therapy.³⁹ Among the 4.2% of patients with a recurrent MI, the in-hospital mortality was 23.6% in patients who were treated medically and did not undergo revascularization compared with 5.2% with PCI; an equivalent benefit was seen with the smaller number of patients who underwent CABG surgery. A similar dramatic reduction in mortality with revascularization was noted in another review.⁴⁰ In GUSTO-I and ASSENT-2, 4% of patients ($n = 2301$) experienced reinfarction after thrombolytic therapy. The 30-day mortality did not differ between the repeat thrombolysis and revascularization groups ($P = .72$), but it was significantly lower in patients treated by these two strategies than in patients treated conservatively (11% and 11% versus 28%; $P < .001$). Stroke rates did not differ significantly between the three treatment strategies ($P = .49$).⁴⁰

PCI or surgery is also warranted in patients with STEMI who, after fibrinolytic therapy, develop spontaneous symptomatic angina or inducible post-MI ischemia on a predischARGE exercise test. Benefit from invasive therapy was shown in the DANAMI trial, in which 1008 patients were randomly assigned to conservative therapy or to revascularization with PCI or CABG surgery 2 to 10 weeks after MI.¹¹³ Revascularization was associated with a lower rate of reinfarction and admission for unstable angina; mortality after a median follow-up of 2.4 years was equivalent in both groups.

The efficacy of retreatment with a fibrinolytic agent primarily has been evaluated in patients with threatened reocclusion. There are two major problems with repeat fibrinolysis: excess bleeding risk, particularly with early reuse, and decreased efficacy, in view of initial treatment failure. Most retreatment studies have involved alteplase and, to a lesser degree, other

nonantigenic agents such as tenecteplase. Streptokinase should be avoided because of antigenicity and relative resistance.

Numerous reports have shown the feasibility and efficacy of repeat fibrinolytic therapy with alteplase.¹¹⁴⁻¹¹⁶ A retrospective study assessed the outcome of repeat infusions of alteplase in patients who developed early recurrent myocardial ischemia with threatened reinfarction after initial therapy with either alteplase (46 patients) or streptokinase (6 patients).¹¹⁴ Complete resolution of acute ischemia within 1 hour of the second infusion was achieved in 85%; half of these patients had a sustained response and avoided further coronary intervention. Bleeding complications occurred in 19%, but only 4% required transfusion.¹¹²

A later study evaluated the effects of retreatment with alteplase given for early signs of reocclusion after fibrinolysis, as manifested by recurrent chest pain lasting for more than 30 minutes with re-elevation of the ST segment.¹¹⁶ This complication occurred in 26 of 652 patients (4%) treated with alteplase, usually within 24 hours of the first infusion, particularly if intravenous heparin was not used. The second dose of alteplase was 50 mg when threatened reocclusion occurred within 24 hours of initial therapy and 100 mg after 24 hours. All patients had a good clinical response to retreatment; the new ST segment changes disappeared, and pain resolved within 100 minutes (median 50 minutes). Angiographic findings, determined at 1 hour, were less favorable. Coronary artery patency was observed in 73% of patients who had received intravenous heparin and only 40% of patients not receiving heparin. Bleeding rates were similar to those after a single dose of alteplase.

Randomized trials have not been performed to assess the comparative efficacy of repeat fibrinolysis and PCI in patients with recurrent ischemia or threatened reinfarction. As mentioned before, this issue was assessed in a retrospective review of GUSTO-I (alteplase) and ASSENT-2 (tenecteplase) trials.⁴⁰ Repeat fibrinolysis and revascularization with PCI or surgery were equally effective and were associated with significantly lower 30-day mortality than conservative therapy without any increase in the rate of stroke.

A few adjunctive agents have been proposed for threatened reocclusion or reinfarction, but clinical experience is limited. These agents include optimal antithrombin therapy (e.g., optimal heparin dosing) and antiplatelet therapy (e.g., with a GP IIb/IIIa antagonist). As noted earlier, the response to repeat alteplase is reduced in patients who are not treated with heparin.¹¹⁶ Suboptimal or inadequate anticoagulation with heparin is also associated with lower coronary patency rates,⁷⁸ whereas overly aggressive heparin is associated with an increased risk of hemorrhagic events.^{87,90} Several trials have evaluated the efficacy of a GP IIb/IIIa inhibitor with lower doses of fibrinolytic therapy to improve early reperfusion success and reduce subsequent reocclusion and reinfarction.¹¹⁷ No mortality benefit has been shown so far, and there is an increased risk of bleeding, particularly in elderly patients. GP IIb/IIIa inhibitors have not been formally tested for threatened reocclusion after fibrinolysis. The ability of abciximab to stabilize and reverse threatened reocclusion after coronary angioplasty has been reported.¹¹⁶

CABG surgery is performed infrequently for revascularization after fibrinolysis. In TIMI and InTIME-II trials ($N = 20,092$ patients), CABG surgery was performed in 1048 (5.2%) patients.³⁹ PCI is preferred in this setting because of increased risks of perioperative mortality and major hemorrhage with CABG surgery, especially if the interval between administration

of the fibrinolytic agent and surgery is short (<24 hours).¹¹⁸ Survivors of the perioperative period have better long-term outcome, however, than patients treated medically.^{39,118}

Based on available data, reopening an infarct vessel days after occlusion is not recommended.¹¹⁹⁻¹²¹ Previous smaller studies provided conflicting evidence,¹²²⁻¹²⁷ but the more recent OAT trial showed that performing late angioplasty plus stenting and optimal medical therapy on a persistent total occlusion 3 to 28 days after MI does not reduce rates of death (9.1% versus 9.4%), reinfarction (7% versus 5.3%), or New York Heart Association class IV heart failure (4.4% versus 4.5%) compared with optimal medical therapy alone.¹²⁸ Patients treated with PCI showed a trend toward more repeat MIs than patients treated medically.

A total of 381 patients enrolled in the OAT study were included in the TOSCA-2 ancillary study, in which coronary and left ventricular angiography was performed 1 year after randomization. Earlier studies have suggested that PCI beyond the accepted period of myocardial salvage might lead to improved left ventricular function and slow left ventricular remodeling. TOSCA-2 results indicated that 83% of PCI-treated patients had patent infarct-related arteries at 1 year compared with 25% in the medical therapy group ($P < .001$). Left ventricular ejection fraction improved in both groups by approximately 4%, but with no significant differences between the two groups. Change in left ventricular end-diastolic volume index was smaller in the PCI group, at 3.2 mL/m² versus 5.3 mL/m² in the medical therapy-only group, suggesting that PCI had a favorable effect in terms of reducing ventricular enlargement. This finding only trended toward statistical significance.¹²⁹

OAT trial results were taken into account in the 2007 update of the ACC/AHA/SCAI (American College of Cardiology/American Heart Association/Society of Coronary Angiography and Intervention) PCI guidelines. PCI is now not recommended in patients 24 hours to 28 days post-MI with one or two vessel disease and a totally occluded coronary artery if they are hemodynamically and electrically stable and have no ongoing or easily provoked chest pain. PCI might be used selectively, however, in patients who do not continue to do well on drug therapy alone.^{119,120}

Management

Reperfusion Strategies
New Approaches
Prognosis
Conclusion

DRAMATIC ADVANCES during the past several decades in diagnosing, monitoring, and treating patients with acute myocardial infarction (MI) have decreased hospital mortality rates by 50%. The organization of coronary care units in the 1960s to treat lethal arrhythmias¹ and the development of fibrinolytic therapy in the 1980s to reduce infarct size²⁻⁵ were the biggest breakthroughs. Cardiogenic shock, not arrhythmia, is now the most common cause of death in patients hospitalized with acute MI. However, neither the incidence nor the mortality rate associated with cardiogenic shock has been reduced by modern cardiac intensive care unit interventions, including vasopressor and inotropic drug infusions, hemodynamic monitoring, and intra-aortic balloon pump (IABP) counterpulsation (Table 17-1).⁶⁻¹² More recent reports show a survival advantage, however, for patients who undergo successful reperfusion with percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery.¹³⁻¹⁹ This chapter reviews the epidemiology, pathogenesis, clinical presentation, and current management of cardiogenic shock.

Epidemiology

Definition

Circulatory shock is characterized by the inability of tissue blood flow and oxygen delivery to meet metabolic demands. Cardiogenic shock is a type of circulatory shock resulting from severe impairment of ventricular pump function rather than from abnormalities of the vascular system or blood volume. It is important to separate the shock state, in which tissue perfusion is inadequate, from hypotension, in which tissue metabolic demands may be met by increasing cardiac output or decreasing systemic resistance.

The diagnosis of cardiogenic shock should include the following:

1. Systolic blood pressure less than 80 mm Hg without inotropic or vasopressor support, or less than 90 mm Hg with inotropic or vasopressor support, for at least 30 minutes.
2. Low cardiac output (<2 L/min/m²) not related to hypovolemia (i.e., pulmonary artery wedge pressure <12 mm Hg), arrhythmia, hypoxemia, acidosis, or atrioventricular block.
3. Tissue hypoperfusion manifested by oliguria (<30 mL/hr), peripheral vasoconstriction, or altered mental status.

Table 17-1. Historical Milestones in Cardiogenic Shock

1934	Fishberg et al ⁶ described the shock state as a peripheral complication of myocardial infarction
1942	Stead and Ebert ⁷ attributed the shock state to extreme myocardial dysfunction
1954	Griffith et al ⁸ used L-norepinephrine as pressor support
1967	Killip and Kimball ¹ showed no survival advantage with coronary care unit monitoring
1968	Kantrowitz et al ⁹ described the clinical use of the IABP
1972	Dunkman et al ¹⁰ showed successful treatment with CABG surgery
1973	Scheidt et al ¹¹ showed no survival advantage with IABP
1976	Forrester et al ¹² defined hemodynamic subsets using the pulmonary artery catheter
1980	DeWood et al ¹³ showed a survival advantage with early CABG surgery
1980	Mathey et al ¹⁴ showed successful treatment with fibrinolytic therapy
1982	Meyer et al ¹⁵ showed successful treatment with PTCA
1988	Lee et al ¹⁶ showed a survival advantage with PTCA
1999	Hochman et al ¹⁷⁻¹⁹ proved a survival advantage with revascularization in the SHOCK trial

CABG, coronary artery bypass graft; IABP, intra-aortic balloon pump; PTCA, percutaneous transluminal coronary angioplasty.

The failure to define cardiogenic shock consistently or to confirm hemodynamically the presence of an elevated pulmonary capillary wedge pressure and low cardiac index have previously confused the clinician and confounded the literature.

Etiology

The most common cause of cardiogenic shock is acute MI.²⁰ Often, anterior MI from acute thrombotic occlusion of the left anterior descending artery results in extensive infarction. Alternatively, a smaller MI in a patient with borderline left ventricular function

may be responsible for insufficient cardiac output. Large areas of ischemic nonfunctioning but viable myocardium occasionally lead to shock in patients with MI. The delayed onset of shock may result from reocclusion of a patent infarct artery, infarct extension, or metabolic decompensation of non-infarct zone regional wall motion. Occasionally, right ventricular MI from occlusion of a proximal large right coronary artery in a patient with inferior MI is the cause.²¹

Mechanical complications unrelated to infarct size account for approximately 12% of cases. The papillary muscle of the mitral valve may infarct or rupture, causing acute, severe mitral regurgitation.²² Rupture of the interventricular septum causing ventricular septal defect²³ or rupture of the left ventricular free wall producing pericardial tamponade²⁴ also needs to be considered. Other causes of cardiogenic shock that are not emphasized in this chapter include end-stage cardiomyopathy, myocardial contusion, myocarditis, hypertrophic cardiomyopathy, valvular heart disease, pericardial disease, and post-cardiopulmonary bypass.

Incidence

Before the emphasis on time-to-treatment and primary PCI, the incidence of cardiogenic shock had remained unchanged for more than 25 years with approximately 8% of patients with ST segment elevation myocardial infarction (STEMI)^{25,26} and 2.5% of patients with non-ST segment elevation MI^{27,28} developing cardiogenic shock. The latter group is more likely to have circumflex artery occlusion, comorbid disease, and severe three-vessel disease or left main disease.²⁸ Cardiogenic shock usually develops early after onset of symptoms, with approximately half of patients developing shock within 6 hours and 72% developing shock within 24 hours.²⁹ Others first develop a preshock state manifested by systemic hypoperfusion without hypotension.³⁰ These patients benefit from aggressive supportive therapy, and revascularization; early intervention may abort the onset of cardiogenic shock.

Pathogenesis

Pathology

The early development of cardiogenic shock is usually caused by acute thrombosis of a coronary artery supplying a large myocardial distribution, with no collateral flow recruitment.³¹ Frequently, this is the left anterior descending artery, although shock may result from coronary thrombosis in other sites if previous MI has occurred. Multivessel disease is present in two thirds of patients.³²

Autopsy studies have consistently shown that at least 40% of the myocardium is infarcted in patients who die of cardiogenic shock.³³ Various ages of infarction reflect previous infarction, reinfarction, or infarct extension.

The infarct border zone in patients without hypotension is clearly demarcated. In patients dying of shock, it is irregular, with marginal extension. Focal areas of necrosis remote from the infarct zone are also present. These findings result from progressive cell death owing to poor coronary perfusion, are reflected by prolonged release of cardiac enzymes, and contribute to hemodynamic deterioration.³⁴

Pathophysiology

Progressive hemodynamic deterioration leading to cardiogenic shock results from a sequence of events (Fig. 17-1). A critical amount of ischemic or necrotic myocardium decreases

contractile mass and cardiac output. When cardiac output is low enough that arterial blood pressure declines, coronary perfusion pressure decreases in the setting of an elevated left ventricular end-diastolic pressure. The resulting reduction in coronary perfusion pressure gradient from epicardium to endocardium exacerbates myocardial ischemia, further decreasing left ventricular function and cardiac output, perpetuating a vicious cycle. The speed with which this process develops is modified by the infarct zone, remote myocardial function, neurohumoral responses, and metabolic abnormalities.

The infarct zone can be enlarged by reocclusion of a patent infarct artery. Alternatively, infarct extension can result from side branch occlusion from coronary thrombus propagation or from thrombosis of a second stenosis stimulated by low coronary blood flow and hypercoagulability. Infarct expansion or aneurysm formation promotes left ventricular dilation, which increases wall stress and oxygen demand in the setting of decreased oxygen supply owing to low cardiac output.

Preclinical and clinical studies³⁵ have shown the importance of hypercontractility of remote myocardial segments in maintaining cardiac output in the setting of a large MI. This compensatory mechanism is lost when multivessel disease is present and produces ischemia in noninfarct segments.

A series of neurohumoral responses is activated in an attempt to restore cardiac output and vital organ perfusion. Decreased baroreceptor activity secondary to hypotension increases sympathetic outflow and reduces vagal tone; this increases heart rate, myocardial contractility, venous tone, and arterial vasoconstriction. Vasoconstriction is most pronounced in the skeletal, splanchnic, and cutaneous vascular beds to redistribute cardiac output to the coronary, renal, and cerebral circulations. An increase in the ratio of precapillary to postcapillary resistance decreases capillary hydrostatic pressure, facilitating movement of interstitial fluid into the vascular compartment. Increased catecholamine levels and decreased renal perfusion lead to renin release and angiotensin production. Elevated angiotensin levels stimulate peripheral vasoconstriction and aldosterone synthesis. Aldosterone increases sodium and water retention by the kidney, increasing blood volume. Release of antidiuretic hormone from the posterior pituitary by baroreceptor stimulation also increases water retention. Local autoregulatory mechanisms that decrease arteriolar resistance and increase regional blood flow are stimulated by hypoxia, acidosis, and accumulation of vasoactive metabolites (e.g., adenosine).

Enhanced anaerobic metabolism, lactic acidosis, and depleted adenosine triphosphate stores result when compensatory neurohumoral responses are overwhelmed, depressing ventricular function further. Arrhythmias may additionally reduce cardiac output and increase myocardial ischemia. Loss of vascular endothelial integrity because of ischemia culminates in multiorgan failure. Pulmonary edema impairs gas exchange. Renal and hepatic dysfunction can cause fluid, electrolyte, and metabolic disturbances. Gastrointestinal ischemia can lead to hemorrhage or entry of bacteria into the bloodstream, causing sepsis. Microvascular thrombosis owing to capillary endothelial damage with fibrin deposition and catecholamine-induced platelet aggregation impairs organ function further.

A systemic inflammatory state with high plasma levels of cytokines (e.g., tumor necrosis factor- α , interleukin-6) and inappropriate nitric oxide production additionally may depress myocardial function or impair catecholamine-induced

Figure 17-1. The vicious circle of mechanical and neurohormonal events that lead to progressive cardiogenic shock and death in acute myocardial infarction. ANP, atrial natriuretic peptide. (Adapted from Califf RM, Bengtson JR: *Cardiogenic shock*. *N Engl J Med* 1994;330:1724.)

vasoconstriction. All of these factors lead to diminished coronary artery perfusion and trigger a vicious cycle of further myocardial ischemia and necrosis resulting in even lower blood pressure, lactic acidosis, multiple organ failure, and ultimately death.³⁶

Clinical Presentation

History and Physical Examination

The diagnosis of acute MI must be confirmed. Noncardiac causes of shock need to be ruled out, including aortic dissection, tension pneumothorax, massive pulmonary embolism, ruptured viscus, bleeding, and sepsis. Risk factors for developing cardiogenic shock include older age, anterior MI location, hypertension, diabetes mellitus, multivessel coronary artery disease, prior MI, prior congestive heart failure, STEMI, or left bundle branch block.^{37,38}

Patients usually appear ashen or cyanotic, with cold and clammy skin. They may be agitated, disoriented, or lethargic from cerebral hypoperfusion. The pulses are rapid and faint, the pulse pressure is narrow, and arrhythmias are common. Jugular venous distention and pulmonary rales are usually present in left ventricular shock, but they may be absent. Jugular venous distention, Kussmaul sign (a paradoxical increase in jugular venous pressure during inspiration), and absent rales are found in right ventricular shock. Left ventricular dyskinesia may produce a precordial heave. A systolic thrill along the left sternal border is

consistent with mitral regurgitation or ventricular septal defect. The heart sounds are distant. Third and fourth heart sounds or a summation gallop can be auscultated. The systolic murmur of mitral regurgitation is often present; ventricular septal defect also produces a systolic murmur. The absence of a murmur does not exclude these complications, however. The extremities are usually vasoconstricted.

Electrocardiography and Laboratory Testing

A large anterior or anterolateral MI pattern is often present. Old anterior Q waves or new ST segment elevation in the right precordial leads consistent with right ventricular MI may be noted with acute inferior MI. Multiple lead ST segment depression without an injury current is another pattern that can occur with multivessel or left main disease. New left bundle branch block and third-degree atrioventricular conduction block are ominous findings. A relatively normal electrocardiogram (ECG) should alert one to other causes of shock.

Troponin and creatine kinase levels are elevated, may peak late because of prolonged washout or ongoing necrosis, and can increase secondarily with infarct extension. Lactic acidosis, hypoxemia, and mixed venous oxygen desaturation are usually present.

Echocardiography

Echocardiography can be performed rapidly and offers valuable information on the extent of left ventricular dysfunction. A dilated, hypokinetic left ventricle suggests left ventricular

shock, whereas a dilated right ventricle suggests right ventricular involvement. Normal ventricular function, low cardiac output, and mitral regurgitation are consistent with acute severe mitral regurgitation. Pericardial tamponade from hemorrhagic effusion or free wall rupture can be detected quickly. The Doppler evaluation can easily confirm the presence of significant mitral regurgitation or ventricular septal rupture. Transesophageal echocardiography is helpful in patients in whom image quality is inadequate, or when a flail mitral leaflet is suspected but not seen on transthoracic echocardiography.

Management

General Measures

Numerous supportive measures need to be instituted quickly (Fig. 17-2). If there is no clinical evidence for pulmonary edema, a fluid bolus should be given to exclude hypovolemia as a cause of hypotension. Patients with a history of inadequate fluid intake, diaphoresis, diarrhea, vomiting, or diuretic use may not have pump failure and improve dramatically with fluid administration. Because preload is critical in patients with right ventricular shock, fluid support and avoidance of nitrates and morphine are indicated (Table 17-2).

Oxygenation and airway protection are crucial. Intubation and mechanical ventilation are usually required, followed by sedation, and often muscular paralysis. These interventions also improve the safety of electrical cardioversion or cardiac catheterization, if needed, and decrease oxygen demand. Positive end-expiratory pressure decreases preload and afterload.

Hypokalemia and hypomagnesemia predispose patients to ventricular arrhythmias and should be corrected. Because metabolic acidosis decreases contractile function, hyperventilation should be considered, but sodium bicarbonate should be avoided because of a short half-life and the large sodium load.

Arrhythmias and atrioventricular heart block have a major influence on cardiac output. Atrial and ventricular tachyarrhythmias should be electrically cardioverted promptly, rather than treated with pharmacologic agents. Severe bradycardia secondary to excess vagotonia can be corrected with atropine. Temporary pacing should be initiated for high-degree heart block, preferably with a dual-chamber system. This is especially important in patients with right ventricular infarction who depend on the right atrial contribution to preload.

Aspirin and monitored unfractionated heparin should be administered to decrease the likelihood of reinfarction, ventricular mural thrombus formation, or deep venous thrombosis in the setting of low flow and hypercoagulability. Clopidogrel is best withheld until cardiac catheterization has determined the need for emergency surgery because of its prolonged action and increased risk for perioperative bleeding. Morphine sulfate decreases pain and anxiety, excessive sympathetic activity, preload, and afterload, but should be administered only in small increments. Diuretics decrease filling pressures and should be used to control volume. β blockers and calcium channel blockers should be avoided because they are negative inotropic agents. An insulin drip may be required to control hyperglycemia.

Hemodynamic Monitoring

Central hemodynamic monitoring is crucial for confirming the diagnosis and guiding pharmacologic therapy (Table 17-3). Urine output needs to be monitored hourly through catheter

drainage. An arterial catheter allows constant monitoring of the blood pressure. A pulmonary artery catheter should be inserted as soon as feasible to measure intracardiac pressures, cardiac output, systemic resistance, and mixed venous oxygen saturation. Although use of the pulmonary artery catheter has not been associated with mortality benefit in patients without MI, it is very helpful in the titration of fluids and medications in patients with cardiogenic shock.

The hemodynamic profile of left ventricular shock, as defined by Forrester and coworkers,¹² includes pulmonary artery wedge pressure greater than 18 mm Hg and a cardiac index less than 2.2 L/min/m². Others have used a pulmonary artery pressure of 15 mm Hg or 12 mm Hg and a cardiac index of 2 L/min/m² or 1.8 L/min/m². The hemodynamic profile of right ventricular shock includes right atrial pressure of 85% or more of the pulmonary artery wedge pressure, steep γ descent in the right atrial pressure tracing, and the dip and plateau (i.e., square root sign) in the right ventricular waveform. Large v waves in the pulmonary artery wedge tracing suggest the presence of severe mitral regurgitation. An oxygen saturation step-up (>5%) from the right atrium to the right ventricle confirms the diagnosis of ventricular septal rupture. Equalization of right atrial, right ventricular end-diastolic, pulmonary artery diastolic, and pulmonary capillary wedge pressures occurs with severe right ventricular infarction or pericardial tamponade owing to free wall rupture or hemorrhagic effusion. Cardiac power (mean arterial pressure $\times$ cardiac output/451) is the strongest hemodynamic predictor of hospital mortality.³⁹

Pharmacologic Support

Vasopressor and inotropic drug support are the major initial interventions for reversing hypotension and improving vital organ perfusion (Table 17-4). Failure to improve blood pressure with these agents is an ominous prognostic sign. Continued hypotension results in progressive myocardial ischemia and deterioration of ventricular function. Although many patients temporarily respond to therapy, hospital mortality rates remain unchanged without successful reperfusion therapy.

Dobutamine, a synthetic catecholamine with predominantly β_1 -adrenergic effects, is the initial inotropic agent of choice for patients with systolic pressures greater than 70 mm Hg. It has some chronotropic effect, but it has no significant vasoconstrictor, arrhythmogenic, or renal effects. Cardiac output is increased, and filling pressures are decreased.

Dopamine, a natural catecholamine, is the initial vasopressor of choice when the systolic pressure is greater than 70 mm Hg. Low dose (2 to 5 μ g/kg/min) increase stroke volume and renal perfusion by stimulating dopamine receptors. Intermediate doses have a dose-dependent β_1 -adrenergic receptor effect, increasing inotropy and chronotropy. High doses (15 to 20 μ g/kg/min) activate α -adrenergic receptors, increasing vascular resistance.

Norepinephrine is a natural catecholamine with predominantly peripheral α -adrenergic effects. It is used when the systolic pressure is less than 70 mm Hg because it is a potent venous and arterial vasoconstrictor.

Catecholamine infusions should be carefully titrated. A delicate balance must be obtained between increasing coronary perfusion pressure and increasing oxygen demand, so that

Figure 17-2. Emergency management of complicated ST segment elevation myocardial infarction. ACE, angiotensin-converting enzyme; BP, blood pressure; MI, myocardial infarction; SBP, systolic blood pressure; SL, sublingual. (From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation* 2004;110:e82.)

myocardial ischemia is not exacerbated. Excessive peripheral vasoconstriction decreases tissue perfusion, increased afterload increases filling pressures, and excessive tachycardia or arrhythmias can be stimulated. Extravasation of dopamine or norepinephrine can cause tissue necrosis.

Cardiac glycosides have no significant inotropic effect in patients with severe pump failure, and they increase oxygen consumption. Ischemic myocardium is susceptible to the arrhythmogenic effects of digoxin, and intravenous administration causes coronary and peripheral vasoconstriction. Digitalis

may be employed for supraventricular tachyarrhythmias to control heart rate.

Vasodilators are useful if adequate blood pressure and coronary artery perfusion pressure can be restored. Nitroprusside is an arterial dilator and a venodilator, whereas nitroglycerin is predominantly a venodilator. Afterload reduction increases stroke volume and is especially important when mitral

regurgitation or ventricular septal rupture is present. Preload reduction decreases filling pressures and oxygen demand by reducing wall tension. The major hazard is that reduction in preload and afterload could decrease diastolic arterial pressure, compromising coronary artery perfusion pressure and resulting in extension of ischemic myocardial injury. Reflex tachycardia increases oxygen demand. Nitroglycerin and nitroprusside can be started at low-dose infusions and titrated against blood pressure and pulmonary capillary wedge pressure. There are no data on phosphodiesterase inhibitors (e.g., milrinone) for cardiogenic shock, but they can be useful in low-output states when the patient is relatively stable by augmenting myocardial contractility and producing peripheral vasodilation.

Mechanical Support

When pharmacologic therapy provides insufficient hemodynamic support, mechanical circulatory assistance can be instituted, especially when revascularization or surgical repair of mechanical complications is planned (Fig. 17-3). IABP counterpulsation reduces systolic afterload and augments diastolic perfusion pressure. The usual result is a decrease in filling pressures, systolic blood pressure, heart rate, mitral regurgitation, and left-to-right shunting across a ventricular septal rupture, along with an increase in diastolic and mean blood pressure, stroke volume, cardiac output, and urine output. Subendocardial blood flow is improved, and in contrast to vasopressor support, oxygen demand is decreased.

Kantrowitz and colleagues⁹ first reported the use of IABP counterpulsation in treating cardiogenic shock. Mueller and coworkers⁴⁰ showed improved hemodynamics and myocardial metabolism associated with IABP therapy. Weiss and associates⁴¹ showed improvement in infarct zone regional wall motion, but not adjacent non-infarct zone regional wall motion. No improvement in coronary blood flow occurs in highly stenotic coronary arteries.⁴² The IABP favorably influences systemic hemodynamics, but it does not improve ischemic zone blood flow or non-infarct zone wall motion.

The failure to improve ischemic myocardial blood flow probably explains why, despite temporary hemodynamic and clinical improvement in 75% of patients, no obvious difference in enzymatic infarct size or mortality rate with IABP counterpulsation

Table 17-2. Conventional Therapy for Cardiogenic Shock

1. Maximize volume (RAP 10-14 mm Hg, PAWP 18-20 mm Hg)
2. Maximize oxygenation (e.g., ventilator)
3. Correct electrolyte and acid-base imbalances
4. Control rhythm (e.g., pacemaker, cardioversion)
5. Sympathomimetic amines (e.g., dobutamine, dopamine, norepinephrine)
6. Phosphodiesterase inhibitors (e.g., milrinone)
7. Vasodilators (e.g., nitroglycerin, nitroprusside)
8. Intra-aortic balloon counterpulsation

PAWP, pulmonary artery wedge pressure; RAP, right atrial pressure.

Table 17-3. Hemodynamic Profiles

Left ventricular shock	High PCWP, low CO, high SVR
Right ventricular shock	High RA, RA/PCWP >0.8, exaggerated RA y descent, RV square root sign
Mitral regurgitation	Large PCWP v wave
Ventricular septal defect	Large PCWP v wave, oxygen saturation step-up (>5%) from RA to RV
Pericardial tamponade	Equalization of diastolic pressures approximately 20 mm Hg

CO, cardiac output; PCWP, pulmonary capillary wedge pressure; RA, right atrium; RV, right ventricle; SVR, systemic vascular resistance.

Table 17-4. Pharmacologic Treatment for Cardiogenic Shock

Drug	Doses	Side Effects
Dobutamine	5-15 $\mu\text{g/kg/min}$ IV	Tolerance
Dopamine	2-20 $\mu\text{g/kg/min}$ IV	Increased oxygen demand
Norepinephrine	0.5-30 $\mu\text{g/min}$ IV	Peripheral and visceral vasoconstriction
Nitroglycerin	10 $\mu\text{g/min}$, increased by 10 μg every 10 min, maximum 200 $\mu\text{g/min}$ IV	Headache, hypotension, tolerance
Nitroprusside	0.3-10 $\mu\text{g/min}$ IV	Hypotension, cyanide toxicity
Milrinone	50 $\mu\text{g/kg}$ over 10 min IV, then 0.375-0.75 $\mu\text{g/kg/min}$	Ventricular arrhythmia
Furosemide	20-160 mg IV	Hypokalemia, hypomagnesemia
Bumetanide	1-3 mg IV	Nausea, cramps

IV, intravenously.

Figure 17-3. Recommendations for initial reperfusion therapy. CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; IABP, intra-aortic balloon pump; IRA, infarct-related artery; LBBB, left bundle branch block; MI, myocardial infarction; PCI, percutaneous coronary intervention. (From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation* 2004;110:e82.)

has been mentioned in the literature.^{10,11} The mortality rates in a large cooperative trial were 60% during IABP support, 77% during hospitalization, and 91% at 1 year for 87 patients.¹¹ The only randomized trial was performed by O'Rourke and colleagues.⁴³ No difference in enzymatic infarct size or mortality was observed.

IABP counterpulsation offers little support to shock patients with extensively scarred ventricles or after late presentation. The best use is in patients with ischemic, viable, but nonfunctioning myocardium that can be revascularized, or with mitral regurgitation or ventricular septal rupture amenable to surgical repair. Dunkman and colleagues¹⁰ showed that the addition of CABG surgery to IABP support decreased mortality from 84% to 60%.

Several reports have examined the use of IABP counterpulsation in conjunction with fibrinolytic strategies.⁴⁴⁻⁴⁸ There were some favorable trends, but significantly more bleeding episodes. Only one randomized controlled trial has compared IABP counterpulsation plus fibrinolytic therapy with fibrinolysis alone. The TACTICS trial⁴⁸ sought to enroll 500 patients with acute STEMI complicated by shock; only 57 patients were actually enrolled. Six-month follow-up showed a trend toward mortality reduction in the IABP group, but this was not significant because of small sample size. The strategy of early fibrinolytic therapy and

IABP counterpulsation, followed by immediate transfer for PCI or CABG surgery, may be appropriate for hospitals that do not have revascularization capability.

The use of IABP therapy in patients undergoing primary or rescue PCI has been evaluated in a few studies. Early data suggested a reduction in infarct artery reocclusion rates and improvement in clinical outcome in patients without cardiogenic shock.^{49,50} A more recent trial⁵¹ failed to show any improvement in recovery of left ventricular function or survival, however, and its use is best restricted to patients with hemodynamic instability. In patients with cardiogenic shock, the IABP catheter needs to be inserted before angiography to provide optimal hemodynamic support during the procedure.

The American College of Cardiology (ACC)/American Heart Association (AHA) STEMI guidelines have given a class I (general agreement that a procedure/treatment should be performed/administered) recommendation to IABP therapy for (1) cardiogenic shock not quickly reversed with pharmacologic therapy as a stabilizing measure for angiography and prompt revascularization, (2) acute mitral regurgitation or ventricular septal defect complicating MI as a stabilizing therapy for angiography and repair/revascularization, and (3) refractory post-MI angina as a bridge to angiography and revascularization.⁵²

Contraindications for IABP counterpulsation therapy include aortic regurgitation, aortic dissection, and peripheral vascular disease. Complications occur in 10% to 30% of patients with cardiogenic shock, and include limb ischemia, femoral artery laceration, aortic dissection, infection, hemolysis, thrombocytopenia, thrombosis, and embolism.

Devices that offer greater circulatory support than IABP counterpulsation are available and have been used in cardiogenic shock as a bridge to recovery or to transplantation. These devices may be classified into devices that can be placed percutaneously and devices that require surgical placement. It is crucial to recognize which patients would require greater hemodynamic support than provided by IABP therapy.

Percutaneous cardiopulmonary bypass can be initiated at the bedside via the femoral artery and vein, and can provide 3 to 5 L/min of nonpulsatile flow and a mean aortic pressure of 50 to 70 mm Hg despite cardiac standstill.⁵³ Support is limited to several hours because of blood cell destruction. A review of 42 studies (533 patients) suggested a mean survival to discharge of 51% (median 38%) in patients with cardiogenic shock treated with percutaneous bypass.⁵⁴ Extracorporeal life support also has been used in critically ill patients, and 33% survival to discharge for adult cardiogenic shock patients has been reported.⁵⁵ These results are encouraging because extracorporeal life support in these cases has typically been placed percutaneously during arrest or near-arrest circumstances, when the expected mortality would be 100%. Left ventricular decompression is impossible with these devices.

Another strategy has been to use ventricular assist devices as a bridge to recovery or to transplant or even as destination therapy.⁵⁶ These devices can be placed percutaneously or surgically. The standard left heart support configuration of the percutaneous ventricular assist device (Tandem-Heart; Cardiac Assist, Pittsburgh, PA) uses a 21F femoral cannula placed across the interatrial septum into the left atrium, whereas a shorter 15F or 17F cannula is placed in the iliac artery, allowing left atrial to arterial assist pumping by an extracorporeal centrifugal continuous flow pump.^{56,57} This device has been successfully used in cardiogenic shock from left ventricular failure⁵⁶ and right ventricular failure (right atrial-to-pulmonary artery bypass).⁵⁸

A small trial compared IABP counterpulsation and the percutaneous ventricular assist device in patients undergoing primary PCI for acute MI complicated by cardiogenic shock. Although the percutaneous ventricular assist device provided better hemodynamic support, the risk of complications was higher, and there was no difference in 30-day mortality.⁵⁹ Surgically implanted ventricular assist devices have also been used in cardiogenic shock. These devices require placement via thoracotomy, but can be left in place long-term. In a single-center series, the Thoratec (Pleasanton, CA) biventricular assist device was used as a successful bridge to cardiac transplantation in 11 of 19 patients in cardiogenic shock.⁶⁰ Percutaneous and surgical ventricular assist devices are available only at selected centers, and early transfer of patients to these facilities should be considered for patients failing standard supportive measures.

Reperfusion Strategies

Fibrinolytic Therapy

Several multicenter randomized megatrials have shown that fibrinolytic therapy reduces mortality from acute MI.²⁻⁵ The greatest survival benefit has been confirmed for patients with

the most jeopardized myocardium (e.g., anterior infarction, new left bundle branch block). It is paradoxical and disappointing that no obvious survival benefit has been realized for the subset of patients with cardiogenic shock.⁶¹

Mathey and colleagues¹⁴ first reported that the shock state could be reversed with successful reperfusion secondary to intracoronary streptokinase administration. A multicenter registry report on 44 patients treated with intracoronary streptokinase documented a 66% in-hospital mortality rate.⁶² The importance of successful reperfusion and outcome was first suggested by this report, however. Only 43% of the patients had successful reperfusion compared with 71% for the entire study, but their mortality rate was 42% compared with 84% for unsuccessful reperfusion.

Compared with placebo, intravenous fibrinolytic therapy reduces the risk of subsequent cardiogenic shock in patients who initially present without shock.^{3,4,63} Comparative trials of fibrinolytic agents have shown variable results. Trials that show no difference in mortality between agents also do not show a reduction in the incidence of cardiogenic shock with any one agent.⁶⁴⁻⁶⁶ In contrast, comparative trials that show a mortality benefit in favor of one agent also showed a significant reduction in the incidence of cardiogenic shock in favor of that agent.⁶⁷⁻⁶⁹ Therapy with fibrinolytic agents in acute MI significantly reduces the subsequent development of cardiogenic shock, and agents that are associated with higher patency rates and improved survival in comparative studies also lead to lower rates of shock.

Fibrinolytic therapy for patients presenting in manifest cardiogenic shock is associated with low reperfusion rates and no clear-cut treatment benefit.⁶¹ Mean arterial pressure must be greater than 65 mm Hg for coronary blood flow to be maintained; flow ceases when mean arterial pressure is less than 30 mm Hg. Vasoconstriction and passive collapse of the arterial wall are additional factors that may limit the ability of the fibrinolytic agent to penetrate an intracoronary thrombus.⁷⁰ Canine studies showed that restoration of blood pressure to normal ranges with norepinephrine infusion improved reperfusion rates, suggesting that coronary perfusion pressure, not cardiac output, is the major determinant of fibrinolytic efficacy.^{71,72}

The trials that compared streptokinase with alteplase showed mortality benefit for shock patients randomly assigned to streptokinase, despite the fact that patients treated with alteplase fared better.^{64,68} Streptokinase may be beneficial in this subset of patients because it causes a prolonged lytic state in the setting of low coronary blood flow (which may reduce the risk of reocclusion), and because it is less fibrin-specific and may penetrate the thrombus better because it does not bind preferentially to the surface of the clot. Because of the limitations of fibrinolytic therapy for cardiogenic shock, it should be considered as a secondary treatment option when revascularization therapy with PCI or CABG surgery is not rapidly available. Viable patients should be transferred to a hospital with revascularization capability as soon as possible so that the potential benefits of revascularization therapy may still be obtained.

Percutaneous Coronary Intervention

Meyer and associates¹⁵ were the first to use PCI to treat cardiogenic shock. The first treatment series were reported in 1985. O'Neill and colleagues⁷³ obtained successful reperfusion in 24 (88%) of 27 patients, with an in-hospital mortality rate of 25%.

Brown and coworkers⁷⁴ had a 61% successful reperfusion rate, associated with a 42% mortality rate; the mortality rate was 82% when reperfusion was unsuccessful. Multiple small observational reports since then have consistently shown a survival benefit for patients in whom PCI was successful compared with patients in whom PCI was unsuccessful or with historical controls.

There have been a few large observational reports on reperfusion therapy for cardiogenic shock. The GUSTO-1 trial⁷⁵ included 2972 patients with cardiogenic shock treated with fibrinolytic therapy. There was a lower 30-day mortality rate for the 22% of patients who were subsequently treated with PCI compared with patients receiving only medical therapy (43% versus 61% with shock on arrival, 32% versus 61% for patients who developed shock after arrival). Another GUSTO-1 analysis included 2200 patients with cardiogenic shock.⁷⁶ Compared with a delayed strategy, angiography within 24 hours of shock onset with revascularization by PCI or CABG surgery when deemed appropriate was independently associated with reduced 30-day mortality (38% versus 62%).

A more recent large registry evaluated the outcome of 1333 patients undergoing primary PCI for cardiogenic shock.⁷⁷ The in-hospital mortality in this cohort was 46%. The independent predictors of mortality were left main disease, TIMI flow less than 3 after PCI, older age, three-vessel disease, and longer time interval between symptom onset and PCI.

None of these reports represents randomized, controlled studies of PCI. A selection bias favoring PCI over historical controls could easily have resulted from excluding elderly patients or patients in extremis or with comorbid disease. Hochman and colleagues⁷⁸ documented that patients with cardiogenic shock who are selected for cardiac catheterization are younger and less likely to die (51% versus 85%), even when not revascularized. Nevertheless, several studies and clinical experience clearly show the favorable impact a patent infarct artery can have on reversing the shock state.

Two small randomized trials have been performed. SMASH⁷⁹ randomly assigned 55 patients to undergo either emergency angiography and revascularization when indicated or initial medical management, but the trial was terminated prematurely because of poor enrollment. Mortality at 30 days was 69% in the invasive arm versus 78% in the medical arm. At 1 year, the mortality figures were 74% and 83%. Although the study failed to reach statistical significance because of sample size, the trend was clinically important.

The SHOCK trial¹⁷⁻¹⁹ randomly assigned 302 patients to emergent revascularization or immediate medical stabilization. Concurrently, the 30 participating sites collected registry data on 1190 patients presenting with cardiogenic shock who were not randomly assigned.⁸⁰ Medical stabilization included fibrinolytic therapy in more than half of the patients and inotropic and vasopressor agents. IABP counterpulsation was used in 86% of the patients. In the revascularization arm, 97% of patients underwent early angiography; 64% underwent PCI, and 36% had CABG surgery. There was no statistically significant difference in 30-day mortality between the revascularization and medical therapy groups (46.7% versus 56%; $P = .11$), but by the 6-month end point, a significant survival advantage had emerged for patients randomly assigned to revascularization (50.3% versus 63.1%; $P = .027$) that was maintained at 1 year (53.3% versus 66.4%) (Fig. 17-4).

Figure 17-4. Mortality rates in the SHOCK Trial. ERV, early revascularization; IMS, immediate medical stabilization. (Data from Hochman JS, Sleeper LA, Webb JG, et al: Early revascularization in acute myocardial infarction complicated by cardiogenic shock. SHOCK Investigators. Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock. *N Engl J Med* 1999;341:625; and Hochman JS, Sleeper LA, White HD, et al: One-year survival following early revascularization for cardiogenic shock. *JAMA* 2001;285:190.)

Emergency PCI is recommended by the ACC/AHA STEMI guidelines for patients younger than 75 years who develop shock within 36 hours of MI and who are suitable for revascularization that can be performed within 18 hours of shock, unless further support is deemed futile.⁵² The best candidates for PCI are patients without prior MI who are younger than 70 years with fewer comorbidities and symptom duration less than 12 hours. The severity, distribution, and diffuseness of coronary artery disease and the degree of left ventricular disease also influence outcome. Poor candidates because of very high mortality risk are patients with rapidly progressive hemodynamic deterioration despite therapeutic interventions and elderly patients with comorbid disease. Additionally, patients with life-shortening illnesses, no vascular access, previously defined coronary anatomy that was unsuitable for revascularization, anoxic brain damage, and prior cardiomyopathy are poor candidates. Except for elderly patients, all other subgroups had treatment benefit with revascularization in the SHOCK trial.¹⁷

Analysis of the elderly patient subgroup in the SHOCK registry⁸¹ was performed to gain further insight in patients 75 years old and older. Although the randomized trial included only 56 patients in that age group, the registry included 277 patients. Overall, in-hospital mortality in the elderly versus the younger age group was 76% versus 55% ($P < .001$). The 44 elderly patients selected for early revascularization showed a significantly lower mortality rate, however, than patients who did not undergo revascularization (48% versus 81%; $P = .0002$). Other reports⁸²⁻⁸⁴ also support the use of primary PCI in selected elderly patients with cardiogenic shock complicating MI, so age alone should not be an exclusion for selecting patients for cardiac catheterization. Prior functional status, comorbidity, and patient and family preferences are important selection criteria.

Emergency angiography determines revascularization suitability. Angiographic exclusions for PCI include unprotected left main disease, infarct artery stenosis less than 70% with TIMI-3 flow, or lesion morphology that is high risk for no-reflow or other

complications. Emergency CABG surgery may be considered for patients with left main disease, severe coronary anatomy unsuitable for PCI, multivessel disease, mechanical complications, or failed PCI if there is ongoing myocardial ischemia.

The procedure is performed most safely with the patient ventilated and sedated or paralyzed. Gas exchange is maximized, risk of aspiration is minimized, cardioversion can be performed easily, and patient movements do not interfere with the procedure. Both femoral arteries and veins are cannulated with vascular sheaths. An IABP is inserted through one femoral artery for counterpulsation support, and a pulmonary artery catheter is inserted through a femoral vein. Interventions to control volume and pressure are titrated against the systemic and pulmonary artery wedge pressures. Electrolytes and blood gases are obtained, and abnormalities are corrected. A temporary pacemaker is inserted, if necessary.

PCI should be performed only when the patient is maximally supported. Using a low osmolar ionic contrast medium, two orthogonal injections of the left coronary artery and one left anterior oblique injection of the right coronary artery are made in an attempt to identify the infarct artery. Left ventriculography should usually be avoided because of the contrast load. If PCI is to be attempted, it should be performed as quickly and efficiently as possible with limited contrast injections. Although PCI for STEMI is usually limited to the infarct artery, patients in cardiogenic shock with multivessel disease may have the best survival chance with PCI of all proximal discrete lesions. Early resolution of arrhythmias, conduction blocks, or hypotension suggests an important therapeutic benefit. Conversely, failure to improve within the first 24 hours usually predicts mortality.

Coronary stents decrease restenosis rates by 50% in elective PCI compared with balloon angioplasty, but have not reduced mortality rates in primary PCI.⁸⁵ Some observational studies in cardiogenic shock that have not completely corrected for confounding variables suggest lower mortality rates with stents than percutaneous transluminal coronary angioplasty,⁸⁶⁻⁸⁸ but others show no benefit⁸⁹ or higher mortality rates.⁹⁰ Randomized studies have not been performed. Most patients undergoing primary PCI for cardiogenic shock receive stents because they improve the immediate angiographic result and decrease subsequent target vessel revascularization in survivors.

The use of platelet glycoprotein IIb/IIIa inhibitors has been shown to improve outcome of patients with acute MI undergoing primary PCI.⁹¹ Observational studies suggest a benefit of abciximab in primary stenting for cardiogenic shock.^{87,89,90,92} Although there are no randomized controlled trials evaluating use of abciximab or other glycoprotein IIb/IIIa inhibitors in cardiogenic shock, they are commonly used as adjunctive therapy.

Surgery

Dunkman and associates¹⁰ were the first to report the use of CABG surgery for cardiogenic shock. Emergency CABG surgery is associated with mortality rates ranging from 25% to 60%. In the SHOCK trial,¹⁷ one third of the patients randomly assigned to revascularization were treated with a surgical approach. Patients were more likely to have left main disease or three-vessel disease than patients treated with PCI. Thirty-day mortality for patients undergoing surgery was equivalent to PCI mortality (42% versus 45%). The high degree of surgical expertise required, the inherent time delays, the increasing hesitancy of surgeons to operate on patients with high operative mortality

risk because of “scorecard” medicine, and the favorable results with PCI make emergency CABG surgery an increasingly rare intervention. It is more often performed electively in survivors with multivessel disease.

Surgical repair of acute mitral regurgitation,²² ventricular septal defect,²³ and free wall rupture²⁴ can be accomplished, although mortality rates are high. The use of emergency cardiac transplantation has been reported.⁹³

New Approaches

New approaches to cardiogenic shock have focused on mechanisms beyond mechanical support and revascularization. A significant proportion of patients in the SHOCK trial exhibited a systemic inflammatory response syndrome marked by fever, leukocytosis, and low systemic vascular resistance.⁹⁴ Complement activation, release of inflammatory cytokines, expression of inducible nitric oxide synthase, and inappropriate vasodilation were deemed culpable, and inhibition of nitric oxide production was explored as a therapeutic strategy. Early single-center clinical studies indicated a dramatic benefit from inhibition of nitric oxide synthase.^{95,96} The phase 2, dose-ranging trial SHOCK-2 showed modest early changes in hemodynamic parameters, but no effect on survival.⁹⁷ The large multicenter TRIUMPH trial was halted after no benefit was seen during an interim analysis.⁹⁸

There is intense clinical and basic science activity exploring delivery of stem cells to the infarcted myocardium to improve left ventricular recovery. Although the early studies remain inconclusive, it is likely that cardiogenic shock patients will be enrolled in the pivotal trials when an effective strategy to salvage or revive the infarcted myocardium is discovered.

The more recent emphasis on reperfusion therapy for all patients with STEMI, the importance of time-to-treatment, and the increasing use of primary PCI as the reperfusion modality have dramatically decreased the number of patients developing cardiogenic shock as a complication of STEMI.⁹⁹ Because cardiogenic shock is usually an in-hospital complication of MI occurring hours after infarct artery occlusion, early restoration of infarct artery patency to prevent development of the shock state is the best approach to this complication.

Prognosis

The historical early mortality rate for cardiogenic shock complicating acute MI treated with medical therapy was 65% to 80%. Current rapid reperfusion strategies and adjunctive therapies have reduced that rate to approximately 50%. Rigorous observation of high-risk patients (e.g., age >75 years, history of prior MI, ejection fraction <35%, large MI, diabetes, female gender); rapid diagnosis (e.g., careful physical examination, hemodynamic monitoring, echocardiography, cardiac catheterization); and prompt correction of arrhythmias, electrolyte and blood gas abnormalities, volume status, and hypotension may prevent the patient from spiraling into the shock state.

In the SHOCK registry,¹⁰⁰ in-hospital mortality rates increased from 34% to 51% as the number of diseased arteries increased from one to three. After PCI, the mortality rate was 86% with absent reperfusion (TIMI 0/1 flow), 50% with incomplete reperfusion (TIMI 2 flow), and 33% with complete reperfusion (TIMI 3 flow). Similarly, final TIMI flow was a major predictor of

outcome in the ALKK registry, with mortality rates of 78%, 66%, and 37% for TIMI 0/1, TIMI 2, and TIMI 3 flow.⁷⁷

In the SHOCK trial, 87% of the 1-year survivors were in New York Heart Association functional class I or II.¹⁰¹ The rate of 13 lives saved per 100 patients treated with early revascularization in the SHOCK trial at 6 months and 1 year was maintained at 3 and 6 years.¹⁹ Overall survival rates at 6 years were 32.8% in the early revascularization group and 19.6% in the initial medical stabilization group (Fig. 17-5). The 6-year survival rates for the hospital survivors were 62.4% versus 44.4%.

At 30 days in the GUSTO-1 trial,¹⁰² 20,360 (88.9%) patients without shock and 953 (50.4%) patients with shock were alive. After a median of 11 years, 69.4% without shock and 55.2% with shock remained alive. Patients receiving PCI were less likely to die (24.1% versus 34.6%). Beginning in the second year, mortality rates were 2% to 4% per year for all patients regardless of shock status (Fig. 17-6).

Figure 17-5. Long-term survival in the SHOCK Trial. ERV, early revascularization; IMS, immediate medical stabilization. (From Hochman JS, Sleeper LA, Webb JG, et al: Early revascularization and long-term survival in cardiogenic shock complicating acute myocardial infarction. *JAMA* 2006;295:2511.)

Figure 17-6. Long-term mortality rate in 30-day survivors in the GUSTO-I trial. (From Singh M, White J, Hasdai D, et al: Long-term outcome and its predictors among patients with ST-segment elevation myocardial infarction complicated by shock. *J Am Coll Cardiol* 2007;50:1752.)

Conclusion

Patients with cardiogenic shock complicating MI have a substantial survival benefit with PCI compared with no or late in-hospital revascularization. These patients need to be directly admitted or transferred to tertiary care shock centers with expertise in acute revascularization and advanced intensive care, unless further care is deemed futile. Novel therapies are needed to decrease mortality rates further in patients who develop cardiogenic shock, which remain high despite reperfusion therapy.

Complications
Prognosis
Conclusion

INFARCTION OF the right ventricle, previously considered rare and clinically unimportant,^{1,2} is now recognized as a common clinical event, occurring in one third of patients with inferior myocardial infarction (MI).³⁻⁵ Right ventricular (RV) infarction confers a worse prognosis in patients with inferior wall MI.⁴ Prompt recognition and appropriate treatment of RV infarction require a thorough understanding of the unique anatomy and pathophysiology of the right ventricle.

Historical Perspective

In 1930, Sanders⁶ reported the first clinical description of RV infarction. During the following 4 decades, RV infarction received attention mainly in autopsy series.⁷ At that time, any shock syndrome was considered the result of left ventricular (LV) infarction.^{1,2} This view was buttressed by evidence from open pericardium dog models in which destruction of the right ventricle was not associated with shock.^{8,9} The development of surgical procedures that bypassed the right ventricle, such as the Glenn and Fontan procedures, furthered the belief that the right ventricle is mainly a volume conduit contributing little to cardiac output.^{10,11}

In 1974, Cohn and coworkers¹² first called attention to RV infarction as a unique clinical and hemodynamic syndrome, characterized in its extreme form by shock, distended neck veins, and clear lung fields. During the ensuing 2 decades of intense investigation into the syndrome, the crucial role of ventricular interdependence through the pericardium and the septum was recognized.¹³⁻¹⁶ Today, a rational approach to therapy of RV infarction based on an understanding of its pathophysiology is possible.

Coronary Circulation and the Right Ventricle

In patients with right dominant coronary circulation (85% of the population), the right ventricle receives its blood supply almost exclusively from the right coronary artery (RCA), with the septum and part of the posterior wall supplied by the posterior descending artery, and the anterior and lateral RV walls

supplied by acute marginal branches of the RCA.^{17,18} The left anterior descending (LAD) artery supplies a small portion of the anterior wall of the right ventricle. In a left dominant circulation, the left circumflex coronary artery supplies the posterior descending artery, and a nondominant RCA supplies the acute marginal branches. Isolated RV infarct without LV involvement can occur with a nondominant RCA.

The angiographic hallmark of RV infarction is thrombotic occlusion of the RCA proximal to the origin of the acute marginal branches. Angiographic flow studies suggest the status of RV branch perfusion is the critical determinant of RV ischemic dysfunction.¹⁹ Proximal RCA occlusions would typically limit RV branch perfusion, in contrast to distal RCA occlusions. Mid and distal RCA occlusions less commonly cause severe RV ischemic dysfunction by flow impairment in at least one major RV branch attributable to the culprit stenosis, prior severe RV branch stenosis, or presence of RV branch thrombus.¹⁹

Not every case of proximal RCA occlusion results in RV infarction.¹⁸ This relative protection of the right ventricle from infarction is thought to be a consequence of its lower oxygen demand, its continued perfusion during systole, and the existence of collaterals from the LAD artery, which, because of the lower systolic pressure on the right side, are more capable of supplying blood in the direction of the right ventricle than in the reverse direction. The LAD collaterals to the right ventricle are mainly through the moderator band artery, a branch of the first septal perforator.²⁰ Prior severe stenosis or occlusions of the LAD artery can limit the development of collaterals to the right ventricle with the occurrence of an acute RCA occlusion increasing the extent of acute ischemic RV dysfunction.²¹

Conflicting data, particularly in autopsy series, exist concerning RV infarction in the setting of LAD obstruction producing anteroseptal infarction.^{18,22-24} With LAD occlusion, the clinician would expect the septal portion of the right ventricle and a small portion of the anterior RV wall to be affected. Andersen and colleagues,²² in an autopsy study of 107 patients, were able to detect evidence of RV infarction in more than half of the patients with anterior infarcts, but the amount of RV tissue affected was small (1% in anterior infarction versus 15% in posterior infarction). Hemodynamically significant RV infarction with LAD occlusion is probably rare.²² In the case

of a left dominant circulation, the circumflex artery supplies the posterior septum and posterior wall of the right ventricle through the posterior descending artery. Although obstruction of the circumflex artery may lead to RV involvement, hemodynamically significant RV infarctions are uncommon because the nondominant RCA continues to supply the lateral RV wall and most of the anterior RV wall through the acute marginal branches.

Ventricular Interdependence

The concept of ventricular interdependence in RV infarction is central to understanding the pathogenesis of the resultant low cardiac output state. Ventricular interdependence is mediated through the common pericardium and shared septum. In RV infarction, acute RV dilation occurs.^{15,16,24} Because the right ventricle shares a relatively fixed space with the left ventricle, the pericardial pressure abruptly increases, leading to impaired LV filling. In animal models with the pericardium removed, it is difficult to induce hypotension with RV infarction.⁸ When the pericardium is left intact,^{16,25} however, RV infarction is associated with the full syndrome, as originally described by Cohn and coworkers.¹² Incision of the pericardium leads to improvement in cardiac output, pressure equalization, and an increase in RV systolic pressure.¹⁶

The increase in right-sided diastolic pressure that occurs in RV infarction leads to a reversal of the normal left-to-right transeptal diastolic gradient.²⁶ On echocardiography, the septum can be seen to flatten and encroach on the LV diastolic dimension. During systole, the septum can be seen to move paradoxically toward the right ventricle, at times in a piston-like manner.¹⁶

Except in rare cases of isolated RV infarction,^{27,28} LV infarction accompanies RV infarction. The pericardial constraint and alterations in septal geometry lead to reduced LV filling, and cardiac output is diminished further by the decrease in LV systolic function. Development of the shock syndrome with isolated RV infarction²⁷ proves, however, that LV systolic dysfunction is not a necessary component. Echocardiographic assessment in cases of hemodynamically severe RV infarction has confirmed that shock may be present with preserved LV systolic function.¹⁶

The hemodynamic hallmarks of RV infarction (Table 18-1) are a decrease in cardiac output, elevation of right atrial pressure (>10 mm Hg), elevation of RV diastolic pressure, and decrease in RV systolic pressure.²⁹⁻³¹ There is diastolic equalization of

RV and LV pressures, as in cardiac tamponade, and the ratio between right atrial and pulmonary capillary wedge pressure increases. This ratio, which normally is less than 0.65, is usually greater than 0.8 in RV infarction.²⁹ The RV tracing reveals a delayed, depressed, and often bifid peak, indicating systolic RV failure.¹⁶ RV diastolic failure is also manifested by a dip and plateau pattern on the RV pressure tracing.

In most studies, hemodynamic tracings showed a blunted x descent with a prominent y descent, suggesting decreased compliance of the right ventricle, as seen in pericardial constriction (Fig. 18-1).^{18,29-33} In contrast, Goldstein and coworkers,¹⁶ when using RV pressure tracings to time hemodynamic events, described a prominent x descent with blunting of the y descent, as seen in tamponade. They also showed that atrial function was of pivotal importance. In some patients, there was an increase in atrial function, as evidenced by augmented a waves. These patients had a better response to therapy and had a better prognosis than patients with depressed atrial function. The latter group was shown to have more proximal RCA occlusion, affecting the atrial branches of the RCA and causing superimposed atrial infarction. Although the hemodynamic criteria for RV infarction are usually present on admission, volume loading may increase the identification of these abnormalities in a few patients.³⁰

Clinical Presentation

Clinically significant RV infarction occurs mainly in patients with concomitant inferoposterior infarction of the left ventricle, and many of the symptoms overlap. Necropsy studies suggest that RV infarction occurs almost exclusively in patients with transmural posteroseptal MI.³⁴ The size of the LV infarct does not correlate with RV infarct size. The size of the RV infarct influences the severity of RV dysfunction and presentation, however.²¹ What is unique to RV infarction is the occurrence of a syndrome of RV diastolic and systolic failure that, in its extreme form, is characterized by a triad of signs: hypotension that can progress to cardiogenic shock, elevated neck veins, and clear lung fields.^{6,12,18,35}

When RV infarction is hemodynamically significant, the physical examination is a sensitive method of detection.

Table 18-1. Hemodynamic Findings in Cases of Right Ventricular Infarction

Elevated right atrial pressure (>10 mm Hg)
Right atrial pressure/pulmonary wedge pressure ratio >0.8
Noncompliant jugular venous pattern (prominent y descent)
Dip and plateau right ventricular diastolic pressure pattern
Depressed and delayed (often bifid) right ventricular systolic pressure
Decreased cardiac output
Hypotension

Figure 18-1. Hemodynamic tracings in RV infarction. Noncompliant pattern of RV infarction, with elevated right atrial pressure, a deep y descent in the atrial tracing, a dip and plateau diastolic pattern in the right ventricle, and relatively low pulmonary artery pressure. (From Lorrell B, Leinbach RC, Pohost GM, et al: Right ventricular infarction: clinical diagnosis and differentiation from cardiac tamponade and pericardial constriction. *Am J Cardiol* 1979;43:465-471.)

Dell'Italia and colleagues³⁵ found elevated jugular venous pressure to be 88% sensitive, with a specificity of 69% for inferior wall MI with RV involvement. Kussmaul sign, an inspiratory increase in the jugular venous pressure, was found to be 100% sensitive and specific in the same series, and Bellamy and coworkers³⁶ found it to have a sensitivity of 59% and a specificity of 89%. Other associated findings include a high frequency of bradycardia and atrioventricular (AV) block and atrial arrhythmias, including supraventricular tachycardias and atrial fibrillation or flutter. A right-sided fourth heart sign was described in 11 of 16 patients in one series, with 4 of 16 having a right-sided third heart sound.³⁷ Tricuspid regurgitation may be audible. Pericardial friction rubs may be heard because infarction in the thin right ventricle is usually transmural.³³

The differential diagnosis includes tension pneumothorax, cardiac tamponade, constrictive pericarditis, and pulmonary embolism. When the full triad is present, and ST segment elevations are observed in inferior leads, the diagnosis is straightforward. A potential pitfall is the occurrence of isolated RV infarction, which may manifest with the full clinical picture, but without electrocardiogram (ECG) evidence of MI on the standard 12-lead ECG.²⁷ Pulmonary embolism occasionally mimics RV infarction and may be a predisposing factor,³⁸ leading to occult RV infarction. Conversely, RV infarction with thrombus formation in the right ventricle can lead to pulmonary embolism. Dyspnea is usually more severe in pulmonary embolism, and RV and pulmonary artery pressures and pulmonary vascular resistance are higher than in RV infarction. Cardiac tamponade may be acute and may manifest with a similar triad of elevated neck veins, hypotension, and clear lungs, but it can be distinguished easily at the bedside with echocardiography. Pulsus paradoxus, a hallmark of tamponade, is unusual in RV infarction, which tends to resemble pericardial constriction.³³

Diagnosis

Electrocardiographic Diagnosis

ST Segment

The ECG remains the most useful tool for the diagnosis of RV infarction.³⁹ The hallmark of acute RV ischemia is ST segment elevation in the right precordial leads, a finding first reported in 1976 by Ehrhard and coworkers,⁴⁰ who used lead CR₄₁ located in the fifth intercostal space at the right mid-clavicular line. The importance of obtaining right-sided chest leads on presentation in patients with suspected MI, particularly with evidence of inferior wall involvement, cannot be overemphasized (Fig. 18-2).

Several studies have documented that ST segment elevation of 0.05 mV or greater (0.5 mm when using standard settings of 10 mm/mV) in lead V_{4R} in the setting of inferior MI is sensitive and specific for RV involvement, as documented by postmortem examination⁴¹ or by radionuclide,^{39,42,43} echocardiographic,⁴² hemodynamic,³⁹ or angiographic studies.^{33,43} Braat and colleagues⁴² found that ST segment elevation of 1 mm or greater in lead V_{4R} had a sensitivity of 93% and a specificity of 95% in a series of 67 patients with inferior MI. ST segment elevation in lead V_{3R} was also specific (97%), but less sensitive (69%). In a series of 110 patients with acute inferior MI, Klein and coworkers,⁴⁴ using the 0.5-mV criteria, reported a sensitivity of 83% and a specificity of 77%, with a positive predictive value of 70% and a negative predictive value of 88%. Infrequently, ST segment

elevation in V_{5R} or V_{6R} occurs in the absence of elevation in V_{4R}.^{39,42} Zehender and colleagues^{43,49} confirmed the utility of 0.1-mV ST segment elevation in any of the right precordial leads (V_{4R}-V_{6R}) in a series of 200 patients, showing a sensitivity of 89% and a specificity of 83%.

The ECG findings in RV infarction of right precordial ST segment elevations are the result of a rightward and anteriorly directed vector. Using Grant's method of spatial vector analysis, Hurst⁴⁵ emphasized that the clinician can diagnose RV infarction from the standard 12-lead ECG because the ST segment vector is shifted rightward (>90 degrees) toward the site of infarct. A larger RV infarct would be expected to result in greater rightward ST segment vector deviation (>150 degrees). Andersen and coworkers⁴⁶ showed that ST segment elevation in lead III exceeding that in lead II (i.e., ST segment vector directed rightward) is sensitive (68%) in diagnosing RV infarction. This criterion had a specificity of only 11% and a positive predictive value of 58% in Zehender's series of 200 patients with inferior MI. Andersen's criteria were confirmed as being highly sensitive, however (95% in Zehender's series).

Certain special situations with variant ECG findings that may cause confusion warrant mention. Geft and colleagues⁴⁷ described five patients with ST segment elevations in leads V₁-V₅ who on catheterization were shown to have RCA occlusion and acute RV infarction. All five patients had minimal or absent ST segment elevations in the inferior leads. The authors speculate that in the usual cases of RV infarction, ST segment elevations in leads V₁-V₅ are blocked by the dominant electrical forces of inferoposterior MI, resulting in isoelectric or even depressed ST segments in the left precordium. When these forces are absent, because of isolated RV infarction⁴⁸ or because of minimal posterior involvement, as may be seen in a patient with a codominant circulation,⁴⁷ ST segment elevation in the left precordial leads mimicking anterior wall infarction may be seen. A distinguishing characteristic in RV infarction may be that the ST segment elevations are highest in leads V₁ or V₂ and decrease toward lead V₅, a pattern opposite that seen in anterior MI.⁴⁷

If septal involvement can mimic RV infarction, a left lateral wall infarction or a large true posterior infarction can be expected to cancel right precordial ST segment elevations. Such cases of false-negative findings have been described.^{44,49}

Figure 18-2. ST segment elevations in right precordial leads. A case of RV infarction in a 35-year-old heavy smoker who presented with 1 hour of substernal chest pain. The 12-lead ECG showed an acute inferoposterior infarction. Right-sided leads V_{4R}-V_{6R} show ST elevation, indicating RV involvement.

Most studies of right precordial lead ST segment elevation have been limited to patients with evidence of inferior wall MI. In anterior MI, ST segment elevation in right precordial leads has also been documented and has been found to be predictive of proximal LAD occlusion before the first septal branch, suggesting that the right precordial lead ST segment elevations are the result of septal current of injury.⁵⁰ A distinguishing characteristic in cases of LAD occlusion is that the ST segment elevation has a leftward axis, in contrast to the rightward ST segment in RV infarction, as emphasized by Hurst.⁴⁵ Other causes of right precordial ST segment elevation in the absence of RV infarction include pericardial disease, left anterior hemiblock, and pulmonary embolism.⁵¹

The time course of ST segment elevation in RV infarction warrants emphasis. Braat and colleagues⁴² reported that ST segment elevations in lead V_{4R} resolve within 10 hours after the onset of chest pain in half of patients. Similar findings were reported by Klein.⁴⁴ It is important to obtain a right-sided ECG soon after the patient's presentation.

Q Waves in Right Ventricular Infarction

Because patients may present after the ST segments have returned to baseline, criteria using Q waves in the right precordial leads have been sought. In normal subjects, an rS pattern is always present in V_{3R} and usually (>90%) in V_{4R}. In one series⁵² of patients with autopsy-documented RV infarction, the presence of a Q wave in these leads (as a QS or a QR pattern) was 100% specific and 78% sensitive. The high specificity (>90%) of Q waves was confirmed in Zehender's³⁹ series of 200 patients with inferior wall MI. Early in the course of infarction, Q waves are still absent, and the sensitivity is low, particularly for patients presenting early. In patients admitted late (>12 hours after the onset of symptoms), the sensitivity increases to 95%.

Bundle Branch Block

RV infarction, especially when extensive, has been shown to be associated with an incomplete and often transient right bundle branch block. The block is postulated to occur distally. Because there may also be precordial ST segment elevation in RV infarction, the right bundle branch block may be difficult to detect in lead V₁. Kataoka and coworkers⁵³ pointed to a cove-shaped ST-T elevation in lead V₁ as suggestive of an underlying right bundle branch block.

Atrioventricular Block

Significant AV block is more common in inferior wall MI with RV involvement.⁵⁴ The presence of ST segment elevation in V_{4R} was shown to predict the development of high-grade AV block, with 48% of patients in one series developing AV block during the first 3 days of infarction compared with only 13% without evidence of RV infarction.⁵⁵

After AV block develops in the setting of RV infarction, it has specific implications for therapy. Because cardiac output depends on preload and right atrial function, RV pacing alone may be inadequate. Sequential AV pacing may have a marked salutary effect on cardiac output,^{51,56} and should be considered in patients with RV infarction and AV dissociation. Effective RV transvenous pacing may be more difficult to achieve in RV infarction because of muscle necrosis or scarring. A higher pacing threshold should be anticipated and accepted.^{57,58} Caution should be employed when placing a pacing wire in an area

of infarction because the risk of rupture may be increased. If transvenous pacing fails, transcutaneous external pacing may be successful.⁵⁹

Arrhythmia

Atrial arrhythmias are common in RV infarctions. Because of the propensity for low cardiac output and preload dependence, these arrhythmias are poorly tolerated and should be treated aggressively. Early cardioversion and antiarrhythmic therapy for atrial fibrillation are recommended.⁵¹ One study of patients with RV infarction did not reveal an increase in ventricular arrhythmias compared with patients with inferior infarctions without RV involvement.⁶⁰

Prognostic Implications

ECG findings for RV infarction have marked prognostic implications, even in the absence of hemodynamic abnormalities. In the series of 200 patients by Zehender and associates,⁶¹ ST segment elevation in lead V_{4R} was shown on multiple logistic regression analyses to be the strongest predictor of in-hospital morbidity and mortality. Patients with ST segment elevation in V_{4R} had a mortality rate of 31% compared with 6% for patients without such evidence of RV involvement. Similarly, major complications (e.g., ventricular fibrillation, sustained ventricular tachycardia, cardiogenic shock, cardiac rupture, high-grade AV block, reinfarction) were markedly more common (64% versus 28%; $P < .001$) in patients with ECG evidence of RV involvement. In one series, the presence of AV block in RV infarction was found to be associated with a mortality rate of 41%, whereas the mortality rate for patients with inferior wall infarction with RV infarction but without AV block, and for patients with inferior MI with AV block but without RV infarction was only 11% to 14%.⁵⁸

Echocardiography

Two-dimensional echocardiography is sensitive (80% to 90%) and specific (>90%) in the detection of hemodynamically significant RV infarction.⁶²⁻⁶⁵ The diagnosis rests on the demonstration of RV wall motion abnormality RV dilation, abnormal (paradoxical) septal motion, as and flattening of the septum⁶⁵ and reduced septal thickening.

Echocardiography is particularly useful in assessment of RV infarction because it also provides information on LV function, associated valvular regurgitation, and possible differential diagnoses such as cardiac tamponade. Echocardiography may also detect important complications, such as thrombus formation or pericardial effusion. Two-dimensional contrast echocardiography may help detect right-to-left shunting through a patent foramen ovale.⁶⁶ Because of its noninvasive nature, portability, and the added hemodynamic and morphologic data that it provides, echocardiography is the imaging modality of choice in the Cardiac Intensive Care Unit.

Cardiovascular Magnetic Resonance Imaging

Late enhancement cardiovascular magnetic resonance imaging (MRI) has greater sensitivity at detecting RV infarction than ECG, physical examination, or echocardiography. Late enhancement cardiovascular MRI findings of injury of the right ventricle in the acute phase persist 13 months, suggesting that this imaging modality can predict the extent of irreversible RV injury in the acute phase.⁶⁷

Figure 18-3. Algorithm for evaluation and treatment of RV infarction. PTCA, percutaneous transluminal coronary angioplasty; SBP, systolic blood pressure.

Treatment

Figure 18-3 presents an algorithm for the evaluation and treatment of patients with RV infarction. The goals of therapy are to restore arterial pressure, maintain AV synchrony, and achieve rapid coronary reperfusion.

Reperfusion Therapy

Given the adverse prognostic effect of RV infarction in inferior MI, establishing reperfusion by primary percutaneous coronary intervention (PCI) or thrombolytic therapy is particularly important in this subgroup of patients. Meta-analyses have shown that, overall, PCI results in superior outcomes compared with thrombolysis when performed rapidly by an experienced team.⁶⁸ PCI should be the reperfusion modality of choice where available. If PCI is unavailable, thrombolysis is appropriate therapy that has been shown to reduce mortality. In a nonrandomized trial of therapy in inferior wall MI by Zehender and associates,⁴ the mortality benefit of thrombolytic therapy was limited to the patients with RV involvement, with a reduction in the mortality rate from 42% to 10%. Patients without RV infarction had a similar mortality rate (6% to 7%) with and without thrombolytic therapy. Similarly, in the TIMI II trial, thrombolytic therapy reduced the incidence of RV infarction from 42% to 13% for patients with inferior MI.⁶⁹ Radionuclide studies have confirmed a marked reduction in extent of RV infarction in patients who achieved early reperfusion.^{70,71} Thrombolytic therapy is relatively ineffective, however, in the presence of cardiogenic shock. In the presence of shock not responsive to volume replacement and inotropic therapy, primary PCI is the preferable approach even if the patient requires transfer to another facility.

Volume Infusion

Based on hemodynamic data from dog models,¹⁶ early studies emphasized the importance of volume infusion in RV infarction. The right ventricle is preload-dependent, and in the setting of ischemia with decreased diastolic compliance, the right ventricle may benefit from an augmentation in preload. If hypovolemia is present, there may be a marked improvement with fluid administration. When marked RV dilation has already occurred, however, further increases in RV preload do not result in an increase in RV stroke volume and may impair LV filling further through increased septal shift and increased pericardial constraint.¹⁴ Cardiac output and arterial blood pressure may not increase. In various studies,⁷²⁻⁷⁴ an increase in mean right atrial pressure to 10 to 14 mm Hg was followed by an improvement in stroke volume, but further augmentation was associated with no improvement or a decrease in stroke volume.⁶²⁻⁶⁵ Volume infusion should be used cautiously and only to bring the right atrial pressure to 10 to 14 mm Hg. Invasive hemodynamic monitoring is usually necessary to guide therapy.

Inotropic Support

Dobutamine and dopamine have been evaluated in the setting of severe RV infarction (with right atrial pressure >13 mm Hg) and have consistently been found to increase RV stroke work and cardiac output, where volume loading and nitroprusside were generally ineffective.⁷³ Dobutamine, which also has arteriolar vasodilating effects, usually does not increase mean arterial pressure significantly. Dopamine, by activating dopaminergic and α -adrenergic receptors, increases mean arterial pressure and should be used preferentially when patients are severely hypotensive.¹⁴ After the systolic blood pressure increases

greater than 90 mm Hg, dobutamine may be used, alone or in combination with dopamine. Tricuspid regurgitation has been found to render dobutamine ineffective because the increase in RV contractility was offset by an increase in the regurgitant fraction.⁷⁴

The use of milrinone,⁷⁵ a phosphodiesterase inhibitor, has been shown to be beneficial in chronic right heart failure, increasing myocardial contractility. Milrinone has the advantage of reducing pulmonary vascular resistance and unloading the right ventricle. Its use in RV infarction has not been systematically evaluated, however.

Right Ventricular Assist Devices

More recent reports of the use of percutaneous RV assist devices in patients with shock complicating RV infarction are encouraging. These reports have largely involved the use of the Tandem Heart (Cardiac Assist, Pittsburgh, PA) device. Two 21F cannulae are placed via both femoral veins, one in the right atrium, and the other in the pulmonary artery with assist pumping using an extracorporeal centrifugal pump. The temporary use of such invasive RV assistance is justified by the frequent observation of RV functional recovery over time. This unloading of the right ventricle allows reduction in RV dilation, reducing pericardial pressure and improving LV filling in the setting of shock owing to RV infarction.^{76,77}

Pulmonary Vasodilator Therapy

The use of selective pulmonary vasodilators might be expected to provide afterload reduction for the failing right ventricle without concurrent systemic vasodilation and hypotension, potentially resulting in improved cardiac output. Inhaled nitric oxide acts as a selective pulmonary vasodilator, producing smooth muscle cell relaxation and vasodilation in the pulmonary circulation without systemic vasodilation owing to its active binding to hemoglobin and inactivation in circulating erythrocytes.⁷⁸ Inhaled nitric oxide has been studied and verified to decrease pulmonary vascular tone in adults and children with pulmonary hypertension of varying etiologies.^{79,80}

Ingleiss and colleagues⁸¹ administered short-term inhaled nitric oxide for 10 minutes to 13 patients with RV infarction and cardiogenic shock, and showed temporary beneficial hemodynamic effects reflected by significantly reduced right atrial and mean pulmonary pressures, reduced pulmonary vascular resistance, and increased cardiac indices and stroke volumes. No changes in systemic pressure and pulmonary capillary wedge pressure were noted. Reduced right-to-left shunting by contrast echocardiography was noted in three patients with patent foramen ovale, with subsequent improvement in arterial oxygen-hemoglobin saturations.⁸¹ Further study is necessary to determine if these effects of inhaled nitric oxide used in patients with RV infarction and cardiogenic shock translate into improved survival or early recovery. Uses of other pulmonary vasodilators such as sildenafil or prostacyclin in RV infarction warrant evaluation.

Preload and Afterload Reduction

The right ventricle is sensitive to preload, particularly in the setting of RV infarction. Hypotension provoked by nitroglycerin, morphine sulfate, or diuretics should alert the clinician to the possibility of a preload-sensitive state such as RV infarction. The routine use of these agents should be discouraged in patients

with acute inferior MI until RV involvement is ruled out. Sodium nitroprusside may result in marked afterload reduction, which if ineffective in increasing right-sided output, results in systemic hypotension.⁷³ In some clinical situations, such as combined right and left heart failure with severe LV dysfunction or when fluid administration has been overzealous, the cautious use of vasodilators may be attempted.¹⁴ Invasive hemodynamic monitoring should be used, and the right atrial pressure should be maintained greater than 10 mm Hg.

Hemodynamic Monitoring

In a patient with hemodynamic instability in the setting of RV infarction, the use of a pulmonary artery catheter often helps guide therapy. Extra caution should be employed in the placement of the catheter because a higher incidence of ventricular arrhythmias, including ventricular fibrillation, has been described in the setting of RV infarction (4% versus 0.3% in patients without RV infarction).⁸² Flotation of the catheter under fluoroscopic guidance by a cardiologist or other intensivist may help minimize the risk.

Pacing and Treatment of Arrhythmias

Significant AV block and atrial arrhythmias, particularly atrial fibrillation, are detrimental in the setting of RV infarction because of the importance of AV synchrony and intact atrial contraction to the maintenance of RV and LV stroke volumes.^{14,55,83} High-grade AV block, significant bradycardia, and atrial arrhythmias should be treated aggressively.

Complications

Patients with inferior wall MI and accompanying RV infarction have a much higher rate of complications than patients with inferior wall MI without RV involvement, accounting for part of the adverse prognostic implications of RV infarction (Table 18-2). Some complications may occur in any inferior wall MI, but are more common in the setting of RV infarction; these include AV block, atrial arrhythmias, and pericarditis. The coronary care physician should also be aware of several, less common complications.^{66,84-87}

Patent foramen ovale is present in 25% of the population. In the setting of RV infarction and elevated right-sided pressures, right-to-left shunting may occur, with resulting hypoxemia. Maneuvers that reduce LV pressures, such as afterload reduction, exacerbate this shunting. Percutaneous closure of the patent foramen may be necessary in extreme cases.⁶

Table 18-2. Complications of Right Ventricular Infarction

Atrioventricular block
Atrial tachyarrhythmias
Tricuspid regurgitation
Right-to-left shunting
Right ventricular thrombus
Pulmonary embolism
Paradoxical embolism
Septal rupture
Free wall rupture

As in LV infarction, RV infarction may predispose to thrombus formation in the infarcted ventricle, with possible pulmonary embolism. In the presence of a patent foramen ovale, paradoxical embolization may lead to systemic emboli. Thrombus has been identified in the right ventricle of patients with RV infarction (3 of 33 [9%]) and in patients without RV infarction with posterior wall MI (4 of 106 [4%]).⁸⁸

Severe tricuspid regurgitation secondary to papillary muscle necrosis or severe RV dilation has been described in the setting of RV infarction. In extreme cases, refractory heart failure has necessitated valve replacement.⁸⁹ Other complications include septal rupture,⁸⁷ RV free wall rupture,⁸⁹ and pericarditis, which is common in RV infarction because of the thinness of the RV wall.

Prognosis

RV infarction is associated with markedly increased complication and mortality rates.³⁸ The reduction in mortality by reperfusion therapy is dramatic. Aggressive reperfusion therapy is indicated to maximize survival in the absence of severe mitigating circumstances.

After RV infarct, RV function generally improves.⁹⁰ Long-term prognosis is determined, however, by residual LV rather than RV function, with similar posthospital courses for patients with and without RV infarction.³⁸ A strong correlation exists between the outcome of RV infarction and age.^{34,91} In acute inferior MI, RV infarction substantially increases the risk of death and major complications in elderly patients.³⁴

Conclusion

RV infarction occurs mainly in the setting of inferior wall MI with proximal RCA occlusion. RV involvement in inferior MI has a marked adverse effect on complication rate and prognosis. Patients with RV infarction benefit, however, from reperfusion therapy. Complications such as hypotension, AV block, and atrial tachyarrhythmias should be treated aggressively. Although the short-term prognosis in RV infarction is poor, if the patient survives the acute illness, the long-term prognosis is good.

Mechanical Complications of Acute Myocardial Infarction

Kanu Chatterjee, Stuart J. Hutchison, Tony M. Chou,
Edward McNulty

CHAPTER

19

Free Wall Rupture
Mitral Regurgitation
Ventricular Septal Rupture

Dynamic Left Ventricular Outflow Tract Obstruction
Complicating Acute Myocardial Infarction

MECHANICAL COMPLICATIONS of acute coronary syndromes are associated with very poor prognosis unless prompt diagnosis and aggressive interventions are instituted. In many of these patients, the size of the myocardial infarction (MI) may not be large.^{1,2} Mechanical complications are frequently associated with cardiogenic shock, and approximately 12% of patients with cardiogenic shock have these complications. Early detection and intervention have the potential to improve the otherwise grim prognosis. The mechanical complications of acute MI are outlined in this chapter and summarized in [Table 19-1](#).

Free Wall Rupture

Acute rupture of a free wall is a sudden, usually catastrophic complication of acute MI. It is the second most common cause of post-MI death after cardiogenic shock without mechanical defects.³ More recent studies have reported that free wall rupture accounts for 3% to 20% of all deaths resulting from acute MI.⁴ The overall incidence of free wall rupture is about 2% to 7%, and it accounts for in-hospital mortality of about 15% of all deaths owing to acute MI.⁵ Risk factors for free wall rupture

include female gender, advanced age, single vessel disease, hypertension, transmural MI, and late administration of thrombolytic therapy.⁴⁻⁸ The incidence of rupture for patients with successful reperfusion (0.9%) is less than that without reperfusion treatments (2.7%). The incidence seems to be similar whether reperfusion is achieved by thrombolytic therapy or by angioplasty.

Pathophysiology

The most frequent site of post-MI cardiac rupture is the left ventricular free wall (80% to 90%).^{2,9} Less commonly, the left ventricular posterior wall, right ventricle, or atria may rupture.^{10,11} Rupture may rarely occur at more than one site,¹² and it may be associated with papillary muscle¹² or septal rupture.¹³

Expansion of the infarct area seems to predispose to rupture.¹⁴ When ruptures occur within 24 hours of onset of infarction, however, infarct expansion or infiltration by neutrophils does not seem to contribute to the pathogenesis.¹⁵ The path of the rupture through the wall may be direct (through the center of the necrotic area), but is often serpiginous and often seen at an eccentric position, near the “hinge point” of mobility between the normally contracting and dyskinetic myocardium. These observations suggest that local shear forces contribute to the disruption of tissue.¹⁶ It has been suggested that apoptosis of cardiomyocytes in the region of maximum wall strain contributes to rupture of the ventricular free wall.¹⁷

Infarct expansion and adverse ventricular remodeling has been suggested to contribute to subacute ventricular rupture.¹⁸ Inappropriate changes in the extracellular matrix, in particular, collagen disruption and its inhibition by dysregulation of matrix metalloproteinase metabolism, have been suggested to be important mechanisms in the pathogenesis of ventricular rupture after MI.¹⁹ In experimental animal models, deficiency of local angiotensin type II receptor has been shown to cause decreased collagen deposition and increased incidence of cardiac rupture after MI.²⁰ Angiotensin II induces transforming growth factor- β 1, which promotes fibrogenesis.²¹

Clinical Features

Free wall rupture occurs within 24 hours in 25% to 35% and within the first week in 87% of patients after the onset of acute coronary syndrome.^{22,23} Frequently, rupture occurs in patients

Table 19-1. Mechanical Complications of Acute Myocardial Infarction

with uncomplicated MI. There are no specific symptoms or signs of acute or subacute free wall rupture. Patients may present with syncope or signs and symptoms of cardiogenic shock.^{6,10} Sudden onset of severe chest pain during or after some types of physical stress, such as coughing or straining at stool, may suggest the onset of free wall rupture. Some patients have premonitory symptoms, such as unexplained chest pains that are not typical of ischemia or pericarditis-related chest pains,²³ repeated emesis, restlessness, and agitation.²⁴

Rapid onset of tamponade owing to hemopericardium, resulting in severe hypotension and electromechanical dissociation, characterizes acute rupture, and antemortem diagnosis is almost impossible in these patients. In patients with subacute rupture, relatively slower development of tamponade may allow antemortem diagnosis and corrective surgical therapy with salvage of these patients. Elevated jugular venous pressure, pulsus paradoxus, muffled heart sounds, and a pericardial friction rub may indicate subacute rupture. A new systolic, diastolic, or “to-and-fro” murmur may be present in these patients with or without pseudoaneurysm.²⁵

Diagnosis

In acute free wall rupture, the electrocardiogram (ECG) reveals electromechanical dissociation and terminal bradycardia.^{8,26} In subacute rupture, several ECG findings have been described, including presence of Q waves, recurrent ST segment elevation or depression, pseudonormalization of inverted T waves particularly in the precordial leads, persistent ST segment elevation, and new Q waves in two or more leads.^{5,22,24,26,27} None of the ECG findings is specific or sensitive enough, however, to be of value for early diagnosis of impending rupture.

Transthoracic echocardiography should be performed as soon as the subacute rupture is suspected.^{5-7,26} Color flow Doppler may be useful for the diagnosis of the rupture site.²⁸ The most frequent finding is pericardial effusion. The presence of echogenic masses in the fluid and detection of wall defects enhance diagnostic accuracy. Although transesophageal echocardiography may provide a better delineation of these findings, it should not be performed because of the stress of the procedure until absolutely necessary. Contrast echocardiography may show extravasation of the contrast material into the pericardial space, confirming the diagnosis of free wall rupture.^{28,29}

Determination of hemodynamics and contrast ventriculography are unnecessary for diagnosis and should be avoided. If a balloon flotation catheter is already in place, determination of right heart hemodynamics reveals elevated right atrial and pulmonary capillary wedge pressures and equalization of the diastolic pressures.^{5,26}

Management

Surgical repair is the definitive treatment, and for subacute rupture, salvage rates may be considerable. The operative mortality has been reported to be 24% to 35%, and the total in-hospital mortality is 50% to 60%.^{5,7,26} Currently, conservative surgical techniques using simple sutures supported with felt or application of a patch to the epicardial surface with biologic glue are employed.^{24,30} Temporizing measures include pericardiocentesis, volume loading, inotropic support, and intra-aortic balloon support. In very high-risk elderly patients, nonsurgical conservative treatment with adequate control of blood pressure with angiotensin inhibition and the use of β -blocking agents has been suggested.³¹ The treatment

approach of pseudoaneurysm is similar to that of subacute rupture without pseudoaneurysm.

Mitral Regurgitation

Although mild mitral regurgitation is common in patients with acute coronary syndromes, severe mitral regurgitation owing to papillary muscle and left ventricular wall dysfunction with or without rupture of the papillary muscle is much less frequent. The overall incidence of acute mitral regurgitation in patients receiving thrombolytic therapy was 1.73% in the GUSTO-I trial.³² It has been reported that the incidence is significantly lower (0.31%) in patients undergoing primary angioplasty.³³ The reported incidence of mild to moderate mitral regurgitation is variable and is approximately 29% (mild) and 6% (moderate). The incidence of severe mitral regurgitation complicating MI is approximately 10%,³⁴ and the incidence of mitral regurgitation resulting from papillary muscle rupture is 1%.¹

The risk factors for mitral regurgitation with and without papillary muscle rupture seem to be different, although advanced age and female gender are risk factors for both types.³⁵ In patients without papillary muscle rupture, prior MI, relatively large infarct size, multivessel coronary artery disease, recurrent myocardial ischemia, and heart failure on admission are more prevalent. In contrast, in patients with papillary muscle rupture, absence of previous angina, inferoposterior MI, absence of diabetes, and single vessel disease are more common.

Pathophysiology

Several anatomic and functional derangements may cause mitral regurgitation in patients with acute coronary syndromes. Acute transient papillary muscle ischemia is associated with impaired shortening of the muscle, which usually causes only mild mitral regurgitation. Ischemic dysfunction of anterior and posterior papillary muscles may be associated with more severe mitral regurgitation.³⁶ Ischemia of only papillary muscles without involvement of the adjacent left ventricular walls seldom results in severe mitral regurgitation.³⁷ The subendocardial position of the papillary muscles and their characteristic vascular anatomy (supplied by coronary end arteries) predispose them to ischemia.³⁸ The posteromedial papillary muscle receives its blood supply only via the posterior descending coronary artery, whereas the anterolateral papillary muscle receives its blood supply from the left anterior descending and left circumflex coronary arteries.³⁹ Ischemia of posteromedial papillary muscle is more common than ischemia of anterolateral papillary muscle.

A large posterior MI, including the anchoring area of the posteromedial papillary muscle, may be associated with severe mitral regurgitation. The mechanism seems to be asymmetric annular dilation and misalignment of the papillary muscle and the leaflets during systole causing severe leaflet prolapse.⁴⁰ A small inferior or inferoposterior MI with involvement of the posteromedial papillary muscle can also produce severe mitral regurgitation, however, because of severe leaflet prolapse.

Rupture of the posteromedial papillary muscle is 6 to 12 times more frequent than rupture of the anterolateral papillary muscle, explaining the higher incidence of severe mitral regurgitation in patients with inferior MI.³⁴ In approximately 50% of patients with papillary muscle rupture, the infarct size is small.⁴¹

Mild to moderate mitral regurgitation usually does not induce any additional hemodynamic burden. Neither ejection fraction

nor hemodynamics, such as pulmonary capillary wedge and pulmonary artery pressures and cardiac output, is substantially influenced. In contrast, severe mitral regurgitation imposes sudden additional hemodynamic burden on the left ventricular dynamics and function. Sudden large volume overload, resulting from regurgitation to a left atrium with normal compliance and size, causes a marked increase in left atrial and pulmonary capillary wedge pressure, causing severe pulmonary edema. Because of postcapillary pulmonary hypertension, which increases right ventricular afterload, the right ventricle also fails. Left ventricular forward stroke volume decreases, resulting in a reduction in cardiac output and systemic hypotension. All the hemodynamic features of cardiogenic shock develop rapidly and usually abruptly. Left ventricular ejection fraction may increase because of sudden unloading of the ventricle by the mitral regurgitation. The ejection fraction is still less than normal, however, because of the presence of dysfunctional ischemic or infarcted myocardium.

Clinical Features

Mitral regurgitation not resulting from papillary muscle rupture is detected at a median of 7 days (range 5 to 45 days) after MI. Severe mitral regurgitation secondary to papillary muscle rupture occurs at a median of 1 day (range 1 to 14 days) after the onset of the index infarction; approximately 20% of ruptures occur within 24 hours of onset of infarction.^{1,25,42}

In patients with mild mitral regurgitation secondary to papillary muscle dysfunction, the only clinical indication may be the presence of a pansystolic (holosystolic) or more often a late systolic murmur. In patients with rupture of a papillary muscle, the clinical presentation is characterized by an abrupt onset of severe respiratory distress resulting from flash pulmonary edema. Hypotension and reflex tachycardia rapidly develop. Other clinical features of preshock or shock are also present. A sudden appearance of a pansystolic or an early systolic murmur, radiating to the left axilla or to the base or both, is also a characteristic physical finding. A palpable thrill is uncommon. In some patients, the murmur may be abbreviated or absent. The abbreviation of the murmur results from a rapid decrease in the pressure gradient between the left atrium and the left ventricle.²⁵ "Bubbling" rales of pulmonary edema are present bilaterally and make auscultation difficult.

Diagnosis

The ECG most frequently reveals recent inferior or inferoposterior MI (55%); however, location of the index infarction is anterior (34%) and posterior (32%) in patients with severe mitral regurgitation and cardiogenic shock.³⁴ In occasional patients, only ST-T abnormalities of "shell infarct" are present. Radiographic evidence of acute severe pulmonary edema is invariably present.

Doppler and transthoracic echocardiography should be performed in all patients. Transthoracic echocardiography is less sensitive than transesophageal echocardiography for visualization of the disrupted mitral valve (45% to 50% versus 100%),⁴³⁻⁴⁵ but it is 100% sensitive for the detection by color Doppler echocardiography of the resultant severe mitral regurgitation (Fig. 19-1A).^{43,46}

Echocardiography shows the underlying regional left ventricular wall motion at the site of ischemia/infarction and excludes ventricular septal or free wall rupture.^{43,47} A partial papillary muscle rupture may be detectable by two-dimensional

Figure 19-1. **A**, Systolic frame Doppler image of a patient with rupture of the posteromedial papillary muscle. There is a large eccentric jet of severe mitral insufficiency, directed anteriorly, seen as a conspicuous color mosaic. **B**, Two-dimensional transesophageal echocardiogram (vertical plane image of left ventricle) of a complete rupture of the posteromedial papillary muscle. A mobile mass (ruptured papillary muscle head) attached to the posterior mitral leaflet is seen in the left atrium in this systolic frame. Also seen is segmental dilation of the area of the basal and mid-inferior wall infarction.

echocardiography. A complete rupture is diagnosed when the head of the papillary muscle is seen as a freely moving mobile mass attached to the mitral valve chordae (Fig. 19-1B).^{44,46,48-50}

Right heart catheterization with the use of balloon flotation catheters is unnecessary for the diagnosis of severe mitral regurgitation. If it is undertaken, however, it reveals giant v waves in the pulmonary capillary wedge pressure tracing (Fig. 19-2). Giant v waves may also be present in patients with ventricular septal rupture. In ventricular septal rupture, increased pulmonary venous return owing to the large left-to-right shunt to a left atrium with normal size and compliance is associated with an accentuated v wave. The presence of a reflected v wave in a pulmonary artery pressure tracing is diagnostic of acute or subacute severe mitral regurgitation.⁵¹ For the diagnosis of left-to-right shunt, step-up in oxygen saturation in the pulmonary artery is detected. In some patients with severe acute mitral

Figure 19-2. Acute mitral regurgitation. *Left tracings*, Large v waves in the pulmonary capillary wedge (PCW) tracing. *Right tracings*, Reduction in magnitude of the v wave during sodium nitroprusside infusion.

regurgitation, reflux of the oxygenated pulmonary venous blood occurs in the distal pulmonary artery branches. For the diagnosis of ventricular septal rupture, oxygen saturation should be determined in the proximal pulmonary arteries.

Management

Patients with mild mitral regurgitation do not require surgical intervention. After adequate reperfusion therapy, appropriate adjunctive treatments, such as angiotensin-inhibiting agents, β -adrenergic antagonists, aldosterone antagonists, antiplatelet agents, and lipid-lowering agents, should be employed to decrease the risk of development of heart failure, for reverse ventricular remodeling, and to improve prognosis. Even in patients with mild mitral regurgitation diagnosed during the acute phase of MI, the long-term prognosis is unfavorable, although immediate prognosis is not affected.^{52,53} Aggressive post-MI adjunctive therapies are essential.

Severe mitral regurgitation complicating acute MI with cardiogenic shock requires surgical intervention for mitral valve replacement or repair. In the SHOCK registry, in-hospital mortality without valve surgery was 71% versus 40% with surgery, indicating a significant improvement in immediate prognosis.³⁴

Supportive and stabilizing treatments consist of mechanical ventilation, diuretics, vasodilators, inotropic agents, and, if possible, intra-aortic balloon pump. Vasodilator drugs such as sodium nitroprusside reduce regurgitant volume, decrease pulmonary capillary wedge and pulmonary artery pressures, and increase forward stroke volume and cardiac output.⁵⁴ Hypotension precludes the initial use of vasodilators, but they can be used after institution of intra-aortic balloon pump. Intra-aortic balloon pump reduces left ventricular ejection impedance and maintains perfusion pressure concurrently. The therapeutic approach for mitral regurgitation complicating MI is outlined in Table 19-2.

Ventricular Septal Rupture

The incidence of ventricular septal rupture complicating acute MI is approximately 0.2% in the era of reperfusion.⁵⁵ Before the introduction of reperfusion therapy for MI, the reported incidence was 0.5% to 2%.^{38,56} The clinical risk factors seem to be older age, female gender, lower incidence of diabetes, and history

Table 19-2. Suggested Management of Mitral Regurgitation Complicating Acute Myocardial Infarction

Stabilizing and supportive treatments

Mechanical ventilation, diuretics, intra-aortic balloon pump, vasodilators, vasopressors, inotropic agents

Adjunctive treatments in survivors

Angiotensin-inhibiting agents, β -adrenergic antagonists, aldosterone antagonists, lipid-lowering agents, antiplatelet agents

of smoking.⁵⁷ Although it was previously thought that the incidence of septal rupture increased with thrombolytic therapy, placebo-controlled thrombolytic trials failed to confirm the increased risk of rupture with thrombolytic therapy.^{58,59} Early occurrence of ventricular septal rupture has been observed, however, after thrombolytic therapy.⁶⁰ Whether a history of hypertension increases the risk of ventricular septal rupture remains controversial.⁶¹

Pathophysiology

Most commonly, ventricular septal rupture occurs after a first infarction.^{13,61} In the SHOCK registry trial, the incidence of first infarction was only 17%.⁵⁷ The rupture usually occurs in thin akinetic areas, and it may be direct or “complex.” The complex rupture forms a dissection plane in a serpiginous path in the septum.⁶² Complex ruptures may be associated with concurrent ruptures of other structures, such as ventricular free wall or papillary muscle.¹³ Lack of septal collateral flow, regional distortion, and infarct expansion seem to be important factors for

the development of a ventricular septal rupture.^{14,61} Ventricular septal rupture seems to occur with almost equal frequency in anterior and inferior MI,⁶³ and single or double vessel disease is more common.⁵⁷

Ventricular septal rupture produces a usually large, left-to-right shunt (pulmonary-to-systemic flow >3:1) that places a volume load on the right ventricle, pulmonary circulation, left atrium, and left ventricle. The left ventricular performance, which is depressed by ischemia, is compromised further by the volume overload. In the SHOCK trial registry, the range of ejection fraction in patients with post-MI ventricular septal rupture was 25% to 40%.⁵⁷ Left ventricular forward stroke volume declines, but right ventricular stroke volume and pulmonary flow increase. There is reflex increase in heart rate and systemic vascular resistance, which increases left ventricular ejection impedance, further increasing the magnitude of left-to-right shunt. Right ventricular performance also declines because of the volume load and postcapillary pulmonary hypertension.

Clinical Features

In more than 70% of patients, the clinical presentation is characterized by circulatory collapse with hypotension, tachycardia, and low cardiac output and other clinical features of shock that may develop abruptly or within a few hours after the occurrence of a new systolic murmur.⁴³ The murmur is best heard over the left lower sternal border and may be associated with a palpable thrill. Right-sided and left-sided S₃ gallops with accentuated pulmonary component of S₂ are often present along with findings of tricuspid regurgitation. Pulmonary edema is less abrupt and fulminant than that seen with papillary muscle rupture.

The chest x-ray shows a combination of pulmonary edema and increased pulmonary flow. The ECG shows evidence of MI with or without evidence for ischemia.

Diagnosis

Echocardiography and Doppler echocardiography are mandatory in all patients with suspected ventricular septal rupture. Two-dimensional echocardiography reveals the septal defect in most cases, and shows regional wall motion abnormalities and changes in right and left ventricular function. Doppler echocardiography increases the diagnostic yield by showing transseptal flow (Fig. 19-3).^{43,47} Color flow imaging during echocardiography is very sensitive for diagnosing and characterizing ventricular septal rupture.^{28,43,47} Agitated saline is also used to identify the defect, and it may show negative contrast in the right ventricle. Doppler echocardiography is also performed to estimate the magnitude of left-to-right shunt and right ventricular and pulmonary artery systolic pressures.

Right heart catheterization with the use of balloon flotation catheters is not required for the diagnosis of ventricular septal rupture. If it is undertaken, however, it shows a step-up in oxygen saturation in the right ventricle and pulmonary artery compared with right atrial saturation (Fig. 19-4). The ratio of pulmonary to systemic flow can be calculated, and the hemodynamics can be determined.

Management

Urgent surgical repair of the ventricular septal rupture is a class I indication by the American College of Cardiology/American Heart Association guideline committee.⁶⁴ In the SHOCK

Figure 19-3. **A**, Two-dimensional transesophageal echocardiogram (transgastric basal short-axis plane) of a postinfarction ventricular septal rupture. The left ventricle is displayed above and the right ventricle below. Complex disruption of the interventricular septum is apparent in the midportion of the septum. **B**, Systolic frame color Doppler image of the same patient. There is a mosaic jet through the area of disruption of the interventricular septum, representing transseptal flow. Also seen is the eccentric contraction of the left ventricle, with dilation and dyskinesis of the infarct area involving the septum.

trial registry,⁵⁷ surgical repair of ventricular septal rupture was undertaken in 31 of 55 patients with cardiogenic shock, and 21 of these 31 patients also had concomitant coronary artery bypass graft surgery. Three of these patients also had aneurysmectomy. The overall mortality in the surgical group was 81%. Only 1 of 24 patients not undergoing surgery survived (almost 100% mortality). In the GUSTO-I trial, patients with cardiogenic shock were excluded; mortality for surgical versus medical treatment was 47% versus 94%.³² The results of these studies suggest that surgical repair should be considered if not absolutely contraindicated.

In a few patients, catheter-based percutaneous closure of the ventricular septal rupture has been performed with success.⁶⁵ This technique is promising and may be used for stabilization of patients who cannot undergo surgery urgently.

Figure 19-4. Ventricular septal defect. Oxygen saturation step-up between the right atrium (RA) and pulmonary artery (PA).

Survivors of surgery usually have improved functional class and a favorable late mortality rate.^{66,67} A 10-year survival rate of 50% has been observed after surgical repair.⁶⁸

Medical therapy is required to stabilize patients before surgery. The goal of medical therapy is to reduce the magnitude of the left-to-right shunt, improve cardiac output and systemic perfusion, and decrease pulmonary congestion. The magnitude of the left-to-right shunt in ventricular septal defect is determined by the resistance at the defect and the relative resistances in the pulmonary and systemic vascular beds. When the size of the defect is large, as in patients with post-MI ventricular septal rupture, the magnitude of the left-to-right shunt is principally determined by the ratio of pulmonary to systemic resistance.

Vasodilators such as sodium nitroprusside may increase the magnitude of left-to-right shunt owing to vasodilation of the pulmonary artery. Vasodilators with less vasodilatory effects on the pulmonary vascular bed but significant systemic vasodilatory effect, such as hydralazine or phentolamine, may be more effective in reducing the magnitude of left-to-right shunt. The most effective nonsurgical treatment to decrease the magnitude of left-to-right shunt is an intra-aortic balloon pump, which selectively reduces left ventricular ejection impedance. Inotropic agents and vasopressors are ineffective, although they are used frequently to maintain blood pressure. Diuretics are required to decrease pulmonary congestion. The therapeutic approach for the management of ventricular septal rupture is outlined in Table 19-3.

Dynamic Left Ventricular Outflow Tract Obstruction Complicating Acute Myocardial Infarction

Left ventricular outflow tract obstruction is a rare mechanical complication of acute MI.⁶⁹ It should be considered in the differential diagnosis of a new systolic murmur in a patient with acute MI.⁷⁰ Some patients with this syndrome develop hypotension and other features of cardiogenic shock. The mechanism of the outflow obstruction in these patients is very similar to that in patients with hypertrophic obstructive cardiomyopathy. A marked systolic anterior motion of the mitral valve obstructs the left ventricular outflow tract, reduces forward stroke volume and cardiac output, and causes hypotension and reflex

Table 19-3. Suggested Therapeutic Approach for Patients with Postinfarction Ventricular Septal Rupture

Corrective surgery as soon as feasible if not contraindicated
Intra-aortic balloon pump to decrease magnitude of left-to-right shunt
Vasopressors and inotropic agents
Arteriolar dilators
Diuretics
Survivors—angiotensin-inhibiting agents, β -adrenergic antagonists, aldosterone antagonists, lipid-lowering agents, antiplatelet agents

tachycardia. This dynamic obstruction of the left ventricular outflow tract also is the cause of the systolic murmur, which has the same characteristics of hypertrophic obstructive cardiomyopathy. This complication often occurs in patients with apical MI with hypercontraction of the basal septum.

Diagnosis

Echocardiography and Doppler echocardiography are the investigations of choice. Echocardiography shows systolic anterior motion of the mitral valve and the degree of outflow tract obstruction. The echocardiographic findings are similar to findings in patients with hypertrophic obstructive cardiomyopathy.

Management

The treatment is medical and is to reduce the outflow obstruction. Volume expansion, rather than diuretics, and β -adrenergic antagonists, rather than inotropic agents, are indicated.^{70,71} Vasopressors may be required to maintain blood pressure and to reduce outflow obstruction.^{71,72} There is no indication for intra-aortic balloon pump or surgical therapy in these patients even with cardiogenic shock.

Ventricular and Supraventricular Arrhythmias in Acute Myocardial Infarction

Judith A. Mackall, Mark D. Carlson

CHAPTER 20

Supraventricular Arrhythmias Ventricular Arrhythmias

Prevention of Sudden Cardiac Death Conclusion

CARDIAC RHYTHM abnormalities occur in 72% to 95% of patients with acute myocardial infarction (MI) (Table 20-1).¹⁻³ Because arrhythmias are more likely to occur early, and frequently occur before hospitalization, some cardiologists have suggested that the true incidence of arrhythmias associated with acute MI may be 100%.⁴ Arrhythmias associated with acute MI may occur because of re-entry, abnormal conduction or automaticity, and triggered activity. Several factors, including myocardial ischemia, infarct size, impaired hemodynamics, electrolyte abnormalities, and abnormalities of autonomic nervous system control, may influence these mechanisms and aggravate or cause arrhythmias.^{2,5,6}

Arrhythmias may result in cardiac arrest, syncope, angina, heart failure, palpitation, or no symptoms at all. Whether of supraventricular or ventricular origin, arrhythmias associated with acute MI require treatment when they impair hemodynamics, aggravate myocardial ischemia, or predispose to life-threatening arrhythmias. Timely recognition and therapy for arrhythmias decreases morbidity and mortality associated with MI. This chapter reviews the mechanisms, diagnosis, and therapy for supraventricular and ventricular arrhythmias that occur in acute MI. Conduction disturbances in the setting of acute MI are discussed in Chapter 22.

Supraventricular Arrhythmias

Sinus Tachycardia

Sinus tachycardia is present in approximately 30% of patients with acute MI (see Table 20-1).⁷ This arrhythmia usually represents an increase in sympathetic activity and is more commonly seen in patients with anterior wall MI. Sinus tachycardia that persists beyond the initial 4 hours suggests that other causes of tachycardia may be present. Sinus tachycardia may be an early manifestation of heart failure, and in this setting is a poor prognostic sign. An underlying cause of the tachycardia should be determined (e.g., fever, pericarditis, pain, heart failure, anemia) and treated in an attempt to decrease myocardial oxygen demand. Specific therapy to slow the heart rate in the setting of anxiety and increased sympathetic activity includes administration of a β blocker (Table 20-2).

Atrial Arrhythmias

Atrial arrhythmias occur in 20% to 54% of patients with acute MI.⁵⁻¹¹ Several studies have shown that patients with inferior MI are more likely to develop atrial arrhythmias early in their hospital course, but that patients with anterior MI tend to manifest atrial arrhythmias 12 hours to 4 days after MI.^{12,13} Several factors have been implicated in the pathogenesis of atrial arrhythmias,

Table 20-1. Incidence of Arrhythmias in Acute Myocardial Infarction

Arrhythmia	Incidence (%)
Sinus bradycardia	10-55
First-degree AV block	4-15
Second-degree AV block	
Mobitz type I	4-10
Multilevel AV block	2
Mobitz type II	Rare
Third-degree or complete AV block	
Inferior infarction	12-17
Anterior infarction	5
Asystole	1-10
Sinus tachycardia	30
Premature atrial contractions	54
Supraventricular tachycardia	<5
Atrial fibrillation	9-20
Atrial flutter	1-2
Premature ventricular contractions	90-100
Accelerated idioventricular rhythm	8-20
Ventricular tachycardia	10-40
Ventricular fibrillation	4-18

AV, atrioventricular.

Table 20-2. Antiarrhythmic Agents for Acute Myocardial Infarction*

Class	Drug	Indications	Dosage	Elimination Half-Life	Adverse Effects
IA	Procainamide	AVRT, VT	Intravenous—15 mg/kg at 20 mg/min (load), then 1-6 mg/min (maintenance); oral—50 mg/kg/day in 4 divided doses	2.5-4.7 hr	Hematologic—marrow suppression, lupus-like illness; proarrhythmia; hypotension (with intravenous infusion)
IB	Lidocaine	VT, PVCs, in setting of ischemia	Intravenous—1 mg/kg bolus, then 1-4 mg/min (maintenance)	1.5-2 hr	CNS—drowsiness, agitation, disorientation, tremulousness
II	Esmolol	Short-term rate control of AF, AFL, treatment of AVNRT, AVRT, MAT	Intravenous—500 µg/kg over 1 min (load), then 50 µg/kg/min (maintenance)	2 min	Hypotension; CNS—dizziness, somnolence, headache; bronchospasm at higher doses
	Metoprolol	Rate control of AF, AF; treatment of AVNRT, MAT	Oral—25-100 mg q6h; intravenous—5 mg every 5-15 min up to 15 mg	3-4 hr	As above
	Atenolol	As above	Oral—25-200 mg qd [†]	6-7 hr	As above
	Propranolol	As above	Intravenous—0.5-3 mg, repeat in 2-5 min, then q4h; oral—10-30 mg q6-8h	2 hr (initial dose); 3, 4-6 hr	As above; bronchospasm owing to β ₂ -antagonist activity
III	Amiodarone	VT, VF	Oral—800-1600 mg/day for 1-3 wk (load), 200-400 mg qd (maintenance); intravenous—150 mg/min over 10 min, then 1 mg/min for 8 hr, then reduce to 0.5 mg/min (maintenance)	9-11 days	Conduction disturbances—sinus bradycardia, heart block; abnormalities of thyroid function, liver function; pulmonary toxicity; hypotension more likely to occur with intravenous administration
IV	Diltiazem	Rate control of AF, AFL; treatment of AVNRT, MAT	Intravenous—0.25 mg/kg over 2 min; if no response in 15 min, 0.35 mg/kg over 2 min, then 5-15 mg/hr (maintenance); oral—30-125 mg tid, 120-300 mg CD qd	3.5-10 hr	Hypotension; potentiation of sinus node dysfunction
	Verapamil	As above	Intravenous—5-10 mg, may repeat in 15-30 min with 10 mg; oral—80-120 mg q6-8h or 120-240 mg SR q12-24h	2 hr (intravenous); 4.5-12 hr (oral)	Cardiac effects—congestive heart failure owing to negative inotropic effect, hypotension; gastrointestinal effects—constipation
Other	Digoxin	Rate control of AF, AFL; treatment of AVNRT	Intravenous/oral—0.5 mg (initial), 0.25 mg q4-8h to total of 1 mg (load); 0.125-0.375 mg qd (maintenance) [†]	30 min (intravenous), 34-44 hr (oral)	Toxic side effects—nausea, accelerated functional rhythm, high-grade AV block
	Adenosine	Termination of AVNRT, AVRT, occasionally MAT, and exercise-mediated VT	Intravenous—6 mg rapid bolus, may repeat with 12 mg in 1 min, and then 18 mg	9.5 sec	Dyspnea, chest pain, flushing, sinus tachycardia
	Magnesium	Torsades de pointes	Intravenous—1-2 g (load); 1-7.5 mg/min (maintenance) [†]	—	Hypotension

*The dosages and indications listed are based on current practice standards and therefore are subject to change in the future.

[†]The dosage should be adjusted in the presence of renal insufficiency.

AF, atrial fibrillation; AFL, atrial flutter; AT, atrial tachycardia; AV, atrioventricular; AVNRT atrioventricular nodal re-entry tachycardia; AVRT, atrioventricular re-entry tachycardia; CNS, central nervous system; MAT, multifocal atrial tachycardia; PVCs, premature ventricular contractions; VF, ventricular tachycardia; VT, ventricular tachycardia.

including atrial distention owing to underlying left or right ventricular dysfunction, pericarditis, and atrial infarction.

In a small series of patients with documented inferior MI, Rechavia and colleagues¹² found that there was a significantly higher occurrence of premature atrial contractions and atrial fibrillation in patients with right ventricular dysfunction. It is unclear whether right atrial distention resulting from right ventricular dysfunction caused the premature atrial contractions and atrial fibrillation, or if there was associated right atrial infarction. Studies showing a higher incidence of atrial fibrillation in patients with atrial infarction and in patients with some extent of atrial infarction in right ventricular MI¹⁴ suggest that both factors may play a role.¹⁵ Atrial arrhythmias that occur late in the hospital course have been attributed to underlying left ventricular dysfunction. In these patients, treatment of congestive heart failure may prevent recurrence.^{12,16}

Premature Atrial Contractions

Premature atrial contractions are the most common atrial arrhythmias, occurring in 54% of patients with acute MI (see Table 20-1).^{8,11} These beats may result from heightened sympathetic activity owing to pain or anxiety, or they may result from atrial distention, pericarditis, atrial infarction, or atrial ischemia. Although premature atrial contractions may precipitate other atrial arrhythmias, they are usually asymptomatic and are of no hemodynamic significance. Because premature atrial contractions are not associated with increased mortality, medical therapy to suppress these beats is not indicated.¹¹

Paroxysmal Supraventricular Tachycardia

Paroxysmal atrial tachycardia and other re-entrant supraventricular tachycardias occur in less than 5% of patients (see Table 20-1).^{12,17} Most of these arrhythmias are transient, but the rapid ventricular rate is frequently associated with symptoms. Management of tachycardia should be directed at control of the ventricular rate. This control can be achieved promptly with intravenous administration of a β blocker or calcium channel blocker (see Table 20-2). These drugs or adenosine may terminate the tachycardia if the atrioventricular node is an integral part of the re-entry circuit. Adenosine may also terminate atrial tachycardia; however, it has the potential to result in atrial fibrillation.¹⁸ Caution should be used when administering any agent if symptoms of hypotension and congestive heart failure are present.

In patients with hemodynamic instability, synchronized DC cardioversion is the safest and the most expedient method to terminate the tachycardia. Treatment of underlying heart failure may prevent recurrences.¹²

Atrial Fibrillation and Flutter

Atrial fibrillation occurs in 9% to 20% of patients and is associated frequently with atrial infarction (see Table 20-1).^{8,12,14,19-21} Atrial flutter is uncommon in MI, occurring in only 1% to 2% of patients.^{11,12} There is no association between the occurrence of atrial or supraventricular arrhythmias and outcome.²²⁻²⁴ Earlier studies showed an increased mortality associated with supraventricular arrhythmias in the setting of acute MI.^{15,24,25} A later study designed to determine the prognostic value of supraventricular arrhythmias in the late phase of MI (13 to 19 days) found, however, that left ventricular ejection fraction was the only independent predictor of mortality.¹¹ Serrano and coworkers¹²

determined the short-term and long-term outcomes of patients with supraventricular arrhythmias after MI. Although patients with arrhythmias during the late phase of MI (12 hours to 4 days) had significantly higher mortality rates at 1 month and 47 months, the presence of supraventricular arrhythmias was not an independent predictor of mortality. The increased mortality was not related to left ventricular function, but correlated with the presence of more extensive coronary artery disease.

Patients with atrial fibrillation frequently develop symptoms owing to the loss of atrial contribution to cardiac output associated with these arrhythmias, and owing to the rapid ventricular rates. In the presence of hemodynamic instability, restoration of normal sinus rhythm can be achieved promptly with synchronized DC cardioversion. For a hemodynamically stable patient with atrial fibrillation, the ventricular rate can be controlled with intravenous administration of a β blocker or a calcium channel blocker. Conversion to normal sinus rhythm often occurs spontaneously, but DC cardioversion may be necessary. No data are available on the use of ibutilide, a class III antiarrhythmic drug, in the post-MI period.

Patients with atrial flutter typically have 2:1 conduction, and control of the ventricular rate may be difficult. DC cardioversion or pace termination via temporary atrial transvenous or epicardial wires can be performed to terminate the tachycardia. Recurrent episodes of atrial fibrillation or flutter may be prevented with administration of amiodarone. Patients with recurrent atrial fibrillation who meet current guidelines for anticoagulation should be started on warfarin therapy.²⁶ Clopidogrel (Plavix) and aspirin do not prevent or reduce the risk of thromboembolism from atrial fibrillation.²⁷

Ventricular Arrhythmias

Ventricular tachyarrhythmias are potentially the most dangerous arrhythmias associated with acute MI, occurring in 10% to 50% of patients.^{1,28} These arrhythmias are observed more frequently soon after the onset of MI. In experimental animals, factors that determine the occurrence of ventricular tachyarrhythmias include the size of the ischemic area,²⁹ stress,³⁰ preconditioning,^{31,32} increased heart rate,^{33,34} and autonomic nervous system influences.^{35,36} The occurrence of more than one factor may increase the risk for arrhythmias. Ischemia and sympathetic stimulation are more arrhythmogenic than either factor alone.^{37,38}

Considerable evidence indicates that factors that influence arrhythmias in experimental models also influence the occurrence of ventricular tachyarrhythmias in humans. The incidence of ventricular tachyarrhythmias is related to infarct size and the presence of heart failure.^{36,39,40} Patients with an absolute increase in sympathoadrenal stimulation or decreased vagal efferent activity are at increased risk for sudden cardiac death and ventricular tachyarrhythmias.⁴¹⁻⁴⁴ Acute MI causes several changes in the autonomic nervous system that may facilitate initiation of ventricular arrhythmias. Activation of cardiac mechanoreceptors and cardiopulmonary and carotid baroreceptors results in increased circulating catecholamine levels and increased efferent sympathetic activity. Ischemic damage to cardiac adrenergic neurons results in the release of catecholamines. Transmural MI denervates viable myocardium distal to the infarct site.⁴⁵ Ischemic and denervated viable myocardium are hypersensitive to circulating catecholamines.⁴⁴ Sympathetic

stimulation also enhances automaticity in Purkinje fibers. These effects result in inhomogeneities of repolarization and enhance automaticity.

Electrolyte abnormalities, including hypokalemia and hypomagnesemia, are potentially correctable causes of ventricular arrhythmias associated with MI. Hypokalemia is an independent risk factor for ventricular arrhythmias early in MI.⁴⁶ Hypomagnesemia often accompanies hypokalemia and may result in polymorphic ventricular tachycardia (VT). The use of thrombolytic drugs to treat patients with acute MI has renewed interest in arrhythmias associated with coronary reperfusion. These arrhythmias were observed in 1881, when ventricular fibrillation (VF) was seen within seconds after restoration of coronary flow.⁴⁷ Coronary reperfusion may cause isolated premature ventricular contractions, accelerated idioventricular rhythm (AIVR), VT, or VF, presumably by enhancing automaticity of ischemic myocardium.⁴⁸ The severity of the arrhythmia induced by reperfusion is related to the duration of myocardial ischemia.

The presence of certain antiarrhythmic drugs at the time of MI may facilitate initiation or maintenance of ventricular arrhythmias. This proarrhythmic effect is thought to occur because of changes in the electrophysiologic action of the drugs in the setting of myocardial ischemia. In a canine model, flecainide facilitated induction and sustenance of VT, particularly at shorter cycle lengths.⁴⁹ The effect seemed to result from slowing of conduction in ischemic myocardium. Although less well studied, ischemia-induced proarrhythmia may occur with type IA or type III antiarrhythmic drugs.

Ventricular Premature Beats

Ventricular premature beats occur in almost all patients with acute MI⁵⁰ (see Table 20-1), and are rarely a cause of myocardial ischemia or systemic hypotension. Previously, these beats were thought to be important because of their potential to trigger VT or VF. Early studies suggested that the frequency and timing of ventricular premature beats was associated with the risk for life-threatening arrhythmias.⁵¹ Early ventricular premature beats (R on T phenomenon) were thought to initiate VF because they depolarized the ventricle during the vulnerable period when ventricular refractoriness was inhomogeneous, and re-entry was more likely to occur. Data from animal models and human studies indicate, however, that frequent and complex ectopy is neither a sensitive nor a specific predictor for development of sustained ventricular tachyarrhythmias early after MI.^{28,52-57}

The incidence of frequent ventricular premature beats and the R on T phenomenon is similar between patients who develop VF and patients who do not develop VF.²⁸ Studies of animals and humans have shown that most VT episodes⁵⁸ and 41% to 45% of VF episodes^{52,53} are initiated by late-coupled ventricular premature beats (after the T wave), suggesting that early beats are not required to initiate the arrhythmia. VF occurs in the absence of preceding ventricular ectopy in 40% to 83% of patients.^{52,53}

Ventricular Tachycardia

VT is defined as three or more consecutive ventricular ectopic beats at a rate greater than 100 beats/min. This arrhythmia may be classified as nonsustained (i.e., terminating spontaneously within 30 seconds) or sustained (i.e., requiring intervention or of >30 seconds' duration), as monomorphic or polymorphic (depending on the QRS complex morphology), and as early or late (i.e., occurring <24 hours or >48 hours after the onset of MI).

Table 20-3. Electrocardiographic Criteria That Support the Diagnosis of Ventricular Tachycardia

QRS complex width >0.14 sec
Left-axis deviation
Configuration of QRS complex
In RBBB: monophasic or biphasic complex in lead V ₁
In LBBB: Q wave in lead V ₂
Concordance in the precordial leads
AV dissociation*
Absence of an RS complex in the precordial leads*
If RS complex is present, an RS interval >0.10 sec*

AV, atrioventricular; LBBB left bundle branch block; RBBB, right bundle branch block.

*100% specific for ventricular tachycardia.

From Mackall JA, Buchler CM, Thames MD. The pharmacological approach to the management of the cardiac surgical patient. In Baue AE, (ed): Glenn's Thoracic and Cardiovascular Surgery. East Norwalk, CT, Appleton & Lange, 1998, p 1613.

VT appears on the surface 12-lead electrocardiogram (ECG) as a wide QRS complex tachycardia. Although several criteria and algorithms have been proposed to differentiate this arrhythmia from supraventricular tachycardia with aberrant ventricular conduction, the diagnosis sometimes remains uncertain (Table 20-3).^{59,60} When a definitive diagnosis is impossible, a wide QRS complex tachycardia associated with acute MI should be considered ventricular in origin until proved otherwise.

Additional measures may differentiate VT from supraventricular tachycardia with aberrant ventricular conduction. Vagal stimulation (with a Valsalva maneuver or carotid sinus massage) or administration of adenosine may transiently slow or terminate supraventricular tachycardia, but does not affect most VT.⁶¹ Intracardiac electrograms may be recorded from temporary pacemaker wires to show the relationship of atrial and ventricular activation. The presence of atrioventricular dissociation during a wide QRS complex tachycardia is almost always diagnostic of VT. Administration of lidocaine may be diagnostic and therapeutic because lidocaine has no activity in atrial tissue.

VT occurs in 10% to 40% of patients with acute MI (see Table 20-1).^{1,28} The timing of VT has important implications regarding the mechanism and prognosis of the arrhythmia. VT that occurs late in the course of MI (after 48 hours) is more common in patients with transmural infarction and left ventricular dysfunction.^{1,62} When it occurs late, is sustained, and results in hypotension, VT is likely to recur and is associated with increased in-hospital and long-term mortality rates.⁶²⁻⁶⁴ VT that occurs early is more likely to have reversible causes (e.g., ischemia, reperfusion, autonomic nervous system influences) and is less likely to recur.

Sustained monomorphic VT most often results from re-entry, usually within a single circuit.⁶⁵ Patients with this arrhythmia, even when it occurs less than 48 hours after the onset of acute MI, should undergo a thorough evaluation to determine the risk for recurrence and the need for therapy. VT resulting from reperfusion often occurs within the first hour after administration of thrombolytic therapy, is often associated with a slower rate, and is less likely to recur.

Polymorphic VT differs from monomorphic VT in that the QRS complex morphology varies from beat to beat. This arrhythmia has been reported to occur in 0.7% to 2% of patients hospitalized for acute MI.^{66,67} Although the mechanism for the arrhythmia is unknown, polymorphic VT is not thought to be associated with a stable re-entrant circuit. When the arrhythmia occurs early (within 6.5 hours of the onset of symptoms), it is often associated with coronary reperfusion and a good prognosis.⁶⁷ When it occurs late (2 to 13 days after acute MI), the arrhythmia is associated with recurrent ischemia and a poor prognosis.⁶⁶

Torsades de pointes is a specific type of polymorphic VT, and is usually caused by a proarrhythmic effect of antiarrhythmic drugs. Drugs that prolong ventricular refractoriness (class IA antiarrhythmic drugs and the class III drugs sotalolol, dofetilide, and ibutilide) may prolong the Q–T interval and predispose the patient to this arrhythmia. In this situation, torsades de pointes is thought to result from triggered activity induced by early afterdepolarizations. Early afterdepolarization amplitude depends on heart rate; increased heart rate decreases the amplitude and the probability that the afterdepolarization will reach a threshold potential and “trigger” torsades de pointes. Faster heart rates shorten repolarization and suppress early afterdepolarizations.

Ventricular Fibrillation

VF is caused by multiple electrical activation wave fronts that depolarize the ventricles in a disorganized and chaotic fashion. By definition, this arrhythmia does not terminate spontaneously and is lethal unless converted quickly. The absence of organized ventricular electrical activation results in the absence of QRS complexes and an irregular undulating baseline on the surface ECG.

VF is the leading cause of death early during the course of MI, occurring in 4% to 18% of hospitalized patients (see Table 20-1).^{50,52} The arrhythmia is more likely to occur in patients with a large MI. The incidence of VF is lower among patients with non-Q wave than with Q wave MI. VF occurs with similar frequency, however, in patients with anterior and inferior Q wave MI.²⁸ Although VF that occurs early (≤ 48 hours) is associated with an increased in-hospital mortality, it does not increase long-term mortality.⁶⁸

When associated with acute MI, VF has been classified as primary or secondary. Primary VF occurs early and unexpectedly in the absence of heart failure or other apparent causes. Approximately 50% of these episodes occur within 1 hour, 60% to 80% occur within 4 hours, and 80% occur within 12 hours of the onset of symptoms.^{1,54,66} Secondary VF occurs as a result of severe heart failure or cardiogenic shock and can occur at any time during the course of MI.¹

Whether VF occurs early or late, myocardial ischemia should be considered as the underlying cause, particularly when the arrhythmia recurs frequently. VF may also result from coronary reperfusion. When caused by reperfusion, the occurrence of VF, rather than AIVR or VT, is related to the duration of myocardial ischemia.⁷⁰ In animal models, the incidence of VF increases when ischemia is prolonged from 5 to 20 minutes, but decreases when reperfusion is delayed beyond 30 minutes.

Sudden cardiac death and VF may be the presenting symptoms in patients with acute MI. In these patients, the cause of the arrhythmia or the MI is often unclear. In many patients, VF may be the cause, rather than the result, of MI. In others,

particularly patients with previous MI, VF may have occurred as a result of sustained VT. These are important considerations when evaluating the risk for recurrent ventricular tachyarrhythmias and the need for electrophysiologic testing and long-term antiarrhythmic therapy.

Accelerated Idioventricular Rhythm

AIVR is defined by its rate (60 to 100 beats/min) and is sometimes referred to as slow VT. AIVR occurs in 8% to 20% of patients, usually during the first 2 days after MI. The arrhythmia occurs with equal frequency in patients with anterior or inferior MI and may be provoked by spontaneous or induced coronary reperfusion.^{71,72} AIVR may begin with a premature ventricular beat or may occur as a result of sinus slowing or an increase in the ventricular “escape” rate. Similarly, AIVR may terminate abruptly because the sinus rate increases or because the ventricular escape rate slows. Variation in the rate of this arrhythmia is common.

In humans, AIVR is the most common arrhythmia following coronary reperfusion.^{63,74} Most cases of AIVR probably occur as a result of enhanced automaticity in Purkinje fibers on the endocardial surface near or within the infarction zone.⁷⁴ In vitro studies, using a model of coronary artery reperfusion, have shown AIVRs that were caused by triggered activity associated with delayed afterdepolarization.⁷⁵ Rapid VT with a rate twice that of the AIVR has been observed in some patients, suggesting re-entry with episodic exit block as another possible mechanism for the arrhythmia.^{76,77}

Therapy

Ventricular tachyarrhythmias should be treated when they adversely affect hemodynamics, cause myocardial ischemia, or predispose to life-threatening arrhythmias. Depending on the indication, the goal of therapy may be to convert the arrhythmia, to suppress the arrhythmia, or to prevent a life-threatening arrhythmia.

Reversible causes may be responsible for ventricular arrhythmias and should be addressed in every patient. Acid-base status, systemic arterial oxygen saturation, and serum electrolytes should be evaluated, and abnormalities should be corrected at the time of admission to the cardiac intensive care unit. Proarrhythmia caused by an antiarrhythmic drug may necessitate discontinuation of the drug and additional specific therapy, depending on the offending agent. These and other reversible causes of arrhythmia should be reconsidered when arrhythmias occur.

Recurrent or incessant ventricular tachyarrhythmias are often caused by and may be the only manifestation of myocardial ischemia. In such cases, recognition of myocardial ischemia as the cause of ventricular arrhythmias is particularly important because antiarrhythmic drugs are often ineffective and are more likely to cause proarrhythmia in this setting. Appropriate diagnostic measures and vigorous anti-ischemic therapy should be instituted. Intra-aortic balloon pump counterpulsation or percutaneous coronary intervention, or both, may be required to suppress incessant ventricular arrhythmias.

Cardioversion and Defibrillation

Ventricular Tachycardia

Rapid conversion of VT is imperative because of its adverse hemodynamic effects and its potential to deteriorate into VF. When possible, a 12-lead ECG should be obtained before

conversion of VT. This is important to ensure proper diagnosis and therapy for the arrhythmia.

VT that is associated with hypotension should be treated promptly with a synchronized DC shock. The shock should be administered with paddles placed on conductive pads near the apex and base of the heart. VT sometimes can be terminated with 20 J of external DC energy. When the arrhythmia is associated with hemodynamic collapse and loss of consciousness, the initial shock energy should be 200 J or more with a monophasic shock and 120 to 200 J with a biphasic shock.

Hemodynamically stable VT sometimes can be cardioverted by antiarrhythmic drugs. Chemical cardioversion is usually more time-consuming and is less reliable than electrical cardioversion. Administration of antiarrhythmic drugs is not associated with pain, however, and does not require sedation. Chemical cardioversion is appropriate when VT is hemodynamically well tolerated and is not associated with myocardial ischemia. An external cardioverter-defibrillator should be available if hypotension occurs⁷⁸.

Amiodarone, procainamide, and sotalol can be used to convert VT. Sotalol given orally is often impractical because steady state would not be reached for several days. Intravenous amiodarone, 150 mg over 10 minutes followed by a maintenance infusion (see Table 20-2) and repeating the bolus as necessary, is very effective at converting VT. Intravenous amiodarone may result in hypotension; in case of hypotension, either lidocaine bolus or DC cardioversion should be available.

Lidocaine is safe to use with amiodarone because it has no adverse hemodynamic effects and does not cause Q-T prolongation. Lidocaine has a rapid onset of action and may terminate or suppress ventricular arrhythmias within minutes. The drug can be administered intravenously as a bolus of 50 to 100 mg, followed by a continuous infusion of 1 to 4 mg/min. Because of a significant first-pass effect in the liver, a second bolus can be administered 20 to 30 minutes after the initial dose to maintain a therapeutic serum drug level.

Procainamide is also effective for cardioversion, but requires a longer period to infuse and is sometimes associated with hypotension because of negative inotropic effects and vasodilation. The drug prolongs refractoriness in atrial and ventricular myocardium. Procainamide can be administered intravenously and can be titrated to achieve the therapeutic effect. Procainamide undergoes acetylation in the liver to *N*-acetyl procainamide; both forms have antiarrhythmic activity. Serum concentrations of procainamide can be determined by a bioassay and correlate with efficacy and with toxicity. Because it prolongs ventricular refractoriness, procainamide prolongs the Q-T interval on the surface ECG. It can be used in patients unable to tolerate amiodarone. Because of its Q-T prolonging effect, it should be used cautiously if amiodarone has been given. Q-T prolongation to greater than 550 ms is associated with an increased risk for torsades de pointes, and may be an indication to decrease the dose or discontinue the drug.

Pacing, similar to antiarrhythmic drug therapy, may terminate VT. Pace termination of VT is effective in certain patients with relatively slow and hemodynamically well-tolerated VT. Patients with temporary endocardial ventricular pacing wires and patients with temporary epicardial electrode wires placed during cardiac surgery are ideal candidates for this therapy. Synchronized pacing is performed at a cycle length that is 90% or less than that of the VT. In some cases, VT can be terminated by

a single synchronized beat. More often, 5 to 15 seconds of pacing is required to terminate the arrhythmia. Burst pacing can be repeated if the initial attempt is unsuccessful. Pacing should not be performed at a rate greater than 300 beats/min because of the risk for accelerating the arrhythmia or inducing VF. Pacing should not be performed unless a defibrillator is available. Ramp pacing (i.e., a beat-to-beat decrease in the pacing cycle length) is often successful when bursts at a single cycle length do not terminate VT.

Procainamide may facilitate pace termination of VT by slowing the rate of the arrhythmia and by favorably influencing the re-entrant circuit. In some cases, antiarrhythmic drugs may adversely influence the re-entrant circuit, however, decreasing the effectiveness of pacing despite slowing the rate of the tachycardia.

β blockers are useful in preventing recurrent VT in the setting of ischemia. Calcium channel blockers should not be used in patients with wide QRS tachycardia because they can promote hemodynamic collapse and death in the setting of VT.

Ventricular Fibrillation

The treatment of VF is direct electrical countershock. Because time to definitive therapy for this arrhythmia is directly related to outcome, electrical countershock should be delivered as quickly as possible and should not be delayed by administration of a precordial thump or antiarrhythmic drugs.

Although cardioversion of VT may be accomplished with 20 J of DC electricity, defibrillation usually requires substantially greater energy. Generally, 360 J (monophasic) or 200 J (biphasic) should be delivered at each attempt. Cardiopulmonary resuscitation (CPR) should be initiated whenever electrical countershock cannot be delivered immediately. If defibrillation may be delayed more than 5 minutes, CPR should be performed for 1½ to 3 minutes before shock delivery.⁷⁹ In the setting of hypoxemia, myocardial ischemia, severe heart failure, and acid-base disturbances, VF is likely to recur.

The advanced cardiac life support protocol should be followed giving continuous chest compressions with interruptions of less than 10 seconds for shock delivery. Drugs should be infused during chest compressions. Intravenous amiodarone, 300 mg, should be administered, and a 150-mg dose may be repeated in 3 to 5 minutes if necessary. Lidocaine can be given if amiodarone is unavailable or ineffective.

Special Cases

In patients with frequent or incessant ventricular tachyarrhythmias, adhesive conductive patches should be placed on the back and the precordium and attached to an external cardioverter-defibrillator. This configuration allows for more rapid treatment of the arrhythmia.

Patients with implantable cardioverter-defibrillators represent a small but growing population of individuals admitted to cardiac intensive care units with MI. These devices may be programmed to recognize and treat ventricular tachyarrhythmias automatically either by a countershock or by antitachycardia pacing. This is an appropriate strategy for hospitalized patients with episodes of VT that can be reliably terminated by antitachycardia pacing. Patients with frequent ventricular tachyarrhythmias who are susceptible to multiple shocks are better treated by deactivating the device temporarily and suppressing the arrhythmias with antiarrhythmic drugs.

Suppression

Ventricular Premature Beats

When coronary care units were first developed, therapy focused on suppression of so-called warning arrhythmias (i.e., frequent and complex ventricular ectopy, including R on T ventricular premature beats). Many investigators advocated antiarrhythmic drug therapy for all patients early after MI when it became apparent that the warning arrhythmias were neither sensitive nor specific predictors for VF. Several studies have evaluated the routine administration of antiarrhythmic drugs (e.g., lidocaine, quinidine, procainamide, disopyramide) to all patients with acute MI.^{80,81} These studies have shown that antiarrhythmic drugs suppress ventricular ectopy, and in the case of lidocaine sometimes prevent VF.^{80,82,83} No study has shown, however, that routine administration of these drugs prolongs life.⁸⁴⁻⁸⁷

Fifty percent of patients experience side effects from lidocaine, including slurred speech, confusion, tremor, and seizures.⁸⁸ Compared with the limited number of patients who may benefit from therapy, routine administration of lidocaine to all patients is not justified. When promptly terminated in the cardiac intensive care unit, primary VF has little effect on the prognosis of patients with acute MI.⁸⁹

Because suppression of ventricular premature beats is not associated with improved survival, these beats should be suppressed only when they aggravate myocardial ischemia or adversely affect hemodynamics. Intravenous administration of antiarrhythmic drugs allows for rapid onset of drug activity and titration of the dose to optimize efficacy and minimize side effects. Lidocaine remains the first-line therapy, primarily because of its favorable benefit-to-risk ratio.

Ventricular Tachycardia

Nonsustained VT, similar to ventricular premature beats, should be treated when the arrhythmia aggravates myocardial ischemia and adversely affects hemodynamics. Treatment of asymptomatic nonsustained VT remains controversial because there is little evidence that this strategy improves mortality or morbidity. Sustained VT should be suppressed when it occurs late or frequently. When it occurs early and as a single episode, however, sustained VT is not likely to recur, and suppression with antiarrhythmic drug may not be indicated.

Amiodarone can be administered orally or intravenously to suppress recurrent, sustained VT. An oral loading dose of 1200 to 1600 mg/day is usually administered until a 6- to 10-g load is complete.⁹⁰⁻⁹² If recurrent hemodynamically unstable VT and VF occur, intravenous amiodarone has been shown to reduce the frequency of events during the first 24 hours of infusion.⁹³ The recommended starting dose for intravenous amiodarone is approximately 150 mg over 10 minutes followed by 0.5 to 1 mg/min the first 24 hours of therapy, but may vary according to individual necessity and tolerance. Mean daily doses greater than 2100 mg are associated with an increased risk of hypotension. A maintenance infusion of 0.5 mg/min may be administered for 3 weeks. Experience with infusions longer than 3 weeks is limited.

Lidocaine and procainamide, administered intravenously, are also effective antiarrhythmic drugs for suppression of sustained monomorphic VT. These drugs may be administered alone or in combination with one another. Neither lidocaine nor procainamide transitions easily to oral maintenance therapy. Atrial or ventricular pacing may suppress sustained monomorphic VT

in some patients with monomorphic VT, particularly when the arrhythmia is aggravated by bradycardia.

Torsades de Pointes

Suppression of this arrhythmia depends on increasing the heart rate and eliminating the offending agent. Increased heart rate (usually 90 to 110 beats/min) shortens ventricular repolarization time and suppresses the arrhythmia. Intravenous atropine or isoproterenol (or both) can be administered. Insertion of a temporary atrial or ventricular pacing wire may be necessary. Magnesium, which may shorten ventricular repolarization, has been administered intravenously to treat this arrhythmia.

Ventricular Fibrillation

Intravenous amiodarone is the first-line therapy for recurrent VF. Lidocaine should be administered when amiodarone is ineffective or associated with side effects. Repeat boluses of amiodarone may be given if the arrhythmia proves to be recurrent. Pacing may be an effective adjuvant therapy when the arrhythmia is associated with bradycardia or pauses. If arrhythmia associated with bradycardia or pauses occurs in the setting of ongoing ischemia, severe left ventricular dysfunction, or cardiogenic shock, intra-aortic balloon pump or the need for emergent cardiac catheterization, or both, should be considered.

Prevention of Sudden Cardiac Death

Coronary Care Unit

The institution of coronary care units resulted in a significant decline in mortality for acute MI during the last 3 decades (from 30% to <15%), principally because primary arrhythmias were virtually eliminated as a cause of death.²⁸ These units provide continuous ECG monitoring and access to therapy and trained personnel, allowing immediate detection and treatment of arrhythmias.⁹⁴ Coronary care units provide an environment for delivery of therapies that may decrease the long-term risk for arrhythmias by decreasing myocardial ischemia or limiting infarct size (i.e., early percutaneous intervention, thrombolytic drugs, intravenous nitroglycerin, heparin, and intra-aortic balloon counterpulsation).

The duration of continuous ECG monitoring depends on the risk for a life-threatening arrhythmia. Patients with a large and complicated MI (i.e., heart failure, recurrent myocardial ischemia, or hemodynamically significant arrhythmias) are at the highest risk for early sudden cardiac death and should be monitored continuously for 5 to 7 days. Patients with small uncomplicated MI may not require continuous monitoring for more than 3 days after the event.

Thrombolytic Therapy

Administration of thrombolytic agents has complex effects on the incidence of ventricular arrhythmias after MI. Studies of the influence of thrombolytic therapy on ventricular arrhythmias in acute MI have yielded conflicting results.⁹⁵⁻¹⁰¹ Thrombolytic therapy is associated with coronary reperfusion, which has been shown to cause AIVR, VT, and VF, depending on the duration of ischemia. The incidence of ventricular arrhythmias early after MI may be similar, if not increased, for patients who receive thrombolytic therapy or have patent infarct-occluded arteries. Arrhythmias that occur late are more likely the result of recurrent myocardial ischemia or re-entry related to scar. Early

percutaneous intervention or administration of thrombolytic agents, by decreasing ischemia and infarct size, may decrease the incidence of these arrhythmias.

β -Adrenoceptor Antagonists

Several studies have shown that early administration of intravenous β -adrenoceptor antagonists reduces the incidence of VF during evolving MI,^{102,103} and may reduce the long-term risk for sudden death in these patients.^{104,105} β -adrenoceptor antagonist may prevent ventricular arrhythmias by limiting infarct size, by decreasing heart rate, or by direct antiarrhythmic effects.^{34,40}

Implantable Cardioverter-Defibrillators

Several studies have shown that prophylactic implantation of implantable cardioverter-defibrillators improves survival in patients who are status post MI and have depressed left ventricular systolic function (left ventricular ejection fraction <0.30 to 0.35).¹⁰⁶⁻¹⁰⁹ These studies have generally enrolled patients at least 40 days after MI. The prophylactic use of implantable cardioverter-defibrillators for patients with depressed ejection fraction has not shown a mortality benefit in the acute post-MI period (≤ 40 days)¹¹⁰ or in the acute postrevascularization period (≤ 3 months).¹¹¹

Conclusion

Cardiac arrhythmias are observed frequently in the setting of acute MI because of electrophysiologic alterations that result from myocardial ischemia and necrosis. These arrhythmias, whether supraventricular or ventricular, may precipitate hemodynamic collapse or death. Efforts should be made to identify and correct factors such as electrolyte abnormalities, hypoxia, heart failure, and ischemia, which increase the risk for developing an arrhythmia. The mortality associated with acute MI has been greatly reduced because of the early recognition and prompt treatment of arrhythmias.

Conduction Disturbances in Acute Myocardial Infarction

Raghuveer Dendi, Mark E. Josephson

CHAPTER 21

Anatomy Incidence Specific Conduction Abnormalities

Mortality Management

THE IMPACT of infarction on myocardial conduction tissue can be dramatic and pivotal in altering the consequences of an acute myocardial infarction (MI), and could affect the basic management of a patient presenting with occlusion of a coronary artery. Immediate recognition of emergence of conduction disturbances between the sinoatrial node and the right atrium and between the atrium and the ventricles in the acute phase of MI is of prognostic and therapeutic significance. The nature of conduction disturbance not only can give clues to the location of the infarct, but also aid in prioritizing the management of MI, including, but not limited to, potential need for temporary pacemaker support. Autonomic imbalance and ischemia or necrosis seem to induce these disturbances.

Anatomy

The sinus node, sinoatrial conduction system, atrioventricular (AV) node, bundle of His, right bundle, left bundle dividing into anterior and posterior fascicle, and myocardial Purkinje fibers form components of the conduction system. The sinoatrial node is supplied by the atrial branch of the proximal right coronary artery (RCA) in 55% of cases and the proximal left circumflex artery in 45% of cases.¹ The RCA perfuses the AV node and the proximal portion of the His bundle in most cases (left circumflex artery in 10% of cases). The septal branches of the left anterior descending artery supply the distal part of the His bundle, the right bundle branch, and the anterior fascicle of the left bundle branch. The posterior fascicle of the left bundle is supplied by septal branches from both the left anterior descending artery and the RCA.

Incidence

The overall incidence of conduction disturbances, including bundle branch and fascicular block, during acute MI is approximately 10% to 20%. The incidence of complete heart block may be lower with thrombolytic therapy compared with the prethrombolytic era.

Based on multicenter retrospective reviews in the prethrombolytic era, left bundle branch block (LBBB) was the most common block, occurring in 38% of patients who had preexisting or new intraventricular conduction delay.^{2,3} This statement is controversial, however, because in 1975, Lie and coworkers⁴ found that complete LBBB secondary to acute MI is rare. Right bundle

branch block (RBBB) with left anterior fascicular block (LAFB) was also common, occurring in 34% of patients who developed an intraventricular conduction delay. RBBB, RBBB with left posterior fascicular block (LPFB), and “alternating bundle branch block” occurred in 11%, 10%, and 6% of patients with new intraventricular conduction delay; isolated LAFB and LPFB were uncommon. Twenty-two percent of patients developed high-grade AV block or complete heart block.

In the thrombolytic era, the available data suggest that the incidence of complete heart block in acute MI may be lower with thrombolytic therapy at 4% to 5%,⁵ and the combined end point of complete heart block or second-degree AV block is 7% to 10%. The onset of complete heart block occurred within the first 2 days after MI in 81% of patients who developed complete heart block.

Specific Conduction Abnormalities

Sinoatrial Node

Sinus Bradycardia

Sinus bradycardia is the most common arrhythmia in inferior MI and three times more common in inferoposterior than anterior MI.⁶ Possible mechanisms include increased vagal tone (common), neurologic reflexes, and infarction or ischemia of the sinus node or the surrounding atrium.

Sinoatrial Block and Sinus Arrest

Grade 2 or complete sinoatrial block suggests a proximal occlusion of the RCA or left circumflex artery and is often accompanied by atrial infarction. This is a sign of a large MI, and coronary reperfusion therapy should be initiated rapidly.⁷

Atrioventricular Node

Prolongation of the P–R interval (so-called first-degree block) can arise in the AV node, the bundle of His, or the bundle branches. AV nodal delay is usually seen in cases of occlusion of the RCA proximal to the right ventricular branch.⁸ This conduction abnormality may also manifest as second-degree AV block or complete AV block.

Below the Atrioventricular Node

The various forms of conduction abnormalities known to occur below the AV node include Mobitz II second-degree AV block, 2:1 AV block, and RBBB with or without left anterior or posterior

fascicular block. RBBB is much more common than complete LBBB owing to dual supply of various fascicles of the left bundle and a wide area of distribution within the myocardium. The clinical prognosis is worse when RBBB plus LAFB is the result of the MI, predicting early death owing to pump failure.⁹

Complete heart block with inferior MI generally results from an intranodal lesion. It is associated with a narrow QRS complex, and develops in a progressive fashion from first-degree to second-degree to third-degree block (Fig. 21-1). It often results in asymptomatic bradycardia (40 to 60 beats/min) and is usually transient, resolving within 5 to 7 days. LBBB occurs as a form of aberration during bradycardia—either sinus bradycardia or AV block with a junctional escape mechanism. Complete heart block with anterior MI generally occurs abruptly in the first 24 hours. It can develop without warning or may be preceded by the development of RBBB with either LAFB or LPFB (bifascicular

or trifascicular block) (Fig. 21-2).³ The escape rhythm is wide and unstable, and the event is associated with a high mortality (approximately 80%) from arrhythmias and pump failure. Heart block in this setting is thought to result from extensive necrosis that involves the bundle branches traveling within the septum.

Inferior Wall Myocardial Infarction versus Anterior Wall Myocardial Infarction

High (second or third) degree AV block associated with inferior wall MI is located above the His bundle in 90% of patients.¹⁰ For this reason, complete heart block often results in only a modest and usually transient bradycardia with junctional or escape rhythm rates greater than 40 beats/min (Fig. 21-3). It is common, however, for the junctional pacemaker that controls the ventricles to accelerate greater than 60 beats/min. The QRS is narrow in this setting and is associated with a low mortality.

Figure 21-1. Mobitz type I atrioventricular block and inferior myocardial infarction. (Courtesy of Ary Goldberger, MD.)

Figure 21-2. The 12-lead ECG from a patient with a history of an anteroseptal myocardial infarction (Q waves seen in lead V₁-V₃) shows a typical right bundle branch block and left anterior fascicular block.

Figure 21-3. Sinus rhythm with high-grade atrioventricular block. (Courtesy of Ary Goldberger, MD.)

High-degree AV block associated with anterior MI is more often located below the AV node (more frequently within the His bundle or proximal bundle branches).¹¹ It is usually symptomatic and has been associated with a mortality rate approaching 80% largely because of greater loss of functioning myocardium. The current mortality may be less because of improvements in the management of congestive heart failure and cardiogenic shock, but the risk remains substantial.

Mortality

High-degree AV block is associated with increased mortality in patients with inferior or anterior MI. Most of the increased risk is within the first 30 days.¹² High-degree AV block in patients with an anterior wall MI is associated with a greater increase in in-hospital and 30-day mortality than seen with an inferior wall MI, probably because of more extensive myocardial involvement and a higher incidence of hemodynamic complications.¹³

The presence of a fascicular or bundle branch block during an acute MI is associated with an increased in-hospital and long-term mortality. The 30-day mortality is significantly increased only in patients with a RBBB at baseline and an anterior MI and in patients with a new LBBB or new RBBB with an anterior MI. Piotrowicz and colleagues¹⁴ noted that patients with LBBB, RBBB, or indeterminate ventricular conduction disturbances show longer repolarization duration than patients without these conduction disturbances. Q-T and J-T intervals (as measured by Rautaharju Q-T and J-T (R-R) formulas) significantly and independently predict mortality in patients after MI with conduction disturbances. The authors have noted no evidence of LBBB among 200 consecutive cases of left anterior descending artery percutaneous coronary intervention in the setting of anterior acute MI (personal observation).

Management

Patients with two or more of the following new findings are at 25% to 36% risk of progression to complete heart block: P-R prolongation, second-degree AV block, left anterior or posterior fascicular block, LBBB, and RBBB.¹⁵

Acute Management

In case of ventricular asystole, which is quite rare, prompt resuscitative measures, including chest compressions, atropine, vasopressin, epinephrine, and temporary pacing, should be administered.

Temporary Pacemaker

The purpose of temporary transvenous pacemaker insertion is to maintain circulatory integrity by providing for standby pacing should sudden complete heart block ensue, to increase heart rate during periods of symptomatic bradycardia, and occasionally to control sustained supraventricular or ventricular tachycardia.¹⁶ Whether ventricular or AV pacing should be used depends on hemodynamic considerations. Performance of AV temporary pacing requires additional experience and can be considerably more difficult from a technical standpoint. Because temporary pacemakers are manufactured by many different vendors, physicians credentialed to insert temporary pacemakers should be familiar with the insertion equipment, leads, and external generator used in their own hospitals.

Class I indications for temporary pacing during ST segment elevation myocardial infarction (STEMI) include any complete heart block or alternating LBBB/RBBB, Mobitz II second-degree AV block during anterior STEMI in the presence of fascicular block plus RBBB or new bundle branch block. Class IIa indications during STEMI include any second-degree AV block with new bundle branch block or fascicular block plus RBBB. STEMI with old bundle branch block in the presence of Mobitz II second-degree AV block, and anterior STEMI with fascicular block and Mobitz II second-degree AV block are also class IIa indications. Contraindications to the procedure are few and include the patient's inability to cooperate and lack of therapeutic benefit because of advanced disease. Several approaches to the central venous system have been used, including internal jugular vein, subclavian vein, and femoral vein. Most complications are infrequent and usually minor. Life-threatening complications are rare. Minor complications, such as nonsustained arrhythmias and local phlebitis, are common.

Atrioventricular Nodal Blockers

β blockers are not contraindicated in the presence of prolonged AV conduction (the dose should be decreased), but are a relative contraindication in patients with second-degree block or higher degrees of block. Drugs are usually "related" to the conduction disturbances, but are not the "cause."

Permanent Pacemaker

Indications for permanent pacing are described in detail in Table 21-1.¹⁷

Standard Indications

There is general agreement that placement of a permanent pacemaker after an acute MI is appropriate in the following circumstances:

1. Third-degree AV block within or below the His-Purkinje system
2. Persistent second-degree AV block in the His-Purkinje system, particularly with evidence of extensive conduction disease in the His-Purkinje system (e.g., RBBB with LAFB, RBBB with LPFB, or alternating RBBB and LBBB)
3. Transient advanced infranodal AV block in association with a bundle branch block that is believed to be due to the infarction
4. Symptomatic and persistent second-degree or third-degree AV block at any level

Indications for permanent pacing after STEMI in patients experiencing AV block are related in large measure to the presence of intraventricular conduction defects. In contrast to some other indications for permanent pacing, the criteria for patients with STEMI and AV block do not depend on the presence of symptoms. The requirement for temporary pacing in STEMI does not by itself constitute an indication for permanent pacing. There is general agreement that pacemakers are unnecessary in the following situations:

1. Transient AV block, with or without associated conduction defects (e.g., LAFB). These transient phenomena usually occur in the setting of inferior MI. In the less common situation when transient AV block occurs after an anterior MI, pacemaker implantation may be considered.
2. Acquired LAFB in the absence of AV block
3. P-R prolongation in the presence of bundle branch block that is not believed to be caused by MI

Table 21-1. Use of Permanent Pacemakers**Permanent Pacing for Bradycardia or Conduction Blocks Associated with ST Segment Elevation Myocardial Infarction (STEMI)****Class I**

1. Permanent ventricular pacing is indicated for persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third-degree AV block within or below the His-Purkinje system after STEMI (*level of evidence: B*)
2. Permanent ventricular pacing is indicated for transient advanced second-degree or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary (*level of evidence: B*)
3. Permanent ventricular pacing is indicated for persistent and symptomatic second-degree or third-degree AV block (*level of evidence: C*)

Class IIb

1. Permanent ventricular pacing may be considered for persistent second-degree or third-degree AV block at the AV node level (*level of evidence: B*)

Class III

1. Permanent ventricular pacing is not recommended for transient AV block in the absence of intraventricular conduction defects (*level of evidence: B*)
2. Permanent ventricular pacing is not recommended for transient AV block in the presence of isolated left anterior fascicular block (*level of evidence: B*)
3. Permanent ventricular pacing is not recommended for acquired left anterior fascicular block in the absence of AV block (*level of evidence: B*)
4. Permanent ventricular pacing is not recommended for persistent first-degree AV block in the presence of bundle branch block that is old or of indeterminate age (*level of evidence: B*)

Sinus Node Dysfunction after STEMI**Class I**

1. Symptomatic sinus bradycardia, sinus pauses >3 sec, or sinus bradycardia with heart rate <40 beats/min and associated hypotension or signs of systemic hemodynamic compromise should be treated with an intravenous bolus of atropine, 0.6 to 1 mg. If bradycardia is persistent and maximal (2 mg) doses of atropine have been used, transcutaneous or transvenous (preferably atrial) temporary pacing should be instituted (*level of evidence: C*)

AV, atrioventricular.

From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: executive summary: a report of the ACC/AHA Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines on the Management of Patients with Acute Myocardial Infarction). *J Am Coll Cardiol* 2004;44:671-719.

When a permanent pacemaker is being considered for a post-STEMI patient, the clinician should address two additional questions regarding the patient: Is there an indication for biventricular pacing, and is there an indication for implantable cardioverter-defibrillator use? There are well-established criteria for patients who need implantable cardioverter-defibrillators and biventricular pacemakers more than several months after MI, but the criteria are not established for patients who need pacemakers within 1 month after MI. In patients with MI who presented with bifascicular block with or without complete heart block, if they survived cardiogenic shock, there was a 30% incidence of aneurysm formation associated with increased frequency of ventricular tachycardia and ventricular fibrillation several weeks after MI.

Distal Embolization
Stent Infection
Contrast-induced Nephropathy and Other Contrast Toxicities
Metformin
Complications of Valvular Interventions

SINCE THE advent of percutaneous transluminal coronary angioplasty (PTCA), percutaneous coronary intervention (PCI) procedures have become part of daily clinical practice.¹⁻⁵ Currently, more than 1 million procedures are performed in the United States annually. The immediate success rates of PCI are greater than 95 percent.⁶⁻⁸ Adverse outcomes after PCI have declined significantly over the last 15 to 20 years because of improvement in adjunctive pharmacotherapies and device technologies. The incidence of emergent coronary artery bypass graft (CABG) surgery after PCI decreased significantly to 0.14% in 2000.⁹ In the American College of Cardiology (ACC)–National Cardiovascular Data Registry PCI database, of more than 550,000 PCIs performed between January 2001 and December 2004 for reasons other than ST segment elevation myocardial infarction (MI), the observed frequencies of death, MI, unplanned CABG surgery, and major cardiovascular complications were 0.76%, 1.1%, 0.6%, and 2.4%.¹⁰ Observations from Europe were similar with an overall unadjusted mortality of less than 2% in all patients and mortality of 0.36% to 3.25% in nonemergency compared with emergency cases.¹¹

Not every adverse clinical outcome during and after PCI is a complication of the procedure itself. Adverse events are often the result of the natural history of the disease that initially led to the intervention. This notion is exemplified by the extremely low rate of adverse events in young patients with normal left ventricular function compared with greater than 50% mortality in older patients presenting with cardiogenic shock.^{12,13}

Any attempt at unraveling the risks associated with PCI must deal with the complex interplay of factors relating to the procedure itself and the natural history of the underlying disease occurring in a patient with unique baseline clinical characteristics. Numerous risk models that quantified the risk of major complications have been developed and validated to identify a group of patients with underlying higher risks associated with PCI by using readily available clinical and angiographic characteristics from large databases.¹⁴⁻²⁰ Various scoring systems have been derived from these models allowing clinicians and patients to appreciate the risks in a semiquantitative manner before the procedure (Table 22-1).

These risk models confer good relative predictive accuracy and discriminatory ability in identifying increased risk associated with PCI for the overall cohort from which they were derived. Most of these models, however, lack serial external calibration over time to ensure their continued reliability in contemporary cohorts. The incidence of abrupt vessel closure, one of the dreaded complications in the early years of PTCA, now occurs in less than 1% of all procedures. During this period, potentially fatal complications, such as stent thrombosis, which occurs at a later point in time than abrupt vessel closure, came into existence as a result of novel technologies.²¹⁻²³

Characteristics Predictive of High Risk for Adverse Outcome

Patient Clinical Characteristics

Clinical factors associated with an increased risk of an adverse outcome after PCI as identified by all the models include advanced age, poor left ventricular systolic function, acute coronary syndrome, chronic renal insufficiency, heart failure, peripheral vascular disease, and multivessel coronary disease. Of these characteristics, cardiogenic shock is the most powerful predictor of death after PCI. Patients with impaired renal function, particularly in the presence of diabetes, are at increased risk for contrast-induced nephropathy.²⁴

Target Lesion Anatomic Factors

Particular lesion morphologic characteristics that are predictive of immediate outcome with PCI in these models include multivessel disease, presence of thrombus, left main coronary artery disease, left main intervention, and ACC/American Heart Association (AHA) type C lesion classification (Table 22-2).²⁵ More recent experience indicates that improved devices and techniques have higher success rates in more complex lesions.^{26,27} As a result, lesion morphology is now less predictive of complications than it had been in the past. The Mayo Clinic risk score offers significantly better prediction for cardiovascular

complications than the ACC/AHA classification. Lesion classification by ACC/AHA classification is a better predictor for angiographic success, however.²⁸ In the current PCI device era, the simpler Society for Cardiovascular Angiography and Interventions (SCAI) classification using the seven variables listed earlier predicted interventional success and complications better than the ACC/AHA classification (Table 22-3).²⁹

Classification of Complications

The American College of Cardiology Foundation/AHA/SCAI clinical competence statement proposed classification of complications related to PCI into eight basic outcome categories and three mechanistic categories.³⁰

Outcome Categories

For the purpose of assessing clinical competence, complications may be divided into eight basic outcome categories, as follows:

1. Death—related to the procedure, regardless of mechanism
2. Stroke
3. MI—related to the procedure, regardless of mechanism
4. Ischemia requiring emergency CABG surgery—resulting from either procedure failure or a procedure complication
5. Vascular access site complications
6. Contrast agent nephropathy
7. Excessive bleeding, requiring treatment
8. Other (e.g., coronary perforation and tamponade)

Mechanistic Categories

The three mechanistic categories of complications are as follows:

1. *Coronary arterial injury* can occur when devices are introduced into coronary vessels or result from embolization of thrombotic or atherosclerotic material. Examples include coronary dissection, thrombosis, perforation, and embolization.
2. *Other vascular events* are caused by injury to a peripheral vessel by catheter insertion, manipulation, or removal, or

by embolization of thrombotic or atherosclerotic material. Examples include false aneurysm, retroperitoneal hemorrhage, arteriovenous fistula, and stroke.

3. *Systemic nonvascular adverse events* are caused by the procedure, but are not due to vascular injury. They include all the systemic hazards of cardiovascular radiographic angiography procedures. Examples include contrast agent–induced nephropathy, anaphylactoid reactions, and acute pulmonary vascular congestion.

Recognizing and stratifying risk factors associated with adverse clinical outcomes in an individual patient, and prompt diagnosis and treatment of these complications are integral to daily practice of interventional cardiology. This chapter discusses mechanistic complications of PCI, which together constitute one facet of potential adverse outcomes of PCI (Table 22-4).

Perforation

Perforation or vessel rupture associated with PCI is a rare complication that can potentially result in a catastrophic clinical outcome, particularly if it is not recognized. The incidence has remained constant over the years, ranging from 0.2% to 0.8%.³¹⁻³⁵ Coronary artery perforation accounts for 20% of emergent CABG surgery after PCI.³⁶ The clinical spectrum of perforation extends from small extraluminal extravasation of blood to frank rupture of the epicardial coronary vessels leading to cardiac tamponade and acute hemodynamic collapse. Device oversizing, wire trauma, and atherectomy have been the most frequent causes of perforations since the early days of angioplasty.³⁷⁻³⁹

Coronary perforations are traditionally classified according to the morphologic appearance and degree of extravasations present on the coronary angiogram. Ellis and associates³¹ proposed the following classification: type I, crater extending outside the lumen only in the absence of linear staining suggestive of a dissection; type II, pericardial or myocardial blush without a visible exit hole (≤ 1 mm); type III, frank streaming of contrast material

through an exit hole greater than 1 mm, and perforation into an anatomic cavity chamber such as the coronary sinus or the right ventricle (Table 22-5).

The mortality and morbidity of perforations vary according to the severity of the perforation. The rates of 19% mortality and 63% cardiac tamponade have been reported after type III perforations.³¹ Mortality of 60% has been associated with rapidly developing pericardial tamponade that occurs within the first 20 minutes.⁴⁰ In a more recent series, overall mortality from perforation ranged from 2.5% to 8%.^{34,41} Mortality after type III perforations seemed to remain high over the years (22% to 44%).^{42,43}

Cardiac tamponade after PCI may often be delayed and can occur outside the catheterization suite.⁴⁴ Not all cases of cardiac tamponade owing to hemopericardium are attributable to vessel perforations, however. Spontaneous bleeding into the pericardium after the use of anticoagulants even in the absence of PCI has been described, as has perforation of the right ventricle by percutaneous temporary pacemakers.^{45,46}

Perforations can occur as a result of guidewires, balloons, stents, or atherectomy devices (rotational and directional). One study reported that type 1 and 2 perforations are predominantly caused by hydrophilic or stiff guidewires and rarely require pericardial drainage or surgical intervention, whereas type 3 perforations are more often associated with stent and device use.⁴² The following factors have been associated with this complication in observational data from large consecutive series of patients.

Complex Coronary Anatomy

PCI of chronic total occlusions is arguably the most common angiographic characteristic associated with coronary perforation in contemporary practice. It has been reported that PCI of chronic total occlusions is responsible for 17% of all coronary perforations.⁴⁷ Complex coronary anatomy including calcifications, chronic total occlusion, tortuosity of the vessel, and ostial location is also associated with coronary perforations. Lesions

located on bends and bifurcation are predisposed to perforation, especially after atherectomy procedures.⁴⁸ Traditionally, perforation of part of the venous bypass grafts or of the native vessel beyond the grafts is said to be less likely to be associated with cardiac tamponade secondary to mediastinal scar related to postoperative reaction.³² Occurrence of cardiac tamponade after perforation of a saphenous vein graft has been reported, however.⁴⁹⁻⁵¹

Table 22-5. Anticipated Clinical Outcomes Based on Type of Perforation

Ellis Type	Cardiac Tamponade (%)	MI (%)	CABG Surgery (%)	Death (%)

From Klein LW: Coronary artery perforation during interventional procedures. Cathet Cardiovasc Interv 2006;68:713-717.

Devices

Hydrophilic guidewires and extra-stiff guidewires are most often associated with perforation.^{33,42} Witzke and colleagues³⁴ reported that of 39 cases of coronary perforation among 12,658 patients undergoing PCI during the period 1995-2003, 20 cases (51%) were due to guidewires. Oversizing of the balloon or stents in relation to the vessel diameter is also an important cause of perforation.⁴¹ Since they were first introduced, debulking devices, such as rotablation, directional coronary atherectomy, and laser atherectomy, are associated with a higher incidence of perforation compared with balloon angioplasty.^{31,34,52}

Glycoprotein IIb/IIIa Inhibitors

Even though there were concerns that glycoprotein (GP) IIb/IIIa inhibitors, which are potent antiplatelet drugs, would increase the clinically apparent incidence of perforation during PCI, no studies show an association of increased incidence of perforation or higher adverse events after perforation with these agents. Nonetheless, when perforation is diagnosed, GP IIb/IIIa inhibitors should be discontinued, and platelet transfusions should be implemented if there is evidence of hemodynamic compromise.

Management

Management of patients with coronary artery perforation depends on the extent of the perforation. When coronary perforation is recognized by angiography, treatment strategies are dictated by the extent of perforation and hemodynamic status of the patient. Treatment strategies consist of isolating the perforation and stopping the bleeding, and treating cardiac tamponade. Boluses of intravenous fluid or pressors or both should be started, especially when a decrease in blood pressure is observed, to provide higher venous filling pressure of the right heart chambers. Inotropic agents are not usually helpful because the left ventricle is already hyperdynamic.

Echocardiography to evaluate the extent and physiology of tamponade must be done without delay. Right heart catheterization may also be useful in this setting for continuous monitoring. Pericardiocentesis should be performed promptly for any hemodynamically significant effusion.

Cardiac tamponade may be immediate, and urgent pericardiocentesis may be necessary. Consequently, a pericardiocentesis tray should be made available as soon as a perforation is recognized. Tamponade may be delayed, however, and it is crucial that patients who were seemingly successfully managed

after coronary perforation be closely monitored after the procedure. Occasionally, follow-up angiography to confirm that the communication is sealed may be helpful. In patients with tamponade, serial echocardiography to exclude reaccumulation of pericardial fluid is prudent. In the catheterization laboratory, anticoagulation is discontinued, and prolonged low-pressure balloon inflations are performed in an effort to “seal” the perforation. In limited perforations, this approach was successful for most patients.⁵³ In contrast, larger perforations that often result in tamponade and ischemia frequently require emergency surgical intervention.

Clinical symptoms of perforation include severe chest pain, tachycardia, and hypotension if tamponade ensues. Vagal-mediated symptoms such as nausea and vomiting may occur because of acute increases in pericardial pressure. Persistence of ST segment elevation after balloon inflation is often observed. Occasionally, perforations that occur during balloon inflation are characterized by abrupt expansion of the balloon and rapid decrease in the inflation pressure. In type I perforations, hemodynamic compromise is uncommon. Deployment of a stent is useful over the perforation in vessels larger than 2 mm in diameter followed by close monitoring of patients with repeat echocardiography in a few hours. In smaller vessels, observation alone may be sufficient.^{35,54}

When cardiac tamponade occurs as a result of larger perforation, wire position must be retained, and balloon tamponade of the vessel proximal to or overlying the site of perforation should be carried out without delay. Prolonged inflation of the balloon (10 to 15 minutes) along with cessation of anticoagulation is occasionally sufficient to arrest the bleeding in moderate-sized perforations.

Covered Stents

When the above-described measures fail, placement of a polytetrafluoroethylene (Dacron)-covered stent usually offers a quick, effective solution even for large perforations. The GraftMaster (JoMed, Abbott Vascular, IL, USA) is one such stent. It is made of two stainless steel stents with a layer of polytetrafluoroethylene in between. Because of its larger profile, a 7F guide catheter is required. The available sizes range from 3 to 5 mm in diameter and 12 to 26 mm in length. Postdilation with a noncompliant balloon is essential to ensure the full deployment of the inner stent. Intravascular ultrasound may be useful in this setting to guide optimal stent apposition.

Although initial retrospective studies did not show a decreased incidence of adverse events with this approach,⁴³ multicenter retrospective series have subsequently reported a 97% procedure success rate in a selected population.⁵⁵ Long-term data are not yet available to assess postdischarge thrombosis, restenosis, and vessel reocclusion and endoleak owing to jailing of side branches. Long-term therapy with dual antiplatelet therapy consisting of aspirin and thienopyridines is empirically recommended.

Other Mechanical Measures

Distal vessel embolizations (as in some guidewire perforations) performed with thrombin injection, absorbable gelatin sponge (Gelfoam) particles, polyvinyl alcohol particles, or microcoils have also been described, especially for small vessels.⁵⁶⁻⁵⁹ The incremental advantage, if any, of these techniques remains unknown.

Emergency Coronary Artery Bypass Graft Surgery

Most perforations can be treated without cardiac surgery. The need for emergent CABG surgery and futility of continuing a nonsurgical approach must be promptly recognized, however. Timely referral for bail-out emergent CABG surgery should be made before protracted hemodynamic compromise renders the condition into an irreversible downward spiral, and not as a last-ditch rescue effort to save the various available percutaneous options that have been exhausted.

Abrupt Vessel Closure

Periprocedural vessel occlusion is an important source of morbidity and mortality after percutaneous revascularization. It occurs primarily as a result of acute coronary dissection, thrombosis, or, most often, a combination of both. About 2% to 11% of patients in the early angioplasty era, depending on definitions used and populations studied, have been reported to experience complications.^{60,61} From the 1985-1986 National Heart, Lung, and Blood Institute (NHLBI) Angioplasty Registry comprising 1801 patients, 20% of procedure-related deaths, 40% of MIs, and 25% of all emergency CABG operations occurred in the 6.8% of patients who sustained abrupt closure.⁶² Late adverse events are also increased in patients with successfully treated closure.⁶³ By 6 months, 45.9% of these patients had CABG surgery, 41% had MIs, and 6.6% had died. Following the routine use of intracoronary stents and aggressive periprocedural antiplatelet therapies, the incidence of abrupt closure has decreased in recent years to less than 1% for all PCIs. This low rate seems to have remained unchanged in the era of drug-eluting stents.⁶⁴

Mechanisms, Timing, and Risk Factors Associated with Threatened Acute Coronary Closure

Two important mechanisms of abrupt closure—acute thrombus formation and coronary dissection—often occur together. The underlying mechanism is probably multifactorial, involving a combination of vessel dissection, elastic recoil, local thrombosis, activation of proinflammatory cytokines, vasospasm, and formation of intramural hematomas. The relative contribution of each of these factors varies from patient to patient, and probably varies with the coronary revascularization technology being applied. Abrupt closure is often preceded by either dissection or thrombus formation before distal coronary flow ceases completely, and this condition is termed *threatened acute coronary closure*.

About 75% of abrupt vessel closures occur during the PCI, and most of the remainder occur within the first 24 hours after the procedure. In the early days of PTCA, the incidence of closure was 4.9% to 5.6% within the laboratory, decreasing to less than 2% after the patient leaves the laboratory.⁶⁵ Because most patients are discharged within 24 hours after PCI, ascertainment of late abrupt closure may be less reliable. A vulnerable period for abrupt closure is during and after sheath removal, when anticoagulation has been withdrawn, and vagal-mediated hypotension and hemorrhagic volume depletion may occur.^{66,67}

Numerous investigators have attempted to identify clinical, angiographic, and procedural factors that are associated with abrupt closure in the present era.⁶⁸⁻⁷⁰ Those studies identified many clinical, preangiographic and postangiographic findings and lesion characteristics predictive of abrupt closure. From these studies, the strongest predictor of abrupt closure was the

angiographic finding of preexisting presence of a thrombus.⁷¹ Unstable angina, acute coronary syndrome, and acute MI were also shown to be predictive of abrupt closure. Other clinical risk factors included female sex, diabetes mellitus, and high surgical risk. Angiographic features such as multivessel disease, multiple stenoses in the same vessel, long lesions, severe angulations (>45 degrees), and lesion at branch point were also identified as high risk. In addition, postintervention angiographic observations, such as presence of intimal dissection, residual thrombus, or postprocedure stenosis greater than 35%, were shown to be associated with the complication.

Preventive Measures

Preventive measures consist of mechanical measures to prevent or limit dissection and pharmacologic measures to prevent intracoronary thrombus formation, sometimes as “foundation antithrombotic therapy” and sometimes as adjuncts after a dissection has occurred.

Mechanical Measures

Coronary dissection can occur as a result of guide catheter or wire trauma, but it occurs most frequently after balloon inflation. The presence of dissection is usually sufficient indication for placement of a coronary stent in current practice. Before the availability of intracoronary stents, not all dissections led to abrupt vessel closure. There is a morphologic classification of acute coronary dissection designed with a view to predicting the chance of development of abrupt closure.⁷² This information is still relevant in the current era because the situation may arise where stent placement is not technically feasible or indicated (Table 22-6).

The introduction of coronary stenting for treatment of acute threatened closure after PTCA resulted in reduction in need for emergency CABG surgery after failed angioplasty.^{73,74} This initial success rate of 93% to 98% in treatment of acute threatened closure or abrupt closure by using early-generation stents was at first offset by subacute stent thrombosis, which was reported to occur in 8% to 16% of patients. Over the ensuing years, improvement in adjunctive pharmacotherapies and device technologies seemed to reduce the need for urgent CABG surgery to less than 1% in contemporary series.⁷⁵⁻⁸³

Diagnosis and Management of Abrupt Closure

The management of abrupt closure or acute threatened closure requires prompt diagnosis followed by restoration of blood flow of the affected vessel. When coronary blood flow becomes compromised, accompanying electrocardiogram (ECG) changes, chest pain, fluctuation in blood pressures, and arrhythmias usually follow, depending on underlying clinical conditions of the patients and degree of acute compromise of blood flow to the dependent myocardium. For patients who develop symptoms consistent with abrupt closure after the procedure, emergency coronary angiography is indicated. In 104 patients with abrupt vessel closure, clinical manifestations included recurrent chest pain (97%), ST segment elevation (77%), ST segment depression (13%), hypotension (20%), and ventricular fibrillation (10%).⁶⁵

Table 22-6. Classification of Dissection

Type	Description	Acute Closure (%)
A	Minor radiolucencies within lumen during angiography without dye persistence	0-2
B	Parallel tracks or double lumen separated by radiolucent area during angiography without dye persistence	2-4
C	Extraluminal cap with dye persistence	10
D	Spiral luminal filling defects	30
E	New persistent filling defects	9
F	Non-A-E types that lead to impaired flow or total occlusion	69

From Huber MS, Mooney JF, Madison J, Mooney MR: Use of a morphologic classification to predict clinical outcome after dissection from coronary angioplasty. *Am J Cardiol* 1991;68:467-471.

When the diagnosis is confirmed, the occluded coronary segment must be recrossed with a guidewire, which can be technically challenging because the wire may follow a dissection plane into the false lumen. It is imperative to maintain the activated coagulation time (ACT) within the “therapeutic range.” The target ACT should be in the range of 250 to 300 seconds with HemoTec device (Medtronic, MN, USA) and 300 to 350 second with HemoChron device (ITC, NJ, USA). For patients who are receiving concomitant GP IIb/IIIa antagonists, a target ACT of 200 to 225 seconds is adequate for both devices.

The mainstay of treatment includes restoration of the patency of the lumen followed by stenting if feasible. Often when flow is restored, a previously unidentified dissection at the margin of a stent or in a balloon-dilated area is recognized. In cases when a stent cannot be delivered to the site of the occlusion, such as in tortuous or rigid vessels, balloon angioplasty of the occluded segment using multiple and prolonged inflations is often successful, although the success rates are lower than for stent placement.^{84,85}

Treatment of Symptoms and Maintaining Stable Hemodynamics

Adequate analgesia should be given at all times while maintaining adequate blood pressure and oxygenation. If blood pressure support is necessary, intravenous boluses of crystalloids or colloid solutions are given initially. Inotropes or pressors may be required. In patients who are hypotensive, it is important to exclude hemorrhage and cardiac tamponade as causes of the hypotension. When sympathomimetic agents such as dopamine or epinephrine are needed, the risk of increasing myocardial oxygen demand must be taken into consideration. Although intracoronary nitroglycerin may be used as a diagnostic test to exclude coronary spasm, there are no data to support the use of intravenous nitroglycerin in this setting. The deleterious effects of vasopressors may be more pronounced in the presence of severe valvular lesions such as mitral regurgitation. Intra-aortic balloon pump counterpulsation may be useful to reduce

myocardial oxygen demand and promote coronary and cerebral perfusion during diastole.

Emergency Coronary Artery Bypass Graft Surgery

Although restoration of coronary flow by percutaneous means is often successful, in cases where the PCI operator knows a priori that no further interventions are likely to succeed, proceeding directly to CABG surgery may be elected.

Air Embolism

Angiographically or clinically evident air embolism occurs in 0.1% to 0.3% of cardiac catheterizations, and it may result in a serious and fatal outcome.⁸⁶⁻⁸⁸ Entrapment of air within the catheters during device introduction or withdrawal, incomplete aspiration of catheters, or aspiration of air through loose connections may result in inadvertent injection of air into the coronary artery. Other mechanisms include balloon rupture and mechanical or structural failures of the equipment. Massive air embolism can also occur during mechanical injection into the left ventricle or aortic root.⁸⁹

Treatment consists of supportive measures with inhalation of 100% oxygen. Oxygen facilitates the outward diffusion of nitrogen from the air bubble by creating a diffusion gradient and improves ischemia. Use of pressors to increase blood pressure so that bubbles are compressed is also recommended. Mechanical interventions such as aspiration and forceful saline injection with successful outcomes have been reported.⁹⁰ In the case of prolonged cardiac arrest, full hemodynamic support with the use of cardiopulmonary bypass has been successfully employed. In this case, the membrane oxygenator may facilitate removal of air from the blood.

Distal Embolization

Distal embolization during PCI ranges from frank distal migration of a visible thrombus or grumous material in a saphenous vein graft to microscopic embolization of atherosclerotic debris.⁹¹ Angiographic distal embolization is believed to be a key mechanism underlying postprocedural non-Q wave MI.⁹²⁻⁹⁵

The term *no-reflow* was originally coined to describe a post-thrombolytic phenomenon in dogs per se, and it has never been characterized precisely in humans.⁹⁶ In the terminology of PCI, the *no-reflow phenomenon* loosely refers to a failure to restore blood flow despite successful treatment of the luminal obstruction. It has been reported to occur in 2% to 3% of PCIs, and is more likely during intervention for acute MI and in saphenous vein grafts.⁹⁷ It is an independent predictor of death and MI.⁹⁸ Numerous factors account for no-reflow, such as microvascular vasoconstriction, reperfusion injury, and endothelial damage, in addition to embolization of atheromatous and thrombotic debris to the microcirculation.

Several strategies to limit the degree of embolization and no-reflow have been examined. Embolic protection devices have been shown to improve clinical outcomes in PCI within saphenous venous grafts. The landmark SAFER trial, examining balloon-occlusive distal protection devices, showed that the primary end point—a composite of death, MI, emergency bypass, or target lesion revascularization by 30 days—was 16.5% in the control group versus 9.6% in the embolic protection device group. This 42% relative reduction in major adverse cardiac

events was largely a consequence of reduction in MI and in the no-reflow phenomenon.⁹⁹ This trial has served as a standard according to which other embolic protection devices have been judged.^{100,101} Conversely, embolic protection devices have not been shown to improve clinical outcomes in PCI for ST segment elevation MI.¹⁰²⁻¹⁰⁴ There is no evidence to advocate routine use of these devices in PCI outside the realm of saphenous vein graft intervention.

Another strategy includes removal of thrombus by mechanical devices such as catheters and rheolytic thrombectomy directly from the coronary vessels. Several such thrombectomy devices are available, including AngioJet (Possis Medical, Minneapolis, MN), Export Catheter (Medtronic, Santa Rosa, CA), Diver CE (Invatec, Roncadelle, Italy), and Pronto Catheter (Vascular Solution, Minneapolis, MN). Numerous studies consistently showed favorable outcomes in surrogate end points such as improved myocardial blood flow, improvement in ST segment changes, and lower incidence of angiographic evidence of distal embolization and no-reflow.¹⁰⁵⁻¹⁰⁷ In the DEAR-MI study, 148 consecutive patients with ST segment elevation MI who underwent primary PCI were randomly assigned to manual thrombus aspiration using the Pronto Catheter or standard treatment. Complete ST segment resolution (68% versus 50%), myocardial blush grade III (88% versus 44%), corrected TIMI frame count (17.3 ± 6 versus 21.5 ± 12), no-reflow (3% versus 15%), angiographic embolization (5% versus 19%), and peak creatine kinase-MB (790 ± 132 $\mu\text{g/L}$ versus 910 ± 128 $\mu\text{g/L}$) all were in favor of aspiration catheter.¹⁰⁸

In a similar context, contrast-enhanced magnetic resonance imaging (MRI) was performed to evaluate microvascular damage and infarct size at days 3 and 30 in patients presenting with ST segment elevation MI (<9 hours from symptom onset) with angiographically confirmed occlusive thrombus. Seventy-five patients were randomly assigned to either thrombus aspiration followed by stenting or conventional stenting. A reduction in microvascular damage and infarct size at 30 days compared with the acute evaluation at day 3 was observed only in the thrombus aspiration group.¹⁰⁹

Although this strategy of adding mechanical thrombectomy seems attractive for improving reperfusion and survival after primary angioplasty for ST segment elevation MI, the definitive clinical benefit of this approach remains inconclusive. Most early studies failed to show any substantial clinical benefits, such as reduction of infarct size, improvement of left ventricular performance, or reduction in adverse cardiac events, by using various forms of this adjunctive approach in ST segment elevation MI even in the presence of a visible thrombus at least in the short-term follow-up.¹¹⁰⁻¹¹³

In the single-center TAPAS study, 1071 patients were randomly assigned to the thrombus aspiration group or the conventional PCI group before undergoing coronary angiography. Aspiration with the Export Catheter was considered to be successful if there was histopathologic evidence of atherothrombotic material. A myocardial blush grade of 0 or 1 was in 17.1% of the patients in the thrombus aspiration group versus 26.3% of patients in the conventional PCI group. Complete resolution of ST segment elevation occurred in 56.6% of patients in the thrombus aspiration group versus 44.2% of patients in the conventional PCI group. At 30 days, the rates of death in patients with a myocardial blush grade of 0 or 1, 2, and 3 were 5.2%, 2.9%, and 1%, and the rates of adverse events were 14.1%, 8.8%, and 4.2%.

This landmark study showed that thrombus aspiration is applicable in most patients with MI with ST segment elevation, and it resulted in better reperfusion and clinical outcomes than conventional PCI regardless of clinical and angiographic characteristics at baseline.¹¹⁴ These findings suggest there may be incremental late benefit associated with mechanical reduction of thrombus burden over and above the routinely employed strategy of primary PCI along with aggressive antiplatelet and antithrombin therapies by further improving perfusion at tissue level during the acute phase.

Treatment

It is important that an adequate ACT be maintained, and GP IIb/IIIa inhibitors can be used as a bailout measure. Although intracoronary nitrates are not shown to have any role in the treatment of no-reflow, they may be given as first-line therapy to relieve vasospasm of epicardial vessels. Intracoronary verapamil, adenosine, and nitroprusside are the first-line drugs for no-reflow because arteriolar vasodilation may allow embolized material to track further downstream, lessening the area subtended by the occluded vessels.

Piana and colleagues¹¹⁵ showed that verapamil (50 to 900 µg) improved intracoronary flow in 89% of patients. Other studies showed similar successful results in degenerated vein grafts and after rotational atherectomy.^{116,117}

Bolus doses of adenosine, 10 to 20 µg, have also been used in this setting as a distal arteriolar vasodilator.^{118,119} Intracoronary sodium nitroprusside in boluses of 50 to 200 µg have been reported to be useful despite a relative paucity of objective evidence.¹²⁰ Intracoronary administration of epinephrine (50 to 200 µg) has been used successfully in refractory cases.¹²¹ Data from post-hoc analysis of pivotal trials have not suggested that GP IIb/IIIa antagonists effectively prevent no-reflow during saphenous vein graft intervention. Embolization of non-thrombotic material may cause elevation in creatine kinase-MB, however, masking an effect of GP IIb/IIIa on decreasing events. A more recent study suggested there is an incremental beneficial role of GP IIb/IIIa in addition to routine use of an embolic protection device during saphenous vein graft intervention.¹²² Other agents given through the intracoronary route, including diltiazem, papaverine, nicardipine, and nicorandil, have been assessed with variable results.¹²³⁻¹²⁷ Intracoronary heparin and thrombolytics (e.g., urokinase, tissue plasminogen activator) have been proven to be of limited use even with the combination of GP IIb/IIIa inhibitors.^{128,129}

Stent Infection

Infection of a coronary stent is extremely rare.¹³⁰ Infection is typically manifest within 1 month of stent placement, with persistent fever and positive blood cultures suggesting endovascular infection. The patient may also complain of chest pain. There are typically no ECG changes or elevation in cardiac enzymes. This complication has been described after placement of bare metal stents, covered stents, or drug-eluting stents.¹³¹⁻¹³³ *Staphylococcus aureus* has been reported as the responsible pathogen in most cases.¹³⁴ Other organisms, such as coagulase-negative staphylococci, *Pseudomonas aeruginosa*, and *Candida*, have also been implicated.^{135,136}

Infective processes of the stent site often result in mycotic aneurysm formation.¹³⁷ Other complications include abscess

formation and suppurative pericarditis.^{138,139} Stent infection may also lead to septic systemic embolism.¹⁴⁰ Various imaging modalities, such as coronary angiography, MRI, computed tomography, and transesophageal echocardiography, are useful to make the diagnosis.¹⁴¹ Prolonged treatment with intravenous antibiotics alone is usually insufficient, and the condition often necessitates surgical intervention for drainage or resection of a false aneurysm and removal of the stent. The mortality has been reported to be 40%.¹³⁰ There is no evidence to support benefit for a preventive strategy beyond compliance with the current standards of prevention of infection, and routine use of prophylactic antibiotics is not indicated.

Contrast-induced Nephropathy and Other Contrast Toxicities

Currently available ionic contrast agents include hyperosmolar media, such as diatrizoate (Hypaque, Renografin), and the low-osmolar agent, ioxaglate (Hexabrix). Nonionic agents consist of low-osmolar agents, such as iohexol (Omnipaque), iopamidol (Isovue), and ioversol (Optiray), and iso-osmolar agents, such as iodixanol (Visipaque). Complications related to contrast agents can be classified into anaphylactoid reaction, nephrotoxicity, and hemodynamic complications (Table 22-7).

Anaphylactoid Reaction

Severe anaphylactoid reaction is the rarest but most severe contrast-related toxicity. Although the exact etiology of this reaction remains unknown, it is thought to result from mast cell degranulation resulting in activation of complement and kinin release through mechanisms independent of IgE.¹⁴² It may occur on first exposure to contrast agents.¹⁴³ The incidence has been reported as 5% for all reactions (including mild ones) and 0.1% for severe reactions. The risk of a repeat reaction can be 15% in patients with a history of anaphylactoid reaction to an iodinated contrast agent.¹⁴⁴

Clinical features of anaphylactoid reaction range from relatively mild reactions, such as generalized pruritus and urticaria, to bronchospasm, angioedema, vasodilation, and hypotension. Progression to hemodynamic collapse or total airway obstruction may occur in severe cases.

The cornerstone of management of anaphylactoid reaction is prevention: identifying patients at risk and appropriate use of prophylactic pharmacologic agents. Although there are studies suggesting that pretreatment with corticosteroids and antihistamines in unselected patients significantly reduces the incidence of reactions, the usefulness of applying this strategy routinely remains doubtful because numerous patients would need to receive premedication to prevent each potentially serious reaction.^{145,146} This notion was reinforced more recently by a meta-analysis that included nine trials with a total of 10,011 adults. In two trials, 0.4% of patients who received oral methylprednisolone, 32 mg twice, or intravenous prednisolone, 250 mg, had laryngeal edema compared with 1.4% of controls. In two other trials, 0.2% of patients who received oral methylprednisolone, 32 mg twice, had shock, bronchospasm, or laryngospasm compared with 0.9% of controls. In one trial, 0.5% of patients who received intravenous clemastine, 0.03 mg/kg, and cimetidine, 2 to 5 mg/kg, had angioedema compared with 8 of 194 (4.1%)

Table 22-7. Types of Contrast Agents

Product	Type of Contrast Agent Concentration	mg (I/mL)	Osmolality (mOsm/L)
Monomers			
Iohexol (Omnipaque)	Nonionic LOCM	350	844
Iopamidol (Isovue)	Nonionic LOCM	370	796
Ioxilan (Oxilan)	Nonionic LOCM	350	695
Iopromide (Ultravist)	Nonionic LOCM	370	774
Ioversol (Optiray)	Nonionic LOCM	350	792
Dimers			
Iodixanol (Visipaque)	Nonionic IOCM	320	290
Ioxaglate (Hexabrix)	Ionic LOCM	320	600

controls. None of the studies exclusively included patients with a prior history of anaphylactoid reaction.¹⁴⁷

There are no randomized data evaluating the role of prophylactic medications exclusively in patients with a prior history of reaction to contrast media. In a nonrandomized series, only 10.8% experienced reactions after pretreatment with prednisone and diphenhydramine. Transient hypotension occurred in only 0.7% of these patients. The addition of ephedrine to the regimen was associated with an incidence of 5%.¹⁴⁸ Lasser and coworkers¹⁴⁵ showed that methylprednisolone given as two doses, 12 hours and 2 hours before ionic dye exposure, was associated with fewer reactions compared with one dose of corticosteroid 2 hours prior. Based on these studies, treatment with diphenhydramine, cimetidine, or ranitidine before the procedure and preferably two doses of corticosteroids at 12 hours and 2 hours before the procedure is advocated empirically for patients with a previous history of reaction to intravenous contrast agents.

Management of a mild or moderate reaction includes administration of H₁- and H₂- histamine antagonists and fluid resuscitation. In patients who developed a more severe form of reaction during the procedure such as wheezing, laryngospasm, or hypotension, intravenous treatment with 1:10,000 epinephrine, 0.5 to 1 mg intravenously; hydrocortisone, 100 to 200 mg; and intravenous H₁- and H₂- antagonists is indicated. In cases of severe laryngospasm with acute or impending airway compromise, endotracheal intubation or surgical control of the airway may be required.

Contrast-induced Nephrotoxicity

Contrast-induced nephropathy is responsible for 11% of hospital-acquired renal insufficiency, and is the third leading cause of hospital-acquired renal failure. It is associated with significant morbidity and mortality.^{149,150} In 7586 patients undergoing cardiac catheterization, an absolute increase of 0.5 mg over the baseline level of creatinine occurred in 3.3% of patients overall, and in 25% of patients with a baseline serum creatinine greater than 2 mg/dL.¹⁵¹ The serum creatinine becomes elevated on day 2 or 3 after exposure to contrast medium, although the peak usually occurs on day 5 or 6. The creatinine usually returns to the baseline value within 2 weeks.^{152,153} Renal function may not return to its baseline level, however, and development of renal failure after PCI is independently associated with increased mortality.^{154,155}

Moderate to severe chronic kidney disease is the most important risk factor for the development of contrast-induced nephropathy.¹⁵⁶ Other major risk factors include advanced age, diabetes mellitus, higher dose of contrast agent, recent contrast agent administration, concurrent use of nephrotoxic drugs, dehydration, and any other condition associated with decreased effective circulating blood volume and reduced renal blood flow.¹⁵⁷⁻¹⁵⁹ Serum creatinine overestimates actual creatinine clearance, particularly in elderly patients. Treatment of this condition is expectant with conservative measures. Approximately 5% to 10% of patients may require transient dialysis, and about 1% need long-term renal replacement therapy.

Metformin

The insulin-sensitizing drug metformin carries a risk of causing lactic acidosis of 0.03 per 1000 cases per year. Lactic acidosis in this setting is associated with a mortality rate of 50%. Metformin is excreted unmetabolized by the kidneys and may accumulate in patients with renal failure. The half-life of metformin is 2 to 6 hours in healthy individuals. Although metformin use is not a risk factor for nephropathy, there is a concern that the likelihood of lactic acidosis may be higher after contrast-induced nephropathy in patients who are taking metformin.^{160,161} It is recommended that metformin be withheld perhaps at least 6 hours before the procedure, and it is recommended not to resume the therapy until it is clear that renal function has not significantly deteriorated.^{162,163}

Complications of Valvular Interventions

Mitral Balloon Valvuloplasty

Percutaneous mitral balloon valvuloplasty is an effective means of nonsurgical treatment of selected patients with mitral stenosis.¹⁶⁴ Short-term and intermediate-term outcomes of single and double balloon valvuloplasty compare favorably with results of closed and open surgical mitral commissurotomy.¹⁶⁵⁻¹⁶⁹ Mitral valve area is often increased twofold with this procedure, and most patients experience marked alleviation of symptoms.¹⁷⁰ The combined incidence of major events (death, surgery, new percutaneous mitral balloon valvuloplasty) is low in the first 5 years. The frequency of events progressively increases thereafter, however, reaching a total of 47.2% at 15-year follow-up.¹⁷¹

Complications

Complications after mitral valvuloplasty occur primarily as a result of cardiac tamponade, mitral regurgitation, or embolization. In 787 patients enrolled into the NHLBI mitral balloon angioplasty registry, the global incidence of major complications was 12% with a mortality rate of 1.6% at 30-day follow-up.¹⁷² Other series subsequently reported the mortality rate 0% to 3%.¹⁷³

Hemopericardium

The incidence of hemopericardium and cardiac tamponade, at average rates of 1% to 3%, is related to transseptal puncture or perforation of the left ventricular apex by the guidewire or by the balloon itself.¹⁷⁴⁻¹⁷⁶ Left ventricular laceration produces immediate hemodynamic deterioration and requires emergency corrective surgery.^{177,178}

The most frequent complication of valvuloplasty is worsening of preexisting mitral regurgitation. Among reported series of patients, mitral regurgitation develops or worsens in 30% to 40%.¹⁷⁹ Severe mitral regurgitation was an infrequent complication of percutaneous balloon mitral valvuloplasty (7.5% of 280 patients) and resulted from disruption of the valve integrity, including chordal rupture (43%) and leaflet tearing (30%). Heavily calcified posterior leaflets may be at greater risk of tearing, and most patients who develop severe regurgitation (77%) ended up requiring nonemergency mitral valve replacement.¹⁸⁰

Kaul and associates¹⁸¹ performed a retrospective analysis of 3650 patients (median age 26 years). Significant mitral regurgitation (moderate or severe) occurred in 8.4% of patients, of whom 116 (3.2%) required mitral valve replacement urgently or on follow-up. All patients whose mitral regurgitation was due to rupture of valve leaflets (usually the posterior one) required urgent valve replacement.

The occurrence of severe mitral regurgitation depends more on the location and distribution of the morphologic changes of the valve than on underlying severity, rendering prediction of development of severe mitral regurgitation difficult on an individual basis, and echocardiographic scoring systems do not predict the development of mitral regurgitation.¹⁸² Characteristics associated with development of severe mitral regurgitation have been described as heterogeneous valve thickening with thick areas adjacent to normal ones, involvement of the subvalvular apparatus, and discrete calcification in one or both commissures.¹⁸³ In the valves with heavily diseased commissures, the leaflets ruptured at the least affected portions.¹⁸⁴

Residual Left-to-Right Shunting

After successful atrial puncture, a residual atrial septal defect with left-to-right shunting is detectable in 87% of patients by color flow Doppler ultrasound, but only 1% to 2% of patients with atrial septal defect by echocardiography have hemodynamic evidence of significant shunting (ratio between systemic and pulmonary flow >1.5:1).¹⁸⁵ Most of these shunts resolve as left atrial pressure decreases after the procedure and are of no clinical consequence. Large residual atrial septal defects with significant shunting are rare, usually resulting from inadvertent balloon inflation across the interatrial septum.¹⁸⁶ With recurrent valve stenosis, defects may reappear as the left atrial pressure increases, creating a variation of Lutembacher syndrome.¹⁸⁷

Systemic Embolism

The rate of systemic embolism is 0.5% to 3%. Systemic embolism very seldom causes permanent disability, and even more seldom leads to death.¹⁸⁸

Aortic Valvuloplasty

Percutaneous balloon valvuloplasty for aortic stenosis partially improves valvular stenosis and functional status of patients, but is associated with very high restenosis rates.¹⁸⁹ It is usually reserved for elderly, severely symptomatic patients who are not thought to be surgical candidates. These critically ill patients, who often have multiple comorbid illnesses, are at increased risk for procedural complications. Earlier, vascular complication rates were 15% largely because of the large-bore femoral artery access (12F to 14F) required for the valvuloplasty balloons. Access site complications have decreased significantly with the current generation of catheters, however, and following the use of percutaneous closure devices including preclose technique, wherein placement of surgical sutures percutaneously and progressive dilation are undertaken before the placement of the large-bore sheath.^{190,191}

Hemodynamic instability resulting from these complications may be poorly tolerated by these patients. Other potential complications include severe aortic regurgitation (1% to 2%), systemic embolization (1% to 5%), cardiac perforation with tamponade (1% to 4%), MI (1%), and death (2% to 5%). These rates remain unchanged.¹⁹²⁻¹⁹⁵

Vascular Complications after Percutaneous Coronary Intervention

Ioanna Kosmidou, Dimitri Karpaliotis

CHAPTER 23

**Arterial Access and Sheath Removal
Techniques
Hemorrhagic Complications**

**Arteriovenous Fistula
Thrombotic Complications
Infectious Complications**

VASCULAR ACCESS complications are the most common complications (2% to 6%) after diagnostic cardiac catheterization and coronary interventions despite their significant decline over the last decades.^{1,2} Care providers in the coronary care unit (CCU) should be familiar with the incidence, clinical presentation, and appropriate management of these complications. Critically ill patients admitted to the CCU are at high risk for access complications because of the presence of comorbidities such as peripheral vascular disease, renal failure, and advanced age. These patients are also more likely to be heavily anticoagulated, and to have had high-risk, technically demanding procedures on an emergency basis.^{2,3}

In addition, patients are occasionally admitted to the CCU for management of vascular access complications. A thorough understanding of vascular access issues and prompt recognition of these complications are essential to minimize the substantial morbidity and mortality associated with them.

The complications can be categorized as hemorrhagic or thrombotic/occlusive. Hemorrhagic complications include access site bleeding, retroperitoneal hematoma, pseudoaneurysm, arteriovenous fistula, and vessel laceration. Thrombotic complications include arterial thrombosis, distal embolization, dissection, and rarely venous thrombosis or pulmonary embolism. Risk factors include advanced age, female gender, obesity, peripheral vascular disease, use of large arterial sheaths, intensity of anticoagulation including the use of glycoprotein (GP) IIb/IIIa inhibitors, recent thrombolysis, intra-aortic balloon pump counterpulsation, and prolonged duration of time that the sheath remained in place.⁴⁻⁶ Meticulous technique during cardiac catheterization and during the removal of the sheath is essential in reducing the complications rate.

Arterial Access and Sheath Removal Techniques

A focused but detailed clinical examination of the access site before the patient is taken to the catheterization laboratory is essential. The femoral and distal pulses are palpated, and their presence or absence is documented; the groin is auscultated for bruits and inspected for the presence of infections and surgical

scars that point to prior peripheral vascular bypass procedures. In radial artery cases, a modified Allen test is performed using the waveform of the pulse oximeter to detect distal perfusion.

The femoral approach is the site of choice for most operators. The common femoral artery is the point of entry. In most patients, the bifurcation of the common femoral artery is at the level of the mid third of the femoral head.⁷ Time should be taken to palpate the femoral pulse at the site of maximal impulse. This should be 2 cm below the inguinal ligament, which runs across a line connecting the anterior superior iliac spine and the symphysis pubis. We also strongly recommend the use of fluoroscopy to identify the mid third of the head of the femoral bone as an additional point to assist with orientation; this is particularly important in obese patients in whom the skin landmarks can be deceiving. The additional time required for this extra step is worthwhile, and fluoroscopy should be performed even under the most emergent circumstances. Arterial entry above the inguinal ligament predisposes to retroperitoneal hematomas, whereas low entry predisposes to formation of pseudoaneurysms and arteriovenous fistulas.⁸

Front wall technique should be used. The use of the smallest arterial sheaths that would allow for optimal performance of the percutaneous coronary intervention should be used because it has been shown that larger sheaths are associated with higher incidence of hemorrhagic and occlusive/thrombotic complications.⁹ Patients after fibrinolysis and patients who have been heavily anticoagulated should be catheterized by the most experienced operators. Patients anticoagulated with warfarin should ideally wait until the international normalized ratio (INR) is less than 1.5, although in emergency situations with good access technique and careful sheath removal or the use of closure devices by experienced operators, an INR of 2 to 3 is not an absolute contraindication to the procedure.¹⁰

Patients with severe peripheral vascular disease often are a challenge. Femoral artery atherosclerosis and calcification, iliac tortuosity, and stenosis make arterial access difficult and pose problems to wire advancement, sheath insertion, and catheter manipulation. In situations such as this, when there is any question regarding the intraluminal position of the 0.035-inch wire (resistance, buckling, trapping), we strongly recommend against use of force and further advancement of the wire and against

the introduction of a large sheath. A 4F introducer can be slowly inserted, and after pressure transduction a gentle contrast injection is used to confirm the intraluminal position and to define the vascular anatomy. Stiff hydrophilic wires are useful to negotiate calcified tortuous iliac arteries, but their use should be restricted to experienced operators.

When the sheath is introduced, we use the over the wire exchange technique with the tip of the catheter in the proximal abdominal or distal thoracic aorta. In addition, we often use long, stiff sheaths to facilitate catheter manipulation because otherwise it might be impossible to have control of the coronary diagnostic or guiding catheters. We routinely perform catheter exchanges and observe the wire under fluoroscopy as we advance it in the iliac artery to get a sense of the tortuosity and elasticity of the artery, which determines the use of appropriate equipment to optimize the chances of a successful intervention.

Sheaths should be removed as soon as it is safe after a procedure depending on the anticoagulation regimen used for the intervention. The use of bivalirudin compared with the use of heparin plus GP IIb/IIIa inhibitors is associated with a reduction of vascular complications.³ For anticoagulation with heparin, an activated coagulation time of less than 180 seconds¹¹ is considered the criterion for safe sheath removal. If a GP IIb/IIIa inhibitor is used, some clinicians advocate an activated coagulation time of less than 150 seconds. With bivalirudin use, sheaths can be removed 2 hours after discontinuation of the bivalirudin.³

Throughout the time of sheath removal, the patient's vital signs should be monitored closely, the access site should be assessed for the development of oozing or hematoma formation, and the distal pulses and color of the skin should be continuously assessed to ensure adequate perfusion of the limb. We strongly recommend the presence of at least two experienced nurses (or physicians) during sheath removal, frequent (every few minutes) measuring of the blood pressure, continuous telemetry and pulse oximetry monitoring, the availability of at least two reliable peripheral intravenous access sites, and atropine and normal saline available in the room.

Vagal episodes are common with compression of the femoral artery and are characterized by nausea, vomiting, hypotension, and bradycardia. These episodes usually respond promptly to intravenous fluids and atropine, 0.6 to 1 mg intravenously. If the pressure decreases again, and if there are other signs or symptoms such as flank or abdominal pain or palpable hematoma, the situation should be readdressed quickly because these are warning signs of potentially more serious complications, such as retroperitoneal hematoma or groin bleeding. It is a common mistake to misdiagnose significant bleeding episodes as "vagal episodes" with detrimental delays in appropriate management.

In patients with peripheral bypass grafts, we avoid total occlusion of the femoral artery, and we use continuous Doppler monitoring of the distal pulses to ensure uninterrupted blood flow through the graft. We generally recommend 15 minutes of manual compression for 6F sheaths, and we add 5 minutes for each French increase in size (i.e., 20 minutes for 7F and 25 minutes for 8F sheaths). Alternatively, mechanical compression devices can be used (C-clamp, fem-stop); although more convenient for the staff, these devices have a learning curve and still require the presence of staff members during the application. Closure devices are advocated because they are more comfortable for the patient allowing faster ambulation. In the past, there were concerns that bleeding or thrombotic/occlusive complications

might be increased.¹²⁻¹⁴ With the exception of Vasoseal,¹⁵ however, the complication rate with closure devices is similar to the rate with manual sheath removal except for a slight increase in infectious complications.

Hemorrhagic Complications

The need for transfusion during or after percutaneous coronary intervention is associated with in-hospital and long-term increase in mortality.¹⁶⁻¹⁸ The explanation for this finding is unclear, but could be related to hemodynamic alterations associated with blood loss, the discontinuation of anticoagulation, or the adverse effect of blood transfusion per se.¹⁹

Groin Hematoma

Groin hematoma is a common complication that can occur shortly after sheath removal if there is inability to control the femoral artery. The incidence of access site bleeding requiring transfusion was found to be 1.8% in one study.¹⁸ Heparin is no longer administered routinely after intervention, and this has led to significant reduction in the bleeding complications rate. Newer anticoagulation regimens using bivalirudin and clopidogrel without the use of GP IIb/IIIa inhibitors have also reduced the rate of access site bleeding.^{3,20,21}

Risk factors include obesity, anticoagulation, large sheaths, premature ambulation, and peripheral vascular disease. Poor hemostatic technique increases the risk of localized bleeding further. A common mistake is application of hemostatic pressure on the site of the skin incision, whereas the actual point of entry into the artery is a couple of centimeters above the skin nick, and so pressure should be applied more proximally. Another common mistake is short duration of manual compression and subsequent dislodgment of the immature thrombus. The clinical management depends on the severity of bleeding. In most cases, the bleeding can be controlled with additional manual compression or the use of mechanical hemostatic devices. Reversal of anticoagulation and discontinuation of GP IIb/IIIa inhibitors are indicated. Particularly in obese patients, a significant amount of blood loss can occur in the femur resulting in hemodynamic compromise requiring transfusion. Surgical repair is usually not required, and the hematoma resolves over the ensuing days or weeks.

Retroperitoneal Hematoma

Retroperitoneal bleeding complicates cardiac interventions in less than 1% of the cases.²² High femoral and back-wall sticks above the inguinal ligament are risk factors. The usual clinical presentation is sudden onset of flank or abdominal pain with fullness, guarding, and hypotension. Prompt recognition and immediate aggressive resuscitation with intravenous fluids or blood or both are required. Emergency vascular surgery consultation should be obtained. Manual compression is of little use because the bleeding site is high in the pelvis where the artery is noncompressible.

Prompt hemodynamic stabilization and reversal of anticoagulation are indicated. Heparin can be reversed with protamine (1 mg/100 U of heparin intravenously up to 50 mg maximum). Low-molecular-weight heparin can be partially reversed with protamine as well (1 mg/100 anti-factor Xa U). If fibrinolytics have been used, fresh frozen plasma (15 mL/kg), cryoprecipitate (1 bag per 10 kg), and aminocaproic acid (5 g during the

first hour followed by 1 to 1.25 g/hr for approximately 8 hours or until bleeding stops) are indicated.²³ GP IIb/IIIa inhibitors should be discontinued. Platelet transfusion can be used to reverse the effects of abciximab. The effect of tirofiban or eptifibatide wears off after approximately 4 hours. Ongoing bleeding despite the aforementioned measures is an absolute indication for emergency surgical or endovascular repair. In the endovascular approach, arterial access is obtained from the contralateral side, and the bleeding site can be identified angiographically and occluded with balloon inflation. Options thereafter include either covered stent placement or open surgical repair.

Pseudoaneurysm

A pseudoaneurysm is the formation of a hematoma contained by the surrounding tissues. It is called a *pseudoaneurysm* because there is no aneurysmal sac that contains all the layers of the vessel wall. It manifests as a painful, palpable, pulsatile mass accompanied by a systolic bruit. Pseudoaneurysms less than 2 cm in diameter may resolve spontaneously. If they are greater than 2 cm in diameter, if there are signs of expansion of the hematoma, or if the patient requires anticoagulation, the pseudoaneurysm should be closed.

There are different methods of closure depending on the anatomy and the local expertise.²⁴ Surgical repair with suturing the hole on the arterial wall is the traditional approach and is indicated in cases of rapidly expanding pseudoaneurysms, massive bleeding, and hemodynamic compromise. Alternatively, thrombin injection under ultrasound guidance has a high success rate (Fig. 23-1).²⁵ Meticulous technique is mandatory to avoid

injecting the thrombin in the actual artery, particularly when the neck of the pseudoaneurysm is wide and short. The distal pulses should be examined before the procedure. The pseudoaneurysm is localized by ultrasound and entered with the needle perpendicular to the ultrasound beam. When the sac is entered (the needle can be visualized on ultrasound), a saline bubble injection is performed to ensure that bubbles do not enter the femoral artery. Subsequently, the thrombin is injected slowly, and there should be immediate obliteration of the sac. Bed rest is recommended for 2 hours. The groin ultrasound scan is usually repeated the next morning.

An alternative technique is direct prolonged compression of the pseudoaneurysm with the ultrasound probe. This technique is time-consuming and uncomfortable for the operator and the patient, but series have been described in the literature with reasonably good results.²⁶ It might be suited for relatively small pseudoaneurysms with short “necks” (Fig. 23-2). Endovascular repair with coils has also been described.²⁷ Stent grafting is an option that might be limited by technical considerations such as subacute stent thrombosis, occlusion of major side branches, and compromise of future access.²⁸

Vascular Perforation

Perforation of the iliac arteries is a catastrophic complication that manifests as abdominal pain and hypovolemic shock. Unless promptly recognized and treated, it can be lethal (Fig. 23-3). Reversal of anticoagulation is indicated as soon as it is recognized. Emergency vascular surgery consultation is recommended simultaneously with aggressive resuscitation and hemodynamic support. The bleeding can be controlled with

Figure 23-1. Pseudoaneurysm after stenting of the left anterior descending artery. The patient complained of groin pain exacerbated by ambulation before discharge. **A**, Groin ultrasound scan revealed the presence of a moderate-size pseudoaneurysm originating from the right common femoral artery with a long neck. **B**, Ultrasound appearance immediately after thrombin injection. **C**, Ultrasonography with color Doppler the next morning confirmed the obliteration of the pseudoaneurysm with absence of blood flow in the sac.

Figure 23-2. Pseudoaneurysm after stenting of the right coronary artery. **A**, Groin ultrasound scan revealed a small pseudoaneurysm with a short neck in close proximity to the superficial femoral artery. Given these anatomic characteristics, it was treated with prolonged ultrasound-guided compression. **B**, Complete obliteration of the pseudoaneurysm is shown in follow-up ultrasonography.

Figure 23-3. Right external iliac artery perforation in a patient with inferior ST segment elevation myocardial infarction and slow flow after right coronary artery stenting. Eptifibatide (Integrilin) was initiated, and the decision was made to place an intra-aortic balloon pump. There was resistance with wire advancement, and the patient complained of abdominal pain and became hypotensive. **A**, Iliac angiography via the sheath revealed massive extravasation of the dye. The wire was repositioned in the true lumen, and the lesion was treated with prolonged balloon inflation for immediate control of bleeding. **B**, Final angiography after deployment of a covered stent with complete sealing of the perforation.

prolonged balloon inflations followed by stent graft deployment or open surgical repair.

Dissection

Most retrograde dissections are due to wire entering the subintimal plane. Because the blood flow is from the opposite direction, these dissections usually heal spontaneously. In cases of acute or threatened vessel closure, repair is needed, which can be accomplished with catheter-based techniques and stenting usually by access from the contralateral groin.

Arteriovenous Fistula

Fistulas occur in approximately 0.4% of interventional cases when there is simultaneous puncture of the artery and the vein and the formation of a track, or if ongoing bleeding from the artery is decompressed to the adjacent vein.²⁹ Predisposing

factors are poor access technique and high and low access of the superior femoral artery. Clinically, it is recognized by the presence of a continuous bruit or palpable thrill because the pressure in the artery is higher than in the vein throughout the cardiac cycle. Repair of an arteriovenous fistula is rarely an emergency; however, close follow-up is indicated because fistulas tend to enlarge with time, and repair is eventually required. Other options for repair include coil embolization and endovascular repair with covered stents.

Thrombotic Complications

Arterial thrombosis can occur in any vessel that is accessed for cardiac catheterization. Risk factors include pre-existing peripheral vascular disease, prolonged sheath insertion, and use of large sheaths.³⁰ The classic presentation is the sudden onset of pain and paresthesia, and clinical signs include the loss of distal

pulses. The affected limb is cold and pale. Prompt recognition is essential because restoration of flow is crucial for limb salvage. Urgent vascular surgery consultation is indicated. Angiography confirms the diagnosis. Treatment options include surgical embolectomy and percutaneous thrombectomy.

Occasionally, with sheath insertion, transient limb ischemia can occur because of pre-existing peripheral vascular disease or spasm; it resolves with sheath removal or vasodilator therapy. The risk of distal embolization during sheath removal can be decreased by applying pressure distal to the insertion site and by allowing transient bleeding from the arteriotomy site. We routinely perform this maneuver in cases of radial and brachial access, and after the removal of large femoral artery sheaths and intra-aortic balloon pumps. Femoral vein thrombosis and pulmonary embolism are rare complications and their incidence may be underestimated because they are often clinically silent.³¹

Infectious Complications

Infection is a rare but potentially serious complication, especially if it is not limited to the skin (cellulitis) and involves deep tissues and the artery itself. Meticulous attention to sterile technique is mandatory. If infection occurs, it manifests with fever and systemic signs of infection and local pain, erythema, induration, and swelling. Treatment for superficial infections includes antibiotics that should cover *Staphylococcus* species. Deep tissue infections often require surgical débridement.

Noncoronary Diseases: Diagnosis and Management

SECTION

IV

Acute Heart Failure and Pulmonary Edema

Theo E. Meyer, Rajan Krishnamani, William H. Gaasch

CHAPTER

24

Pathophysiologic Considerations

Clinical Presentation of Acute Heart Failure
Diagnosis and Evaluation of Acute Heart Failure

Treatment of Acute Heart Failure Choice of Therapeutic Regimen

ACUTE HEART failure (AHF) is a clinical syndrome of new or worsening signs and symptoms of heart failure (decompensated), often leading to hospitalization or a visit to the emergency department. Patients with AHF represent a heterogeneous population with high postdischarge readmission rates.¹⁻⁵ Most hospitalized patients have significant volume overload, and congestive symptoms predominate. Fewer patients present with hypotension and symptoms of reduced organ perfusion.¹⁻⁵ A few patients who come to the emergency department with AHF have “flash pulmonary edema.”¹ A few patients have onset of symptoms within 4 hours of arrival; most patients have a slow progression of disease, resulting from cardiac ischemia, medication noncompliance, dietary indiscretion, or exacerbation of hypertension. The average patient has had symptoms for almost 5 days before seeking medical attention.¹⁻⁵

AHF is the most common cause of hospital admission in patients older than 65 years, accounting for 1 million admissions annually.⁶ AHF represents a period of high risk for patients, with a 20% to 30% mortality rate within 6 months after admission.⁷⁻⁹ Early care of AHF and time to treatment are linked to outcome. These patients are generally cared for in telemetry units in the United States. Only 10% to 20% of these patients are admitted to intensive care units (ICUs).^{2,3}

Pathophysiologic Considerations

Integral to the understanding of the pathogenesis and treatment of AHF and pulmonary edema is a basic understanding of the forces involved in fluid retention, capillary-interstitial fluid exchange (Starling relationship), the determinants of myocardial pump performance, and the pathophysiology of AHF.

Chronic Progressive Fluid and Water Retention

Renal sodium and water excretion normally parallels sodium and water intake, so that an increase in plasma and blood volume is associated with increased renal sodium and water excretion. In patients with heart failure, sodium and water are retained, despite an increase in intravascular fluid volume. Renal sodium and water retention in these patients may be regulated not by the total blood volume, but by the degree of filling of the arterial compartment—the so-called effective blood volume. The dynamic equilibrium of the arterial circulation, as determined by cardiac output and peripheral vascular resistance or compliance, is the predominant determinant of renal sodium and water excretion.

Arterial underfilling is sensed by mechanoreceptors in the left ventricle, carotid sinus, aortic arch, and renal afferent arterioles.¹⁰ Decreased activation of these receptors because of a decrease in systemic arterial pressure, stroke volume, renal perfusion, or peripheral vascular resistance leads to an increase in sympathetic outflow from the central nervous system, activation of the renin-angiotensin-aldosterone system, and the nonosmotic release of arginine vasopressin, as well as the stimulation of thirst.¹⁰ These factors together with increased release of endothelin and vasopressin and resistance to natriuretic peptides contribute to sodium and water retention leading to decompensation of chronic heart failure.

Pulmonary Edema

The flux of fluid out of any vascular bed results from the sum of forces promoting extravasation of fluid from the capillary lumen versus forces acting to retain intravascular fluid. This concept of a dynamic equilibration between opposing forces in the lung is given mathematical expression in the Starling equation:¹¹

$$Q_f = K_f (P_v - P_{int}) - K_f (P_v - p_{int})$$

Table 24-1. Classification of Acute Pulmonary Edema

Cardiogenic Pulmonary Edema	
A. Acute Increase in Pulmonary Capillary Pressure	b. Volume load imposed on preexisting LV diastolic dysfunction
1. Increased LA pressure with normal LV diastolic pressure	i. Worsening mitral regurgitation
a. Thrombosed prosthetic mitral valve	ii. Vigorous postoperative fluid administration
b. Obstructive left atrial myxoma	iii. Dietary indiscretion
2. Increased LA pressure owing to elevated LV diastolic pressure	c. Pressure load imposed on preexisting LV systolic dysfunction
a. Acute increases in myocardial stiffness or impaired relaxation	i. Accelerated hypertension
i. Myocardial ischemia	
ii. Acute myocardial infarction	Noncardiogenic Pulmonary Edema
iii. Hypertrophic heart disease complicated by tachycardia or ischemia	A. Altered Alveolar Capillary Membrane Permeability (Adult Respiratory Distress Syndrome)
b. Acute volume load	1. Infectious or aspiration pneumonia
i. Acute mitral or aortic regurgitation	2. Septicemia
ii. Ischemic septal rupture	3. Acute radiation or hypersensitivity pneumonitis
c. Acute pressure load	4. Disseminated intravascular coagulopathy
i. Hypertensive crisis	5. Shock lung
ii. Thrombosed prosthetic aortic valve	6. Hemorrhagic pancreatitis
B. Exacerbation of Chronically Elevated Pulmonary Capillary Pressures	7. Inhaled and circulating toxins
1. Increase in elevated LA pressure with normal LV diastolic pressure	8. Massive trauma
a. Mitral stenosis	B. Acute Decrease in Interstitial Pressure of the Lung
b. Left atrial myxoma	1. Rapid removal of unilateral pleural effusion
2. Increase in elevated LA pressure owing to a further increase in LV diastolic pressure	C. Unknown Mechanisms
a. Further increases in myocardial stiffness or impaired relaxation	1. High-altitude pulmonary edema
i. Cardiomyopathy complicated by myocardial ischemia or infarction	2. Neurogenic pulmonary edema
ii. Hypertrophic heart disease complicated by tachycardia or ischemia	3. Narcotic overdose
	4. Pulmonary embolism
	5. After cardioversion
	6. After anesthesia or cardiopulmonary bypass

LA, left atrial; LV, left ventricular.

where Q_f is net transvascular fluid flow across the pulmonary capillary endothelium; K_f is filtration coefficient of the microvascular endothelium (hydraulic conductivity of the capillary wall $\times$ surface area); P_v is hydrostatic pressure in the pulmonary capillaries; P_{int} is hydrostatic pressure in the pulmonary interstitium; p_V is plasma protein oncotic pressure; and p_{int} is protein oncotic pressure within the interstitial space.

Under normal conditions, the sum of the forces is slightly positive, producing a small vascular fluid flux into the precapillary interstitium of the lung that is drained as lymph into the systemic veins. The capillary coefficient (K_f) determines the effectiveness of the endothelial barrier to protein permeability, and so determines the effectiveness of the oncotic gradient. Because the intravascular pressure in the pulmonary capillaries is always higher than plasma osmotic pressure, transcapillary

fluid flux out of the pulmonary capillary is continuous. When the interstitial fluid exceeds the interstitial space capacity, fluid floods into the alveoli.¹² The interstitial space is drained by a rich bed of lymphatics. It is estimated that pulmonary lymph flow may increase threefold before fluid extravasates into the alveolar airspaces. In patients in the ICU, the two most common forms of pulmonary edema are pulmonary edema initiated by an imbalance of Starling forces and pulmonary edema initiated by disruption of one or more components of the alveolar-capillary membrane. Table 24-1 lists the causes of pulmonary edema based on the initiating mechanism.

It has been shown experimentally that pulmonary edema occurs if the pulmonary capillary pressure exceeds the plasma colloid osmotic pressure, which is approximately 28 mm Hg in humans. The normal pulmonary capillary wedge pressure

is approximately 8 mm Hg, which allows a margin of safety of about 20 mm Hg in the development of pulmonary edema.¹³ Although pulmonary capillary pressure must be abnormally high to increase the flow of the interstitial fluid, these pressures may not correlate with the severity of pulmonary edema when edema is clearly present.¹⁴ These pressures may have returned to normal when there is still considerable pulmonary edema because time is required for removal of interstitial and pulmonary edema.

The rate of increase in lung fluid at any given elevation of pulmonary capillary pressure is related to the functional capacity of the lymphatics, which may vary from patient to patient, and to variations in osmotic and hydrostatic pressures. Chronic elevations in left atrial pressures are associated with hypertrophy in the lymphatics.¹⁵ These lymphatics clear greater quantities of capillary filtrate during acute increases in pulmonary capillary pressure. Clinical experience with patients who have chronically elevated atrial pressures suggests that these patients show minimal or no evidence of interstitial lung edema. The mechanisms by which pulmonary capillary pressure increases when the pumping ability of the ventricle is suddenly impaired are discussed later.

When the alveolar-capillary membrane is injured, proteins leak from the capillary into the interstitium, reducing the oncotic counterpressure tendency to oppose capillary filtration. Interstitial edema and the consequent alveolar edema formation can occur in the presence of low hydrostatic pressures.

Determinants of Left Ventricular Pump Performance

Cardiac output equals the heart rate multiplied by the stroke volume. The stroke volume is the volume of blood ejected with each heartbeat; the magnitude of the stroke volume is governed by ventricular loading conditions and the contractile state of the myocardium. The factors involved in regulating cardiac output are discussed in Chapter 6. The following discussion briefly reviews the determinants of left ventricular (LV) pump performance as it pertains to a patient with AHF.

Preload

Preload is the force or load acting to stretch the LV fibers at the end of diastole, determining the resting length of the sarcomeres.¹⁶ Preload expressed in terms of LV end-diastolic pressure or volume (i.e., dimension) is common, but neglects the confounding influence of the complex geometry of the left ventricle.¹⁷ Preload is probably best measured as end-diastolic wall stress because this reflects the interactions between transmural diastolic pressures, ventricular dimensions, and wall thickness. The level of ventricular preload is influenced by multiple variables, including chamber compliance, overall LV performance, intravascular blood volume and venous return, atrial contribution to ventricular filling, intrapericardial and intrathoracic pressures, right ventricular-LV interaction, and pericardial restraint.¹⁸

Because preload determines the end-diastolic fiber length, it is a major determinant of systolic performance. This phenomenon is generally referred to as Starling's law of the heart. The ability of the heart to increase performance using the Starling mechanism (i.e., preload reserve) is limited by the inherent stiffness of the myocardium. In compliant, normal hearts, the preload reserve is an effective mechanism to increase the stroke volume, but in hypertrophied hearts or in hearts that are already

at the limits of their preload reserve (i.e., end-stage heart failure), stroke volume cannot be substantially increased by this mechanism. When the heart operates on the steep portion of the diastolic pressure-volume curve, small increments in LV volumes are associated with large changes in filling pressures. In other words, large increases in filling pressures are required for a small increase in end-diastolic volume.

Myocardial relaxation is also an important determinant of the fiber length at end-diastole. Impaired relaxation shortens the time available for diastolic filling, and may interfere with fiber stretch when relaxation is markedly prolonged or when the heart rate is rapid. As a result, the force acting to stretch the myocardial fiber is opposed by incomplete relaxation at end-diastole.

Afterload

Afterload is the force opposing fiber shortening after the onset of ejection.¹⁶ This force or stress is not constant because arterial and ventricular pressure changes during ejection. Even if the pressure were constant, the systolic force that the ventricle develops would vary in accordance with a complex relationship between the wall force, ventricular pressure, and ventricular dimension.¹⁹ According to the Laplace equation, wall stress (s) is directly proportional to ventricular systolic pressure (P) and radius (R), and is inversely related to wall thickness (h):

$$s = PR / 2h$$

An increase in wall stress because of an increase in ventricular pressure, an increase in ventricular dimension, inadequate hypertrophy, or any combination of these results in decreased myocardial fiber shortening. Because there has been insufficient time for compensatory hypertrophy to develop in patients with AHF, ventricular pump performance is particularly sensitive to changes in afterload.

Preload and afterload are intimately related. When LV preload is increased in a normal heart, systolic LV pressures generally increase, and as a result systolic wall stress (afterload) increases. Likewise, a decrease in afterload promotes LV emptying, which leads to a decrease in preload.

Contractility

Contractility, or inotropic state, is defined as the property of myocardial fibers that determines the extent of shortening independent of loading conditions. Compared with the control state, a positive inotropic intervention (e.g., epinephrine) increases myocardial fiber shortening and stroke volume at any given preload and afterload. A negative inotropic intervention (e.g., β -blocker) has the opposite effect. For any given increment in afterload, shortening and stroke volume decrease to a greater extent when the contractile state is depressed. Conversely, afterload reduction has a small effect on increasing shortening and stroke volume during a positive inotropic intervention.

Heart Rate

Heart rate affects cardiac output under resting conditions and during exercise. When the heart rate increases, the time available for filling during diastole is substantially abbreviated. When LV diastolic compliance is decreased, tachycardia can produce a decrease in ventricular preload that leads to reduced LV stroke volume despite normal systolic function. In hearts with impaired relaxation (i.e., hypertrophied hearts), a significant increase in

Figure 24-1. Schematic representation of the left ventricular (LV) pressure-volume loop. The aortic valve opens at *b* and closes at *c*. The mitral valve opens at *d* and closes at *a*. The slope of the *broken line* through *c* represents the end-systolic pressure-volume relationship ($E_{\max}$), and the *broken line* through *d* and *a* represents the end-diastolic-volume relationship. As contractile force develops in the left ventricle (LV) in systole, the pressure rapidly increases in the ventricular chamber (*a* → *b*) without changing its volume (i.e., isovolumic phase of systole). When the pressure exceeds the diastolic aortic pressure, the aortic valve opens, and the ventricle ejects its contents into the arterial circulation (*b* → *c*, the ejection phase of systole). At the end of ejection (point *c*), LV pressure decreases, and the aortic valve closes. Pressure rapidly declines at a constant volume (*c* → *d*, isovolumic relaxation) to levels below that of the left atrium. At this point, the mitral valve opens (point *d*), and the relaxing LV fills along the segment *d* → *a*. The trajectory *a* → *b* → *c* represents the contractile or inotropic function of the LV at any given end-diastolic volume, whereas the trajectory *c* → *d* → *a* represents the lusitropic function (relaxation and filling) of the heart at any given end-systolic pressure. The area within the loop graphically depicts the external work (i.e., stroke work) of the ventricle.

heart rate would cause LV filling to occur at the time when the heart is not completely relaxed, which results in increased LV diastolic pressures. In patients with abnormal hearts, tachycardia may cause an exaggerated decrease in stroke volume and an increase in filling pressures.

The normal heart responds to an increase in heart rate by a positive inotropic effect, also known as the *treppe* or *Bowditch phenomenon*.²⁰ In a failing or hypertrophied heart, an increase in heart rate may produce a reduction in, or even a reversal of, the normally positive force-frequency effect.^{21,22} Tachycardia is also likely to increase myocardial oxygen consumption, which may lead to subendocardial ischemia in a heart with a compromised coronary circulation.

Left Ventricular Pressure-Volume Relationships

To appreciate fully the factors that contribute to AHF, it is appropriate to review briefly the pressure-volume relationships of normal and diseased hearts. The relationship between pressure and volume throughout the cardiac cycle can be presented as a pressure-volume loop (Fig. 24-1). The pressure-volume loop encapsulates the systolic and diastolic functions of the heart. Because these loops also circumscribe end-systolic and

end-diastolic volumes, the stroke volume and ejection fraction can be derived. The bottom limb of the loop, called the diastolic pressure-volume curve, describes LV diastolic compliance. The pressure-volume loop can provide a simple but comprehensive description of LV pump function.

Progressive increases in systolic pressure produce a nearly linear increase in end-systolic volume. By matching the end-systolic pressure and volume coordinates from multiple, variably loaded beats, a near-linear relationship is established. The slope of this relationship ($E_{\max}$), determined by altering load, reflects LV contractility (see Fig. 24-1).²³ A positive inotropic intervention is associated with an increased end-systolic pressure and stroke volume and a decreased end-diastolic volume; this results in an increased $E_{\max}$ and a shift of the pressure-volume relationship to the left (Fig. 24-2A). Conversely, a negative inotropic intervention decreases end-systolic pressure and stroke volume and increases end-diastolic volume; this results in a decrease in $E_{\max}$ and a shift of the pressure-volume relationship to the right (Fig. 24-2B).

In the intact human heart, an increase in systolic pressure is associated with an increase in end-systolic volume, and if preload does not increase, stroke volume decreases (Fig. 24-3A). An increase in preload is accompanied by an increase in stroke volume and a modest increase in end-systolic pressure (Fig. 24-3B). Acute and chronic changes in the pressure-volume relationship in the failing heart depend on the underlying myocardial structure and function, the type and extent of injury (e.g., infarction or myocarditis, regional or global myocardial depression), and the severity and nature of the hemodynamic load (pressure versus volume).

Chamber Stiffness

Chamber stiffness is determined by analyzing the curvilinear diastolic pressure-volume relationships (Fig. 24-4). The slope of the tangent (dP/dV) to this curvilinear relationship defines the chamber stiffness at a given filling pressure. An increase in dP/dV because of an increase in volume, shown in Figure 24-4 (A → B), has been called a preload-dependent change in stiffness. When the pressure-volume relationship shifts to the left (A → C), the tangent is steeper at the same diastolic pressure. The latter may be caused by an increase in myocardial mass or intrinsic myocardial stiffness or by changes in several extramycocardial factors. Chamber stiffness of the left ventricle is determined by static factors (e.g., chamber volume, wall mass, stiffness of the wall) and dynamic factors (e.g., pericardium, right ventricle, myocardial relaxation, erectile effects of the coronary vasculature).^{18,24} Most acute alterations in LV chamber stiffness result from a preload-dependent increase in chamber stiffness, a shift to a different pressure-volume curve, or a combination of the two. All can result in elevated left atrial pressures, pulmonary venous hypertension, and the signs and symptoms of acute heart failure.

Compensatory Mechanisms in Acute Heart Failure

Decreases in blood pressure and cardiac output after an acute depression of LV pump performance cause rapid activation of neurohormonal systems, which generate an acute increase in heart rate and arterial resistance and a decrease in capacity of the venous system.^{25,26} The decreased systemic vascular capacity after sympathetic activation is brought on predominantly by changes in the splanchnic vascular bed that result in a leftward

Figure 24-2. Schematic diagrams illustrating the effects of inotropic interventions on the pressure-volume loop. **A**, With a positive inotropic intervention, the pressure-volume loop (*broken line*) is shifted to the left, and the slope of the end-systolic pressure-volume line is increased. **B**, With a negative inotropic intervention, the pressure-volume loop is shifted to the right, and the slope of the end-systolic pressure-volume line is decreased.

Figure 24-3. Schematic diagrams illustrating the effects of changing loading conditions on the pressure-volume loop in the intact heart. **A**, An increase in afterload shifts the pressure-volume loop (*broken line*) to the right, increasing the end-systolic and end-diastolic volumes and the end-systolic and end-diastolic pressures, while decreasing the stroke volume. The slope of the end-systolic pressure-volume line is usually not affected by a pure change in afterload. **B**, An increase in preload also shifts the pressure-volume loop (*broken line*) to the right, increasing the end-diastolic volume and end-diastolic pressure. The increase in preload may be associated further with a small increase in end-systolic volume and a modest increase in end-systolic pressure, but in contrast to the case with an increase in afterload, the stroke volume increases. Similar to an increase in afterload, the slope of the end-systolic pressure-volume line is not affected by a change in preload.

shift of the venous pressure-volume relationship, causing a redistribution of blood from the unstressed to the stressed circulating pool (i.e., central blood pool).²⁷

Hemodynamic Examples of Acute Heart Failure Syndromes

During the hyperacute phase of myocardial infarction (MI) or with acute ischemia, reduced ventricular ejection increases end-systolic volume (residual volume), and reduced LV compliance

increases the filling pressures. It is thought that the lusitropic dysfunction results from an increase in stiffness in the ischemic myocardial segment (possibly caused by slowing and incompleteness of the relaxation process)²⁸ and dilation of the nonischemic segment, causing a preload-dependent increase in chamber stiffness.²⁹ The increase in LV filling pressure that occurs with acute infarction or ischemia is caused by the combination of a preload-dependent increase in chamber stiffness and a leftward shift of the diastolic pressure-volume curve.

Figure 24-4. Schematic diagram of the diastolic left ventricular pressure-volume curve. The slope of the tangent (dP/dV) to this curvilinear relationship defines chamber stiffness at a given filling pressure. An increase in dP/dV owing to an increase in volume, shown diagrammatically as $A \rightarrow B$, has been termed a preload-dependent change in stiffness. When the pressure-volume relationship shifts to the left, $A \rightarrow C$, the tangent is steeper (increased chamber stiffness) at the same diastolic pressure.

Increased diastolic pressures after an acute ischemic insult may also result from the redistribution of blood from the periphery to the central blood pool. The effects of these changes on the pressure-volume relationship are shown in Figure 24-5A.

With acute volume overload, as seen in patients with acute mitral or aortic regurgitation or after ischemic septal rupture, the left ventricle dilates and operates on a steeper portion of its pressure-volume curve. Consequently, small increments in volume result in a marked increase in filling pressures. The effects of these changes on the pressure-volume relationship are shown in Figure 24-5B.

The lusitropic abnormalities of LV hypertrophy secondary to aortic stenosis, severe hypertension, or hypertrophic cardiomyopathy probably are caused by abnormalities of the static and dynamic determinants of chamber stiffness. Increased passive stiffness of the hypertrophied heart results in part from the increased myocardial mass and the low volume-to-mass ratio; abnormal intrinsic myocardial stiffness also may contribute to increased chamber stiffness. Abnormalities of myocardial relaxation further impair filling in the hypertrophied heart. The effects of these changes on the pressure-volume relationship are shown in Figure 24-5C.

Chronic heart failure is characterized by a compressed pressure-volume loop. This compressed loop, characterized by a decrease in end-systolic pressure and an increase in end-diastolic pressure, means that the work of the failing heart is reduced, while maintaining a near-normal stroke volume. Comparable to the changes with ischemia, the elevated filling pressures in chronic heart failure probably are caused by a combination of a preload-dependent increase in chamber stiffness (i.e., left ventricle operates at higher end-diastolic volumes to optimize the Starling relationship) and a preload-independent increase in chamber stiffness (Fig. 24-5D). It should also be evident from the pressure-volume curve that these hearts operate near the limit of their preload reserve; they are extremely vulnerable to any myocardial insult. Even a minor insult, such as

an arrhythmia, infection, or a small area of infarction, is likely to precipitate acute decompensation in these patients.

Clinical Presentation of Acute Heart Failure

The clinical presentation of AHF is largely related to the degree of fluid overload. The onset and severity of symptoms of AHF vary, and depend importantly on the nature of the underlying cardiac disease and the rate at which the syndrome develops. Patients with AHF have worsening chronic heart failure (70% of all cases), present with heart failure for the first time (25%), or present with advanced or end-stage heart failure—patients who do not respond to treatment (5%). A few patients with AHF present with low blood pressure (<8%) or shock (<3%).³⁰ Most patients are elderly, with an average age of approximately 75 years. The heterogeneity of this patient population is evident when one considers that almost all of these patients have preserved LV ejection fraction, 70% have a history of systemic hypertension, 60% have documented coronary artery disease, 45% have had a prior MI, 30% have a history of atrial fibrillation, 40% have diabetes mellitus, and 30% have underlying chronic obstructive pulmonary disease.³⁰ Secondary mitral regurgitation is common. A patient with AHF may have one of several distinct clinical conditions, as described next.

Decompensation of Chronic Heart Failure

Normotensive Decompensation

Normotensive decompensation occurs in patients with an established diagnosis of heart failure who develop increasing signs or symptoms of decompensation after a period of relative stability. This scenario accounts for greater than 70% of all admissions with heart failure. These patients are usually normotensive. Progressive dyspnea is the most common complaint of patients presenting with decompensated chronic heart failure.

Figure 24-5. Schematic diagrams of four different pathophysiologic states. In each diagram, the control pressure-volume loop and the diastolic pressure-volume relationship (curve) are shown in *solid lines*, and the effects of different pathologic states on the pressure-volume relationship are depicted by the *broken lines*. **A**, With acute ischemia or infarction, the pressure-volume curve is shifted upward and to the right. **B**, In a volume-overloaded heart (i.e., valvular regurgitation), the pressure-volume relationship is shifted to the right along the same diastolic pressure-volume relationship. The increase in diastolic pressure is the result of the left ventricle operating on the steeper portion of the diastolic pressure-volume relationship. **C**, With excessive hypertrophy, the pressure-volume relationship is shifted to the left, so that the heart operates at smaller end-diastolic and end-systolic volumes. The increase in chamber stiffness is reflected by the steep diastolic pressure-volume curve. **D**, In chronic advanced heart failure, the pressure-volume loop is often compressed and shifted to the right. This compressed loop, characterized by a lower end-systolic and increased end-diastolic pressure, implies that the work of the heart is reduced, while maintaining a near-normal stroke volume. Comparable to the situation in **A**, the elevated diastolic pressure is caused by preload-dependent and preload-independent increases in chamber stiffness.

The exaggerated uncomfortable awareness of breathing is usually manifest with mild exertion, or even at rest. These patients are often orthopneic. This orthopnea may become so severe that patients cannot lie down at all and must spend the entire night in a sitting position. In addition, some patients experience episodes of paroxysmal nocturnal dyspnea, which usually begins 2 to 4 hours after the onset of sleep and is associated with marked dyspnea followed by coughing, wheezing, and sweating. Family members occasionally report the presence of periodic respiration or cyclic respiration, characterized by periods of apnea followed by hyperventilation (Cheyne-Stokes respiration). This breathing pattern is often a sign of advanced heart failure.

Patients may report ankle swelling and epigastric tenderness or a sensation of abdominal fullness. Abdominal tenderness is

often due to hepatic congestion and distention of the hepatic capsule. With severe hepatic congestion, the patient may also complain of nausea and anorexia. Other symptoms include nocturia and neurologic symptoms such as confusion, headaches, insomnia, anxiety, disorientation, and impaired memory.

Physical signs vary according to the severity of heart failure and the predominant hemodynamic abnormality. An elevated jugular venous pressure, a positive hepatojugular reflux test, and a tender enlarged liver are frequent findings in these patients. Important physical examination findings include inspiratory, crepitant rales over the lung bases. Rales and wheezing may be heard widely over both lung fields in patients with significant pulmonary congestion. The absence of rales does not imply that the pulmonary venous pressures are not elevated. Diminished

air entry at the lung bases is usually caused by a pleural effusion, which is often more frequent in the right pleural cavity than in the left. Leg edema is frequently evident in both legs, particularly in the pretibial region and ankles in ambulatory patients. Sacral edema can be detected in patients who are bedridden.

The cardiac examination may be entirely normal in patients with heart failure secondary to diastolic dysfunction, whereas most patients with advanced systolic dysfunction exhibit a third heart sound and a laterally displaced apex beat. A murmur of mitral regurgitation is often present when the left ventricle is markedly enlarged, or a tricuspid regurgitation murmur is present when the right ventricle is volume or pressure overloaded. These patients often do not have clinical or radiographic signs of marked pulmonary edema.

Hypotensive Decompensation

Systolic blood pressure is less than 90 mm Hg in 8% of patients with decompensated chronic heart failure. Low output heart failure is characterized by symptoms and signs that are related to decreased end-organ perfusion. A typical patient with this clinical syndrome has severely impaired LV function and usually presents with symptoms of fatigue, altered mental status, or signs of organ hypoperfusion, such as prerenal azotemia or abnormal hepatic enzymes. The patient may present with tachypnea at rest, tachycardia, and a cold and cyanotic periphery. The degree of peripheral hypoperfusion may be so advanced that the skin over the lower extremities is mottled and cool. A diminished pulse pressure, consistent with a reduced stroke volume, is often found in patients with AHF. Occasionally, the clinician may detect pulsus alternans—when a strong or normal pulse alternates with a weak pulse during normal sinus rhythm. This physical finding is rare, but when present is a sign of severe LV dysfunction.

Acute Heart Failure

The syndrome of AHF is characterized by a sudden onset of symptoms or signs of heart failure. AHF occurs when there is an acute change in LV systolic or diastolic function, or in the structural integrity of the valves. It most often is related to hypertension. Other causes are acute MI, ischemic mechanical complications such as papillary muscle rupture, fulminant myocarditis, or severe acute valvular regurgitation in the setting of infective endocarditis.

More than 50% of patients who present with classic signs and symptoms of heart failure have an elevated blood pressure on admission.³⁰ There is usually predominant pulmonary rather than systemic congestion. Many patients have a normal LV ejection fraction. Blood pressure elevation could develop rapidly and is likely related to increased filling pressures and enhanced sympathetic tone. Early and aggressive blood pressure control is an important goal in patients with hypertensive AHF.

Acute Heart Failure with Severe Pulmonary Edema

Severe pulmonary edema is seen in less than 3% of all patients admitted with AHF.³⁰ Patients typically experience a sudden and overwhelming sensation of suffocation and air hunger; this is invariably accompanied by extreme anxiety, cough, expectoration of a pink frothy liquid, and a sensation of drowning. The patient sits bolt upright, is unable to speak in full sentences, and may thrash about. The respiratory rate is increased, the alae nasi are dilated, and there is inspiratory retraction of the intercostal

spaces and supraclavicular fossae. Respiration is often noisy, and there may be audible inspiratory and expiratory gurgling sounds. An ominous sign is obtundation, which may be a sign of severe hypoxemia. Sweating is profuse, and the skin tends to be cool, ashen, and cyanotic, reflecting a low cardiac output and increased sympathetic outflow.

The blood pressure and pulse rate are most often elevated secondary to an increased adrenergic drive. When the blood pressure is found to be markedly elevated, it is more likely to be the cause of, or an important contributing factor to, pulmonary edema, rather than the consequence of the condition. The oxygen saturation is usually less than 90% on room air before treatment. Auscultation of the lung usually reveals coarse airway sounds bilaterally with rhonchi, wheezes, and moist fine crepitant rales that are detected first at the lung bases, but then extend upward to the apices as the lung edema worsens. Cardiac auscultation may be difficult in the acute situation, but third and fourth heart sounds may be present. When valvular abnormalities or mechanical complications after MI result in acute heart failure, the murmurs of mitral and aortic regurgitation and the systolic murmur of ischemic septal rupture are often audible, but detection requires a careful and skillful auscultator.

Diagnosis and Evaluation of Acute Heart Failure

There are three key elements to consider when evaluating a patient with AHF: (1) the rapid diagnosis of AHF is necessary to initiate appropriate treatment, (2) early evaluation and treatment is linked to outcome, and (3) risk stratification may aid the appropriate triage of the patient.

Diagnosis

The diagnosis of decompensated chronic heart failure is generally not problematic, especially when a patient presents with the triad of fluid retention, exertional dyspnea, and history of heart failure. Some observations should be kept in mind, however. Worsening exertional dyspnea could also be due to a range of other conditions, including pulmonary embolism, pneumonia, chronic obstructive pulmonary disease, asthma, pulmonary fibrosis, pleural effusion, anemia, hyperthyroidism, and musculoskeletal disorders.

For patients without a prior cardiac history, the diagnosis of AHF should be based primarily on signs and symptoms according to the Heart Failure Society of America.³¹ When the diagnosis is uncertain, determination of plasma B-type natriuretic peptide (BNP) or N-terminal pro-B-type natriuretic peptide (NT-proBNP) concentration should be considered in patients being evaluated for dyspnea who have signs and symptoms compatible with AHF. The natriuretic peptide concentration should not be interpreted in isolation, but in the context of all available clinical data bearing on the diagnosis of AHF.³¹ The Task Force on Acute Heart Failure of the European Society of Cardiology⁴ emphasizes that the diagnosis of AHF is based on the symptoms and clinical findings, supported by appropriate investigations, such as electrocardiogram (ECG), chest x-ray, biomarkers, and Doppler echocardiography.

There is considerable overlap in BNP and NT-proBNP levels in patients with and without heart failure, which makes the test

Table 24-2. Differentiation of Noncardiogenic from Cardiogenic Pulmonary Edema Based on Clinical Data

	Noncardiogenic	Cardiogenic
History	Underlying disease (e.g., pancreatitis, sepsis)	Acute cardiac event (e.g., myocardial infarction)
Physical examination	Warm periphery Bounding pulses Normal-sized heart Normal JVP No S ₃ No murmurs	Cool, mottled periphery Small-volume pulse Cardiomegaly Elevated JVP S ₃ Systolic and diastolic murmurs
ECG	ECG usually normal	ST segment and QRS abnormalities
Chest x-ray film	Peripheral infiltrates	Perihilar infiltrates
Laboratory test	Normal enzymes BNP <100 mg/mL	Elevated biomarkers
Ventilatory needs	Higher Fio ₂ and PEEP to oxygenate	Lower Fio ₂ and PEEP to oxygenate

BNP, brain natriuretic peptide; Fio₂, inspired oxygen concentration;

JVP, jugular venous pressure; PEEP, positive end-expiratory pressure.

Adapted from Sibbald WJ, Cunningham DR, Chin DN: Non-cardiac or cardiac pulmonary edema? A practical approach to clinical differentiation in critically ill patients. *Chest* 1983;84:452-461.

less robust in an individual patient with intermediate levels of BNP (approximately 200 to 400 pg/mL). Because many conditions increase BNP levels, low values of BNP (<100 pg/mL) are most useful because they make the diagnosis of decompensated heart failure very unlikely as an explanation for dyspnea.³² Decision analysis suggests that BNP testing is generally most useful in patients who have an intermediate probability of heart failure.³¹ AHF remains a clinical syndrome that is characterized by a constellation of symptoms owing to a heterogeneous group of cardiac and vascular disorders, whose diagnosis cannot be based on a single laboratory test. Results of BNP testing must be interpreted in the context of the overall clinical evaluation, and such testing must support rather than override careful clinical judgment.

Differentiating Cardiogenic from Noncardiogenic Pulmonary Edema

It is crucial to establish whether respiratory failure (pulmonary edema) is due to cardiogenic or noncardiogenic causes. This distinction can invariably be made by assessment of the clinical context in which it occurs and through examination of the clinical data available (Table 24-2). The clinical data include tests that are routinely done on all critically ill patients, such as ECG, blood gas analysis, blood count, electrolytes, and chest x-ray.

Noncardiogenic pulmonary edema (NCPE) is invariably associated with an underlying disease, which may or may not be readily apparent. The diagnosis of NCPE often depends on

pretest probabilities: acute respiratory distress in a patient with documented sepsis (i.e., peritonitis) or pancreatitis should raise the strong possibility that the respiratory failure is due to NCPE. In contrast to cardiogenic pulmonary edema (CPE), NCPE is uncommonly associated with a well-defined acute cardiac event (i.e., MI). Subtle physical signs may also aid in differentiating NCPE from CPE. NCPE is usually a hyperdynamic illness, clinically apparent as a warm, vasodilated periphery, whereas CPE is frequently associated with a cold and sweaty periphery. The findings of a third heart sound or murmurs of aortic and mitral regurgitation and aortic stenosis may suggest a cardiogenic cause of pulmonary edema.

ST segment changes on ECG consistent with MI or myocardial ischemia would suggest an acute cardiac event as the cause of the pulmonary edema. Also, ECG evidence of LV strain, left bundle branch block, or other abnormalities of the QRS complex might indicate an underlying cardiac pathology. Unless there are major metabolic disturbances, the ECG is usually normal in patients with pure NCPE.

In NCPE and CPE, arterial hypoxemia is due to changes in the ventilation-perfusion ratio and in extent of intrapulmonary shunting. Patients with NCPE usually have a more pronounced defect in oxygenation than is seen in patients with CPE. This is largely due to the greater shunt fractions found in these patients. In the clinical setting, higher concentrations of inspired oxygen concentrations (Fio₂) and larger positive end-expiratory pressures are required to achieve acceptable oxygenation in NCPE compared with CPE.

Similar to other tests, the chest x-ray may be helpful to differentiate NCPE from CPE. With NCPE, the alveolar and interstitial disease might show a predominant peripheral distribution, whereas in CPE, a perihilar distribution is more evident, often associated with Kerley lines or pleural effusions or both. Heart size is more commonly increased in CPE than NCPE, but the lack of cardiomegaly does not exclude CPE. In most patients, the chest x-ray proves to be of little help; this is due partially to the fact that patients are often too ill to be examined by anything other than a portable unit, and such films are usually of sub-optimal interpretive quality. An example of acute CPE and less severe pulmonary congestion is shown in Figure 24-6.

When the cause of pulmonary edema is clearly evident from the clinical data (i.e., MI), no further diagnostic tests are needed. If there is still uncertainty regarding the etiology of the pulmonary edema, further diagnostic tests are appropriate. BNP level of less than 100 pg/mL or NT-proBNP level of less than 300 mg/mL effectively rules out a cardiac cause for respiratory failure. Elevated BNP levels are found in patients with pulmonary hypertension, cor pulmonale, pulmonary emboli, and compensated heart failure. BNP levels are also higher in women, older patients, and patients with renal failure.³³ More recent data have shown that BNP and NT-proBNP values are similarly elevated in patients with severe sepsis or septic shock and AHF, independently of whether they presented with or without shock.³⁴

Clinical judgment is still required to differentiate CPE from NCPE. An echocardiogram should be obtained in all patients with pulmonary edema in whom the cause of pulmonary edema is unclear. Normal Doppler echocardiography assessments of systolic and diastolic function strongly point toward a noncardiogenic cause of respiratory failure. If uncertainty persists, it is reasonable to obtain hemodynamic information via a pulmonary artery balloon flotation catheter to differentiate CPE from

Figure 24-6. Chest x-rays of two patients. **A**, The classic features of acute cardiogenic pulmonary edema. Notice the perihilar alveolar infiltrates. **B**, Marked interstitial changes in the lung bases. Note the Kerley B lines (arrow).

NCPE. With the availability of BNP levels and two-dimensional Doppler echocardiography, however, there seems to be less need to proceed with pulmonary artery balloon flotation catheter placement.

Evaluation and Triage of Patients with Acute Heart Failure

Early Assessment

After the diagnosis of AHF has been established, the initial focus is to ensure optimal oxygenation. Several steps are necessary to evaluate a patient with AHF comprehensively.

Step 1: Define Clinical Severity of Acute Heart Failure

Several grading classifications of the severity of AHF have been in place for many years in coronary care units and ICUs. The Killip classification, based on clinical signs and chest x-ray findings,³⁵ and the Forrester classification, based on clinical signs and hemodynamic characteristics,³⁶ are discussed elsewhere. These classifications have been validated in AHF after acute MI and are most applicable for patients with new-onset AHF. Other authors have proposed a straightforward clinical tool for classifying the severity of chronic decompensated heart failure. This assessment is based on observation of the peripheral circulation (perfusion—warm or cold) and on auscultation of the lungs (congestion—wet or dry). Patients can be classified as warm and dry, warm and wet, cold and dry, and cold and wet.³⁷ Such categorization permits attention to specific therapies. If the patient is wet, diuretics are used.

A pragmatic approach is simply to define the severity of AHF based on oxygen requirements and blood pressure. The sickest patient is the patient with the lowest blood pressure and highest oxygen requirement. A subset of patients with decompensated end-stage heart failure present to the emergency department in occult shock and are clinically indistinguishable from patients with mildly decompensated chronic heart failure and stable heart failure.³⁸ The only parameter differentiating occult shock patients from nonshock patients is a significantly elevated lactic acid level.³⁸

In patients hospitalized with AHF, the risk of in-hospital mortality can be derived from admission clinical and laboratory

variables. A blood urea nitrogen level of 43 mg/dL or greater, serum creatinine level of 2.75 mg/dL or greater, and systolic blood pressure of less than 115 mm Hg are independent predictors of in-hospital mortality.⁸ Several other variables, such as increasing oxygen requirements in the emergency department, a history of multiple hospital admissions, chronic renal insufficiency, ECG evidence of LV hypertrophy, markedly depressed LV function, and a poor response to diuretic therapy, predict in-hospital mortality.

Step 2: Establish Etiology of Acute Heart Failure

The most common causes of AHF are listed in [Table 24-3](#). Echocardiography is an essential tool for the evaluation of the functional and structural changes underlying or associated with AHF.

Step 3: Identify Precipitating Causes of Acute Heart Failure

Precipitating causes are defined as factors that may precipitate acute decompensation in patients with underlying cardiac disease, but are unlikely to cause cardiac decompensation in a patient with a normal heart. Identifying the precipitating causes of acute hemodynamic decompensation has obvious therapeutic implications. [Table 24-4](#) lists common precipitating causes.

Step 4: Decide on Disposition of Patient

Patients with severe respiratory failure and patients in shock or preshock should be admitted to the ICU. Although no validated algorithms exist at this time to guide the clinician for triaging patients with decompensated chronic heart failure to regular floor beds or to the ICU, it seems reasonable that when three or more high-risk variables that predict mortality are present in a patient, serious consideration should be given to admit such a patient to a stepdown unit or ICU. In North America, 14% to 18% of patients with AHF are managed in ICUs.³⁹

Ongoing Evaluation of the Patient

Monitoring of a patient with AHF should be initiated as soon as possible after admission to the emergency department. The type and level of monitoring required for any individual

β -adrenergic blocking agents

patient vary widely depending on the severity of the cardiac decompensation and the response to initial therapy. Generally, the following parameters should be measured in all critically ill patients: blood pressure, temperature, respiratory rate, and heart rate. Some laboratory tests should be done repeatedly (i.e., electrolytes, creatinine, and glucose, or markers for infection or

Table 24-5. Monitoring Patients with Acute Heart Failure

Goals	Parameters
Arterial oxygen saturation >95%	Pulse oximetry, arterial blood gas Consider placement of an indwelling radial artery catheter
Blood pressure	Automated blood pressure recordings Frequent assessments (every 5 min) early on to assess BP response to treatment BP via indwelling radial artery catheter
Normal sinus rhythm	Continuous ECG monitoring
Adequate diuretic response	Hourly urine production, daily weight
Adequate organ perfusion	Reversal of metabolic acidosis, lactic acid levels Adequate urine output Mean BP >65 mm Hg Central venous O ₂ saturation >65%
Improved hemodynamics	Mean BP >65 mm Hg Assessment of JVP Central venous pressure line O ₂ saturation Pulmonary artery catheter*
Maintain calorie and nitrogen balance	Blood albumin concentrations Nitrogen balance
Control hyperglycemia	Glucose concentrations

BP, blood pressure; JVP, jugular venous pressure.

other metabolic disorders). After admission to the ICU or a stepdown unit, a patient with AHF should be carefully monitored to ensure that the treatment goals are met, and continued progress is made toward a stable state; Table 24-5 summarizes these goals.

Pulmonary Artery Catheter

Controversy exists about the use of the pulmonary artery catheter in critically ill patients. The concern about pulmonary artery catheter use arose following prior studies that showed higher mortality for patients thought to require a pulmonary artery catheter during hospitalization. More recent data suggest that the routine use of pulmonary artery catheters in patients with AHF is unnecessary and unlikely to lead to a better outcome.⁴⁰ Apart from patients with cardiogenic shock or rapidly decompensating heart failure, and patients who are being considered for heart transplantation with significant pulmonary hypertension, a pulmonary artery catheter is also likely to be helpful in obese patients who may be very difficult to assess and monitor clinically, and in patients with severe LV and right ventricular dysfunction in whom the response to vasodilator and other therapies may be difficult to predict. Some patients with

advanced heart failure are so tenuous that they can be managed optimally only with hemodynamic data feedback.

Treatment of Acute Heart Failure

The management of patients with AHF is primarily aimed at restoring perfusion of vital organs and relieving pulmonary congestion. In hemodynamic terms, the intention is to increase cardiac output and to decrease LV filling pressure, while preserving adequate coronary perfusion.

General Measures

Several general measures are advisable for treating most patients with AHF. Bed rest should be enforced. Patients feel most comfortable in the semi-upright position, with legs dependent.

Oxygenation

Special attention should be paid to maintaining adequate oxygenation. When there is hypoxia ($\text{PaO}_2 < 60$ mm Hg) without hypercapnia, oxygen-enriched inspired gas may suffice; this can be given through nasal prongs, Venturi masks, or reservoir bag masks, depending on the severity of gas exchange abnormality. Noninvasive ventilation by either continuous positive airway pressure breathing or bilevel positive airway pressure may become necessary when oxygenation cannot be maintained, or there is evidence of progressive hypercapnia despite aggressive treatment. The use of noninvasive ventilation is associated with a significant reduction in the need for tracheal intubation and mechanical ventilation. Failing these interventions, intubation and mechanical ventilation may be needed to improve oxygenation and reverse hypercapnia.

Infections

Patients with AHF are prone to infections. The most common are respiratory or urinary tract infections, septicemia, or nosocomial infections. Infections often manifest atypically in patients with AHF. Many patients are sick without a fever. Scrupulous infection control and measures to maintain skin integrity are mandatory in the ICU. Routine cultures are recommended.⁴ Prompt antibiotic therapy should be given when indicated.

Diabetes

Hyperglycemia occurs commonly in patients with AHF owing to impaired metabolic control. Routine hypoglycemic drugs should be discontinued, and glycemic control should be obtained by using short-acting insulin titrated according to repeated blood glucose measurements. Normoglycemia improves survival in diabetic patients who are critically ill.⁴¹

Deep Venous Thrombosis Prophylaxis

Patients with heart failure who are bedridden are at high risk for developing deep venous thrombosis, and prophylactic measures should be strongly considered.

Medications

Morphine

Morphine remains a valuable drug in the treatment of AHF, especially if the syndrome is associated with anxiety, restlessness, and dyspnea. The drug diminishes the patient's distress and reduces the work of breathing. Morphine achieves its

hemodynamic effects by causing arteriolar and venous dilation through its ability to diminish the vasoconstrictive effects of increased sympathetic tone.⁴² Morphine sulfate is usually administered in doses of 3 to 5 mg intravenously over 3 minutes. This dose may be repeated two or three times at 15-minute intervals. The patient should be monitored for respiratory depression, which can be reversed by the narcotic antagonist naloxone. Morphine should be avoided if the pulmonary edema is associated with hypotension, intracranial bleeding, disturbed consciousness, bronchial asthma, chronic pulmonary disease, or reduced ventilation, specifically in patients with an increased arterial PCO_2 . The use of morphine may be associated with an increase in adverse events, including intubation.³⁰

Vasodilators

Reduction of LV preload is highly desirable in patients with AHF and CPE; it is primarily intended to shift central blood volume to the periphery, LV diastolic volume and pressure. When AHF is associated with an expanded circulating volume, as with acute decompensation of chronic heart failure, substantial preload reduction can be achieved without a significant decline in arterial pressure. In the setting of hypertension and normovolemia, aggressive reduction in preload may lead to a substantial decrease in blood pressure. It is important to decide in advance whether a patient who presents with AHF is likely to be at increased risk of developing hypotension with reductions in LV preload.

Ventricular afterload is increased in most patients with heart failure, and the detrimental effects of afterload excess are proportional to the degree of LV systolic dysfunction. Afterload reduction with vasodilator therapy is directed at reducing excessive LV wall stress, with a resultant increase in stroke volume and a decrease in end-diastolic pressure. A reduction in afterload provides the greatest hemodynamic benefit for patients with the most advanced heart failure; a far greater increase in stroke volume and decrease in end-diastolic pressure are achieved with similar reductions in wall stress in patients with severe LV systolic dysfunction compared with patients with milder forms of heart failure (Fig. 24-7). Vasodilators are indicated in most patients with AHF as first-line therapy.

Nitroglycerin

Actions Nitroglycerin causes vasodilation by stimulating guanylate cyclase within the vascular smooth muscle of arterial resistance and venous capacitance vessels.⁴³ The predominant site of action depends on the dose being administered. At lower doses, nitroglycerin acts principally on the peripheral veins and reduces right ventricular and LV filling pressures. At higher doses, nitroglycerin causes modest arterial vasodilation, and consequently it may improve cardiac output.⁴⁴ Nitroglycerin can reduce the degree of mitral regurgitation^{45,46} and decreases the preload-dependent chamber stiffness by redistributing blood from the central blood pool (heart and lungs) to the periphery (mesenteric bed),^{47,48} decreasing LV volumes, which decreases the pericardial constraint.⁴⁹

Nitrates reduce subendocardial ischemia by coronary vasodilation and by reducing myocardial oxygen requirements through unloading effects. One disadvantage of nitrates is the rapid development of tolerance, especially when given intravenously in high doses, limiting their effectiveness to 16 to 24 hours only. Nitrates should be given at doses aimed at

Figure 24-7. Schematic diagram of the left ventricular wall stress-volume relationship. The loop has the same configuration as the pressure-volume relationship. **A**, With mild heart failure, a decrease in wall stress (arrows) results in an increase in stroke volume. **B**, With more advanced heart failure, a similar decrease in wall stress is accompanied by a marked increase in stroke volume. Vasodilator therapy (i.e., afterload reduction) produces a larger increase in stroke volume in advanced heart failure than in mild heart failure.

achieving optimal vasodilation, leading to an increase in cardiac index and decrease in pulmonary wedge pressure.

Use in Acute Heart Failure Randomized trials in AHF have established the efficacy of intravenous nitrates in combination with furosemide, and have shown that titration to the highest hemodynamically tolerable dose of nitrates with low-dose furosemide is superior to high-dose diuretic treatment alone.^{50,51} Nitroglycerin is effective in relieving the symptoms of acute pulmonary edema and is often the vasodilatory agent of choice in patients with underlying ischemic heart disease. Nitroglycerin should be administered in a manner to ensure the fastest onset of action. The intravenous route generally is preferred. The initial infusion rate is 10 µg/min, and the rate may be increased to 300 µg/min to achieve desired effects. The dose of nitroglycerin should not be increased when the systolic arterial pressure is less than 90 mm Hg. From a practical perspective, a reduction of 10 mm Hg in mean arterial pressure should be achieved.

Nitroglycerin can be administered orally or by inhalation (glyceryl trinitrate spray, 400 µg [2 puffs] every 5 to 10 minutes), or buccally (isosorbide dinitrate, 1 or 3 mg), while monitoring blood pressure. Buccal absorption may be erratic. One should be particularly cautious when administering nitrates to a patient with aortic stenosis or hypertrophic obstructive cardiomyopathy.

Nitroprusside

Actions Nitroprusside infusion improves ventricular performance by decreasing all the major components of LV afterload: systemic vascular resistance, arterial stiffness, arterial wave reflectance, and LV size.⁵² Proper dose selection achieves a reduction in afterload and preload with little change in systemic blood pressure. An often overlooked aspect of afterload reduction is the reduction of right ventricular load. Vasodilators that are associated with a decrease in LV filling pressures invariably unload the right heart.⁵³ Within the confined space of the pericardium, interventions that reduce the excessive volume of the right ventricle have a favorable hemodynamic effect on

the septal interaction between the right and left ventricles, and they consequently may improve LV filling and filling pressures. Nitroprusside is likely to achieve some of its favorable effects through this mechanism of ventricular interaction.

The incidence of side effects and toxicity is directly related to the dose and duration of administration. Cyanide may accumulate with prolonged high doses of nitroprusside and contribute to lactic acidosis. Toxicity can be avoided by monitoring blood lactate and thiocyanate levels.

Use in Acute Heart Failure Intravenous nitroglycerin is usually the vasodilator of choice for most patients with AHF, especially if a patient has underlying ischemic heart disease, but nitroprusside is the vasodilator of choice when a substantial reduction in LV afterload is required. Although both vasodilators affect vascular smooth muscle, nitroprusside and nitroglycerin differ in important ways. Because the magnitude of arterial vasodilation achieved with nitroprusside is greater than that with nitroglycerin, nitroprusside has the greater potential to produce hypotension. Such hypotensive action may lead to more neurohormonal activation, and this may be the reason why rebound hemodynamic effects after abrupt withdrawal of the drug occur more frequently with nitroprusside than with nitroglycerin.⁵⁴

Nitroprusside is reserved for clinical situations requiring acute, short-term afterload reduction. Nitroprusside is most beneficial for hypertensive patients or patients with an elevated LV filling pressure (≥ 20 mm Hg) and a systemic arterial pressure of 100 mm Hg or greater. This clinical picture is commonly encountered in patients with a large MI, with decompensated chronic heart failure, with acute valvular regurgitation, or after cardiopulmonary bypass.

Nitroprusside usually represents a stabilizing pharmacologic bridge to more definitive interventions (e.g., valve replacement or coronary revascularization). The end points of acute vasodilator therapy can vary from patient to patient, but reasonable hemodynamic end points include a reduction in LV filling pressure to 15 mm Hg or less and an increase in cardiac output that

would ensure adequate tissue oxygen delivery (usually a cardiac index >2.5 L/min/m²), while maintaining a systemic blood pressure of 90 mm Hg or greater.

The optimally effective and safe administration of nitroprusside often requires hemodynamic monitoring by means of intra-arterial catheters. The initial dose of 0.10 to 0.20 $\mu\text{g/kg/min}$ is gradually increased as needed to attain the desired clinical and hemodynamic effects.

Nesiritide

Actions Nesiritide is a recombinant human BNP that is identical to the endogenous hormone. Nesiritide has venous, arterial, and coronary vasodilatory properties that reduce preload and afterload, and increase cardiac output without direct inotropic effects.⁵⁵

Use in Acute Heart Failure Nesiritide was compared with intravenous nitroglycerin and resulted in improvement in hemodynamics more effectively and with fewer adverse effects, although this did not translate into improvement in clinical outcome.⁵⁶ Nesiritide may cause hypotension, and some patients are nonresponders. The role of this agent is uncertain in the context of AHF. In most hospitals, nesiritide is not given as a first-line agent, but this medication may be considered when a patient does not respond rapidly to conventional treatment. The recommended dose of nesiritide is an intravenous bolus of 2 $\mu\text{g/kg}$ followed by a continuous infusion of 0.01 $\mu\text{g/kg/min}$.

A U.S. Food and Drug Administration expert panel of cardiologists made specific recommendations for nesiritide use, as follows⁵⁷:

- Consider the risks (e.g., worsening renal function, mortality) and benefits to the patient before initiating therapy.
- Use nesiritide only in hospitalized patients with acutely decompensated congestive heart failure with dyspnea at rest.
- Avoid using nesiritide in place of diuretic therapy.
- Avoid regular repetitive use of nesiritide.
- Avoid use for off-label indications, including enhancing renal function or augmenting diuresis.

Other Vasodilators

The intravenous use of direct-acting vasodilators such as hydralazine has a very limited or no role in the management of AHF and CPE. Other vasodilators, such as calcium antagonists or α -adrenergic blockers, cannot be recommended as first-line therapy for patients with AHF. Angiotensin-converting enzyme inhibitors are not indicated in the early stabilization of patients with AHF, and calcium antagonists are not recommended in the treatment of AHF. Diltiazem, verapamil, and dihydropyridines should be considered contraindicated in the setting of AHF.

Diuretics

Actions

Loop diuretics block the sodium-potassium-chloride transporter, resulting in increased urine volume by enhancing the excretion of water, sodium chloride, and other ions, leading to a decrease in plasma and extracellular fluid volume, total body water, and sodium. These effects result in a reduction in right ventricular and LV filling pressures and a decrease in peripheral and pulmonary congestion. Intravenous administration of loop diuretics also exerts a vasodilating effect, manifested by an early (5 to 30 minutes) decrease in right atrial and pulmonary wedge pressure and pulmonary resistances. These hemodynamic

effects result from the direct peripheral arterial and venodilating actions. It is thought that vasodilation rather than diuresis is the principal early mechanism by which diuretics alleviate symptoms of pulmonary edema.⁵⁸ High bolus doses (>1 mg/kg) of diuretics may lead to reflex vasoconstriction. As opposed to long-term use of diuretics, in severe decompensated heart failure, the use of diuretics improves loading conditions and may reduce neurohormonal activation in the short term.⁵⁹

Use in Acute Heart Failure

Intravenous loop diuretics (furosemide, bumetanide) are the most widely used diuretics in the treatment of AHF and CPE. The dose should be titrated according to the diuretic response and relief of congestive symptoms. Administration of a loading dose followed by continued infusion of furosemide or torsemide has been shown to be more effective than bolus alone.^{60,61} Thiazides and spironolactone can be used in association with loop diuretics; the combination in low doses is more effective and has fewer secondary effects than the use of higher doses of a single drug. Combination of loop diuretics with inotropes or nitrates is another therapeutic approach that is more effective and produces fewer secondary effects than increasing the dose of the diuretic. The diuretic doses for patients with mild congestion and new-onset AHF are generally much lower than doses for patients with advanced fluid overload or patients with renal dysfunction. The doses of diuretics as they relate to severity of AHF and the goals of treatment are summarized in Table 24-6.

Diuretic Resistance

Diuretic resistance is defined as the clinical state in which diuretic response is diminished or lost before the goal of treatment has been achieved. Such resistance is associated with a poor prognosis.⁶² There are two forms of diuretic tolerance: (1) Short-term tolerance occurs when the diuretic effect is attenuated after the first dose has been administered; this can be prevented by restoring diuretic-induced loss of volume. (2) Long-term tolerance is observed after prolonged administration of a loop diuretic, which leads to avid sodium reabsorption at more distal sites. This phenomenon argues for the use of sequential nephron blockade with combinations of loop and thiazide diuretics in patients who do not have adequate responses to optimal doses of a loop diuretic. To overcome inadequate response to diuretics, it is important to adhere to the following principles (see Table 24-6):

1. Diuretics should be used in moderation; excessive doses of any single drug should be avoided.
2. A loop diuretic is the diuretic of choice in patients with renal insufficiency and in patients with more than mild fluid retention.
3. The diuretic response of loop diuretics is not increased by giving larger doses, but it may be increased by giving moderate doses more frequently.
4. The clinician can make use of synergism by adding a thiazide when there is apparent tolerance to loop diuretics. This diuretic regimen can be used to achieve euvolemia. Hydrochlorothiazide combined with triamterene should be considered to prevent excessive potassium wasting. Metolazone, a potent thiazide, could be added to a loop diuretic when hydrochlorothiazide seems to be ineffective in promoting sodium excretion. This combination often causes severe electrolyte disturbances.

Table 24-6. Diuretic Dosing and Goals of Treatment

Clinical Scenario	Diuretic	Dose	Goal/Comments
Moderate fluid overload	Furosemide	20-40 mg IV q12h*	Urine output of >200 mL in the first 2 hr after bolus dose
	Bumetanide	0.5-1 mg IV q12h*	
Severe fluid overload	Furosemide	40-80 mg IV q12h [‡] or Bolus of 80 mg IV + continuous infusion at 10-20 mg/hr	Urine output of >400 mL in the first 2 hr after bolus dose and then 150 mL/hr
	Bumetanide	1-2 mg IV q12h [†]	
Severe fluid overload and renal dysfunction (GFR <30 mL/min)	Furosemide	80-200 mg IV q12h or Bolus + continuous infusion at 20-40 mg/hr	Urine output of >200 mL in the first 2 hr after bolus dose and then 100 mL/hr
Diuretic resistance	Add chlorothiazide to furosemide Acetazolamide [§]	250-500 mg IV 30 min before loop diuretic 0.5 mg IV q12h	Urine output of >200 mL in the first 2 hr after bolus dose and then 100 mL/hr

*Double dose if goal not attained.

†If goal not attained, add chlorothiazide (see diuretic resistance).

‡Lower dose if BP <100 mm Hg.

§Consider in the presence of alkalosis.

5. In patients who have poor responses to intermittent doses of a loop diuretic, a continuous intravenous infusion should be tried.

Positive Inotropic Agents

Positive inotropic agents are indicated in the presence of hypotension and end-organ hypoperfusion (decreased renal function) with or without congestion or pulmonary edema refractory to diuretics and vasodilators at optimal doses. Anecdotal experience suggests that positive inotropic agents may be especially useful in these patients when left and right ventricular systolic function is markedly depressed. Their use is potentially harmful because they increase oxygen demand and calcium loading, and they should be used with caution.⁶³ More recent data do not support the routine intravenous use of these agents as an adjunct to standard therapy in the treatment of patients hospitalized for decompensated chronic heart failure.⁶⁴ The choice of agent depends on the predominant hemodynamic abnormality. The rationales for using certain positive inotropic agents are outlined in Table 24-7.

Dopamine

Actions Physiologically, dopamine is the precursor of norepinephrine and releases norepinephrine from the stores of the nerve endings in the heart. Dopamine has the valuable property in severe heart failure of specifically increasing renal blood flow by activating postjunctional dopaminergic receptors.⁶⁵ This vasodilatory effect is observed at doses of 1 to 2 µg/kg/min and peaks at a dose of 7.5 µg/min, but the vasoconstrictive effect begins at a dose of 10 µg/kg/min. Because the inotropic effects of dopamine result primarily from its indirect effects, its use in advanced heart failure is limited by the neurotransmitter depletion present in the failing heart.⁶⁶ In milder forms of heart

failure, dopamine may have similar effects to dobutamine except for the greater tendency to increase heart rate and a tendency to increase systemic vascular resistance and ventricular filling pressures at medium and higher doses. Dopamine is especially useful in treating acute heart failure when renal blood flow is impaired.

Use in Acute Heart Failure Dopamine should be infused through a long, indwelling catheter because of the risk of extravasation. Extravasation may cause necrosis and sloughing of the surrounding tissue because of the vasoconstrictive effects of the agent. Infusion with dopamine should be started at doses of 2 to 5 µg/kg/min and should not be increased beyond 5 µg/kg/min in patients with blood pressures of 100 mm Hg or greater. This agent may be deleterious in patients with AHF because it may augment the LV afterload, pulmonary artery pressure, and pulmonary resistance. In markedly hypotensive patients with peripheral hypoperfusion, large doses of dopamine can be used to support systemic blood pressure, alone or in combination with norepinephrine.

Dobutamine

Actions Dobutamine is a β-adrenergic agonist that stimulates β₁-adrenergic, β₂-adrenergic, and α₁-adrenergic receptors.⁶⁷ Cardiac contractility is increased by virtue of its β₁ and α₁ effects, but because the α₁-adrenergic effects are generally counterbalanced by the β₂ actions, there is generally little change in blood pressure. Dobutamine markedly increases cardiac output, but produces only modest changes in LV filling pressures and virtually no increase in blood pressure.⁶⁸ Heart rate generally increases only when doses greater than 10 µg/kg/min are used. Compared with dobutamine, dopamine is a better vasoconstrictor,⁶⁸ and milrinone is a better vasodilator.⁶⁹ The elimination of the drug is rapid after cessation of infusion, making it a convenient inotropic agent.

Table 24-7. Treatment for Different Acute Heart Failure Syndromes

Acute Heart Failure Syndrome	Systolic Blood Pressure	First-Line Treatment	Second-Line Treatment	Third-Line Treatment
Hypertensive	>140 mm Hg	Oxygen CPAP if needed Loop diuretic Intravenous nitroglycerin	Increase doses of nitroglycerin or diuretic or both	Intravenous nitroprusside
Normotensive	100-140 mm Hg	Oxygen CPAP if needed Loop diuretic Vasodilators	Increase doses of nitroglycerin or diuretic or both Add thiazide diuretic	Milrinone when there is evidence of prerenal azotemia
Preshock	85-100 mm Hg	Oxygen CPAP Vasodilator and diuretics	Dobutamine or milrinone	Add dopamine
Cardiogenic shock	<85 mm Hg	Oxygen CPAP Volume loading Dopamine >5 µg/kg/min	Norepinephrine	Mechanical support IABP Consider VAD

CPAP, continuous positive airway pressure; IABP, intra-aortic balloon pump; VAD, ventricular assist device.

Adapted from Task Force on Acute Heart Failure of the European Society of Cardiology. *Eur Heart J* 2005;26:384-416.

Use in Acute Heart Failure The usual dose of dobutamine is 2.5 to 15 µg/kg/min. Short-term infusions are often extremely effective in the treatment of unstable AHF, especially when systolic pressures are preserved. Long-term infusion should be avoided because of the development of hemodynamic tolerance.⁷⁰ Dobutamine is likely to increase myocardial oxygen consumption and can cause serious arrhythmias. There are no controlled trials on dobutamine in AHF patients, and some trials show unfavorable effects with increased untoward cardiovascular events.

Milrinone

Actions Milrinone is a type III phosphodiesterase inhibitor that produces dose-dependent increases in cardiac output and decreases in LV filling pressures as a result of the interaction of its positive inotropic, positive lusitropic, and peripheral vasodilator actions.^{71,72} The net result is a hemodynamic profile similar to that of the combination of nitroprusside and dobutamine. Because of its vasodilating effects, milrinone is less likely than dobutamine to increase heart rate and myocardial oxygen consumption. Despite these theoretical advantages, myocardial ischemia has been provoked by these agents, and marked hypotensive episodes have been observed.

Use in Acute Heart Failure Milrinone requires a loading dose of 50 µg/kg over 10 minutes followed by a maintenance infusion of 0.375 to 0.75 µg/kg/min. The dose should be adjusted in patients with decreased renal clearance. This agent may be preferred to dobutamine in patients receiving concomitant β-blocker therapy, or with an inadequate response to dobutamine, or both. The data regarding the effects of milrinone administration on the outcome of patients with AHF are insufficient, but raise concerns about safety.⁶⁴

Digitalis

Digitalis generally has no role in the treatment of AHF, unless the patient has been taking digitalis for chronic heart failure, or if digitalis is given to control a rapid ventricular response in atrial fibrillation.

Vasopressors

Vasopressors are largely used to treat cardiogenic shock and are discussed elsewhere.

Other Treatments

Ultrafiltration

In patients with severe renal dysfunction and refractory fluid retention, continuous venovenous hemofiltration may become necessary. Ultrafiltration has been used in patients with therapy-resistant chronic volume overload. Conventional ultrafiltration requiring central venous access is most often used, particularly if the patient is extremely edematous. Generally, the hemodynamic changes produced by ultrafiltration are modest. The reduction in water with ultrafiltration is accompanied by decreases in right atrial and pulmonary venous pressures. Cardiac output and stroke volume are unchanged or increase slightly. The weight loss is more sustained when contrasted with the weight loss achieved with furosemide treatment.⁷⁴ The typical volume of water removed per ultrafiltration session is 3000 to 4000 mL. This promising therapeutic modality requires further study and refinement before it is more widely used in AHF patients.

Continued Therapy for Chronic Heart Failure

Patients who are admitted with normotensive AHF should be maintained on the usual outpatient doses of β-blockers, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers.

Intra-Aortic Balloon Pump

In patients with refractory heart failure, refractory ischemia, or arrhythmias, an intra-aortic balloon pump placement helps to unload the heart and improve myocardial and systemic perfusion. Absolute contraindications to placement of an intra-aortic balloon pump include aortic insufficiency and aortic dissection.

Surgical Treatment

Surgical therapies for patients with AHF include coronary revascularization, correction of the anatomic lesions, valve replacement or reconstruction, and temporary circulatory support by means of mechanical assist devices.

Choice of Therapeutic Regimen

In choosing the appropriate medical regimen, it is helpful to revisit the different AHF syndromes. These are outlined in Table 24-7. Two special scenarios warrant mention.

Hypertensive Acute Heart Failure

LV systolic function is normal in patients hospitalized with pulmonary edema and hypertension. Vasodilator therapy should aim for an initial rapid (several minutes) reduction of systolic blood pressure of 30 mm Hg, followed by a more measured decrease of blood pressure to the values obtained during stable periods. No attempt should be made to restore normal values of blood pressure because this may cause deterioration in renal function. The initial blood pressure reduction may be achieved by intravenous loop diuretics, particularly if the patient is clearly fluid overloaded with a long history of chronic heart failure, combined with intravenous nitroglycerin or nitroprusside.

Acute Heart Failure with Normal Ejection Fraction

The most effective treatment of patients with AHF with normal ejection fraction is to address the underlying cause. The treatment is similar to hypertensive AHF. In this regard, blood pressure control and the treatment of underlying ischemia are important goals. A major goal of therapy is to reduce the left atrial and pulmonary venous pressures. Diuretics, vasodilators, and other preload-reducing agents are used as discussed previously. The steep or stiff diastolic pressure volume curve (see Fig. 24-4) can be responsible for a substantial decrease in filling pressure with little change in volume; as a result, hypotension often occurs with the usual doses of diuretics. Cautious administration of lower than usual doses of diuretics is advisable. Conversion of an atrial arrhythmia to sinus rhythm is usually beneficial.

CHAPTER 25

Definition
Epidemiology
Pathophysiology
Clinical Presentation

Evaluation Of The SCA Survivor
Therapy
Conclusion

Definition

Sudden cardiac death (SCD) is defined as a natural and unexpected death as a result of cardiac causes that occur within 1 hour of the onset of new symptoms.¹ In some medical circles, the term “sudden cardiac arrest” (SCA) is preferred because the expression “death” conveys finality of the event, which is not necessarily the outcome in all cases. In this communication, both terms will be used as appropriate in the text.

Epidemiology

Cardiovascular disease-related deaths are still the most common cause of mortality in the United States. The two modes of cardiovascular death (i.e., sudden and nonsudden) are equally common. SCD claims 325,000 lives each year in United States,² thus the incidence is 0.1% to 0.2% annually.³ It is usually ascribed to arrhythmic causes and it is the case the vast majority of the time when the initiation of the episode is electrocardiographically documented. However, the victims are seldom under medical observation, thus the exact mechanism leading to cardiovascular collapse is difficult to establish, and the cause is labeled on the basis of presentation and the earliest onsite ECG recordings. Monitored victims and rescue squads encountering individuals with SCA show the following arrhythmias at the time of arrival: ventricular fibrillation (VF) in 80% of the victims, ventricular tachycardia (VT) in 10% who have the best outcome, and bradycardias in 10%.^{4,5} The rhythm disturbance first documented by emergency rescue teams is dependent upon the time elapsed after the cardiovascular collapse. VF is seen early after collapse and progresses to asystole as time passes (Fig. 25-1).

For the most part, patients with bradycardia have little or no response to pacing, suggesting hemodynamic collapse as the underlying problem and bradycardia as the concomitant rhythm (electrical-mechanical dissociation). Occasionally, torsades de pointes may be precipitated by severe bradycardia and cause SCA. The universal futility of cardiac pacing in this setting to improve survival in this population, attests to the possibility that overall, one fourth of SCA victims may have nonarrhythmic etiology. Conduction system abnormalities have been labeled as the cause of SCD in younger population victims without demonstrable heart disease in autopsy studies.⁶

While the possibility of SCA can be literally eliminated for previously identified individuals at high risk, the population at large, for now, must contend with the existing sources of aid (emergency medical services, first responders, rescue squads, etc.) that are available in a given community and their relative effectiveness.

In this communication, more space is provided for lesser known but emerging arrhythmia syndromes and the management approach is mostly geared towards internal or external defibrillation devices. The literature is replete with coronary artery disease (CAD) in SCA and its various presentations; work-up, therefore, will only be briefly discussed.

Pathophysiology

SCA may be best considered as the outcome of an interaction between an abnormal cardiac substrate and a transient functional disturbance, which triggers the arrhythmia at a specific point in time. Increasingly, however, it is being recognized that SCA can occur in the absence of any demonstrable structural heart disease. Furthermore, it is coming to light that for many of these primary arrhythmic etiologies there are identifiable genetic mutations, as will be discussed later in this chapter.

Pathologic Substrates

Over the years, numerous studies have revealed that an overwhelming majority of SCA cases (75% to 80%) are due to acute, chronic, or acute on chronic atherosclerotic CAD.¹ The second most frequent category of disorders is cardiomyopathies, which include both hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM). These pathologic substrates are:

1. CAD:

It has been demonstrated that there are one or more active coronary lesions in up to 90% of SCD victims⁷ that present as an acute, chronic, or acute on chronic process. This association is described as follows:

- Acute:** There is a close association between the occurrence of SCD and the presence of plaque fissuring and/or erosion, platelet aggregation, and acute thrombosis within the matrix of coronary atherosclerosis. However, only 20% of SCD victims have acute myocardial infarction (MI),⁸ likely because the pathophysiologic mechanism leading to that expression

Figure 25-1. Fortuitous Holter recording from a patient who experienced sudden cardiac death outside the hospital documents the usual and typical sequence of events. The initial rapid ventricular tachycardia continues into the second panel with widening of the QRS, probably owing to myocardial metabolic changes. Subsequent transformation to ventricular fibrillation is shown in the third panel, followed by asystole. The initial documented rhythm and, ultimately, the prognosis depend on how soon emergency personnel arrive to treat the individual. (From Akhtar M, Garan H, Lehmann H, et al: *Sudden cardiac death: management of high risk patients*. *Ann Intern Med* 1991;114:499.)

is interrupted by an abrupt cessation of the biologic activity because of lethal arrhythmia.⁹

b. Chronic: Myocardial pathology reflects the presence and extent of chronic coronary atherosclerosis, in that myocardial scars, because of healed MIs, are common.¹⁰

2. Left ventricular hypertrophy (LVH) and HCM:

LVH is now a well-established independent risk factor for SCD,¹¹ both in the presence and absence of concomitant CAD. In fact, the majority of SCA victims with CAD have coexisting LVH, although the mortality associated with LVH does not parallel that of CAD. Hypertrophied ventricular myocytes demonstrate altered membrane electrophysiology, resulting in delayed inactivation of slow inward Ca^{2+} currents and delayed activation of K^{+} rectifier currents accounting for recovery of excitability. Transient ischemia and reperfusion make hypertrophied cells susceptible to afterdepolarizations and triggered arrhythmias.¹² One common feature observed in HCM is myocytes disarray, which is common to most, but not all, genetic forms of the disease. The association between HCM expression and SCA risk is complex because of patterns of inheritance involving not only multiple gene foci but mutation-specific risk.⁹

3. DCM:

The underlying myocardial pathology demonstrated in DCM accounts for approximately 10% to 15% of SCD. The pathologic findings are nonspecific, characterized by dilation

of the ventricles with interstitial patchy fibrosis, myocytes degeneration, and necrosis.

4. Infiltrative, inflammatory, and valvular diseases:

These account for most of the remaining minority of causes of SCA in patients with structural heart disease. Clinically silent myocarditis has been considered among the more common of the causes of SCD in adolescents and young adults.¹³ The pathologic finding in acute viral myocarditis is high-grade inflammatory processes in the myocardium, but some forms of a viral myocarditis may demonstrate diffuse fibrosis, without inflammatory markers.¹⁴

5. Abnormalities of the cardiac conducting tissue:

They are best exemplified by the Wolff-Parkinson-White syndrome (WPW) and diseases of the His-Purkinje system. Patients with WPW who have pathways with short refractory periods are susceptible to VF during atrial fibrillation/flutter.

6. Genetically determined disorders:

They account for a small proportion of SCDs (1% to 2%), occurring predominantly in adolescents and young adults.

a. Inherited: long Q-T syndromes, short QT syndromes, Brugada syndrome, HCM, right ventricular dysplasia, catecholaminergic polymorphic ventricular tachycardia, progressive cardiac conduction defect, sudden infant death syndrome "SIDS," and idiopathic ventricular fibrillation "IVF."^{15,16}

b. Not inherited: congenital cardiac lesions (e.g., anomalous coronary arteries) and myocarditis.¹⁷

Functional Modulators

Functional modulators interact with structural abnormalities, converting them from a stable to an unstable state, promoting the start of fatal arrhythmias. Many of the functional modulators (e.g., transient ischemia and acquired long QT), if sufficiently intense, can initiate a fatal arrhythmia in a victim, in the absence of any structural heart disease. However, this is clinically uncommon.

1. Transient ischemia:

It plays a major role in producing fatal arrhythmias. At the cellular level, acute physiologic changes from ischemia include dispersion of both conduction patterns and refractoriness, providing the environment for reentrant arrhythmias and generating abnormal automatic activity. Ischemia opens up the ATP-sensitive K^+ channels, more in the epicardial than the endocardial cells.¹⁸ This results in heterogeneity in the refractoriness of the two regions, making the myocardium prone to arrhythmias. Reperfusion events may have equally important electrophysiologic consequences. An inward flux of calcium occurs during reperfusion, resulting in overload, and correlates with a burst of spontaneous ventricular ectopy, probably owing to automaticity or triggered activity.

2. Systemic factors:

a. Hemodynamic deterioration:

Acute hemodynamic deterioration may precipitate a secondary cardiac arrest, which unfortunately carries high short-term mortality. The mechanisms could be related to ischemic and metabolic substrates.

b. Electrolyte disturbances:

Hypokalemia has been implicated in an increased risk of sudden and total cardiovascular mortality and plays a particularly important role in the genesis of torsades de pointes and other polymorphic VT.¹⁹

3. Altered systemic autonomic balance:

Structural abnormalities create autonomic disturbances resulting in altered β -adrenergic receptor content, coupling proteins, and adenylate cyclase activity. This causes dispersion of quantitative and qualitative responses to sympathetic stimulation in the abnormal heart, predisposing to arrhythmias. Clinically, altered systemic autonomic balance is manifested as loss of the normal diurnal variation of heart rate variability, which is considered a marker for risk of SCA among MI and SCA survivors.²⁰

4. Drug toxicity:

Drug toxicity, as a cause of SCA, has been documented in connection with a variety of both cardio-active (antiarrhythmic) and noncardiac drugs, such as psychotropic drugs, erythromycin, Seldane, and pentamidine. A variety of electrophysiologic mechanisms are operative in the genesis of lethal ventricular tachyarrhythmias induced by various drugs. However, there may be concurrent structural or functional abnormalities. The latter include transient ischemia, hemodynamic dysfunction, electrolyte abnormalities, and ventricular hypertrophy. Recently, an increased risk of SCA has been reported with the concomitant use of cocaine and alcohol, and is probably because of the generation of a cardiotoxic metabolite, cocaethylene.²¹

5. Acidosis

6. Hypoxemia

Clinical Substrate

To predict SCA, it is important to recognize the conditions leading to abrupt cessation of cardiac output. Figure 25-2 shows data derived from various studies²²⁻²⁶ demonstrating the

Figure 25-2. Prevalence of underlying heart disease in adult patients who have experienced sudden cardiac death, based on data derived from several studies,²²⁻²⁶ shows coronary artery disease, cardiomyopathies, valvular and hypertensive heart disease, and electrical disturbances as the predominant substrates. CAD, coronary artery disease; CM, cardiomyopathy; HHD, hypertensive heart disease; LQTS, long QT syndrome; SVT, supraventricular tachycardia. (From Deshpande S, Vora A, Axtell K, Akhtar M: Sudden cardiac death. In Brown DL [ed]: *Cardiac Intensive Care*. Philadelphia, Saunders, 1998, pp 391-404.)

predominant substrates of SCD. The relative risk for SCD is dependent upon the underlying substrate and is graphically demonstrated for various populations in Figure 25-3.

Coronary Artery Disease (CAD)

CAD is the most common cause of SCA, where it is the responsible substrate in 65% to 90%²⁷⁻³³ of cases. SCA related to coronary events is more common in younger victims, more common in men than in women, and more common in African Americans than in whites. Approximately 20% of SCA victims show evidence of new ST elevation myocardial infarction at the time of cardiac arrest, but 40% to 75% have evidence of healed MI. Fifty percent of post-MI deaths occur in the first 6 months.⁹ Most of the risk factors for CAD are predictors for SCA (e.g., left bundle branch block on ECG, hyperlipidemia, hypertension, cigarette smoking, obesity, diabetes, and lifestyle).³

Nonatherosclerotic CAD

Nonatherosclerotic CAD is also a significant risk for SCA, especially in the younger population. The common nonatherosclerotic coronary artery abnormalities include:

1. Congenital anomalies:

The most common congenital anomaly is the origin of the left main coronary artery from the right sinus of Valsalva, with passage of this vessel between the aorta and the pulmonary trunk.³⁴ Although death is not universal with this anomaly, virtually all such deaths occur during or shortly following vigorous exercise. It is postulated that the left main coronary may be compressed against the root of the pulmonary trunk during exercise when both of these great vessels dilate, thus compromising coronary blood flow and producing myocardial ischemia. Unfortunately, antemortem diagnosis of this anomaly is rare, despite the fact that a significant number of patients experience prodromal symptoms, such as syncope and angina.

Figure 25-3. The incidence and number of patients with sudden cardiac death (SCD) in various subgroups of patients. *Left*, SCD incidence percent per year in each subgroup. *Right*, Total number of SCDs per year ($n \times 1000$). CAD, coronary artery disease; EF, ejection fraction; Hx, history; MI, myocardial infarction; SCA, sudden cardiac arrest; VF/VT, ventricular fibrillation/ventricular tachycardia. (Modified from Myerburg RJ Kessler KM, Castellanos A: SCD: Structure, function, and time-dependence of risk. *Circulation* 1992;85:I-2-I-10.)

Another coronary anomaly that poses risk for SCA in young individuals is the origin of the right coronary artery from the left sinus of Valsalva, with a consequent course between the aorta and pulmonary trunk.³⁵ Some unusual variants of coronary arterial anatomy, including hypoplasia of the right coronary and left circumflex or the anomalous origin of the left anterior descending or right coronary from the pulmonary trunk,³⁶ may in rare instances be implicated in exercise-related sudden cardiac deaths.

2. Embolism:

Coronary artery embolism usually results from endocarditis of the native or prosthetic aortic and mitral valves,³⁷ although rarely, left ventricular or left atrial thrombi may embolize into the coronaries.

3. Arteritis:

Kawasaki disease,³⁸ polyarteritis nodosa,³⁹ and syphilitic aortitis⁴⁰ can affect the coronary circulation, and SCA may be a rare sequelae.

4. Bridging:

SCA has also been reported to occur, especially during exertion, in patients with severe myocardial bridging, particularly of the left anterior descending artery. In this condition, the artery is completely surrounded by myocardium during a portion of its course, instead of being largely epicardial, and a critical degree of systolic compression resulting in myocardial ischemia may occur, even in the absence of underlying atherosclerotic disease.

5. Dissection:

Spontaneous dissection of the coronary arteries in Marfan syndrome⁴¹ and in the peripartum period of pregnancy,⁴² coronary involvement with any type 1 aortic dissection from other causes, or a rupture of the sinus of Valsalva aneurysm involving the coronary ostia can also cause SCA.⁴³

6. Vasospasm:

Vasospastic angina can have ventricular arrhythmias and culminate in SCA.⁴⁴ This is occasionally an etiology for otherwise unexplained SCA and may also occur as a result of cocaine abuse.

Hypertrophic Cardiomyopathy (HCM)

Despite a relatively low incidence of HCM in the general population, it maintains a high profile risk because 50% to 90% of deaths in patients with HCM are sudden, with an annual mortality rate of 2% to 4%.⁴⁵ Unlike most other heart diseases, the risk of SCA in HCM declines with age.⁴⁶ Patients with this disease characteristically have genetic heterogeneity in the amount of hypertrophy in different regions in the left ventricle. It results from multiple diseased genes, encoding sarcomeric proteins. Microscopically, gross disorganization of muscle bundles and myofibrillar architecture, altered gap junctions, increased basal membrane thickness, and connective tissue accumulation are noted.⁴⁷ These patients, therefore, manifest both electrical instability and consequences of myocardial hypertrophy with altered hemodynamics.

The mortality risk, based on the degree of outflow tract obstruction, has not yet been clearly stratified and, therefore, although hemodynamic considerations may play an important role in SCA, no predictive variables have been identified.⁴⁷ Furthermore, the combination of nonsustained ventricular tachycardia (NSVT) and inducible VT at electrophysiologic testing does confer a higher risk, and, conversely, the absence of NSVT and lack of inducibility indicates a lower risk.

The mechanism for SCA in patients with HCM is most often ventricular arrhythmias.⁴⁸ However, left ventricular outflow obstruction, sinus node dysfunction, atrioventricular (AV) conduction diseases, and supraventricular arrhythmias are alternative mechanisms.⁴⁹ The genesis of these arrhythmias is found in a complex interplay of electrophysiologic and hemodynamic abnormalities, primarily from electrophysiologic derangement of the hypertrophied muscle. Fairly often, SCA is the first manifestation of heart disease in these individuals, and thus is implicated as the substrate explaining the occurrence of these arrhythmias in children or young athletes.⁵⁰ Young age, strong family history, worsening obstructing symptoms,⁵¹ prior episode of SCA, failure to raise blood pressure on exercise, and severe ventricular hypertrophy of more than 3 cm thickness⁵² are incremental risk factors for SCA.

Ventricular hypertrophy secondary to systemic or pulmonary hypertension or owing to valvular or congenital heart disease is also associated with an increased risk for SCA.¹¹ This risk is proportionate to the level of severity of the hypertrophy.⁵³

Idiopathic Dilated Cardiomyopathy (DCM)

Overall survival following a clinical diagnosis of DCM is estimated to be 70% at 1 year and 50% at 2 years.⁵⁴ Most of these deaths are sudden in nature, and the incidence ranges in various series from 28% to 72% of total deaths. Syncope is a poor prognostic indicator in patients with DCM and is associated with a 44% incidence of SCD in 4 years.⁵⁵ Patients with preserved left ventricular function may have a lower short-term mortality from pump failure but are at a greater risk for SCA from arrhythmic events. Ventricular tachyarrhythmias⁵⁶ are the most common mode of death, but bradyarrhythmias⁵⁷ occur also, especially in those patients with advanced pump dysfunction. The arrhythmia most commonly implicated in SCA is primary polymorphic VT or VF. Additionally, rapid sustained monomorphic VT, related to bundle branch reentry,⁵⁸ and monomorphic VT, unrelated to bundle branch re-entry, have been seen. The recognition of this arrhythmia is critical because these patients can be successfully cured by catheter ablation of the right bundle branch.⁵⁸ Catheter ablation, at the present time, cannot be considered a curative option in SCA survivors with ventricular tachycardia related to CAD. Monomorphic VT, unrelated to bundle branch re-entry, is probably the result of the presence of smaller re-entrant circuits within the myocardium. In most instances, the triggering mechanism for the onset of primary polymorphic VT or VF is unclear. In some patients, triggers such as hypokalemia, use of antiarrhythmic medications, and hypomagnesemia may be more easily identifiable.

Long QT (LQT)

Patients with LQT have higher risk of SCA as a result of torsades de pointes and VF. This condition might be as a result of congenital substrate such as in LQT syndrome (LQTS), or may be acquired.

1. Congenital LQTS

The long QT syndromes are phenotypically and genotypically diverse, but have in common the appearance of long Q-T intervals in the electrocardiogram (ECG), an atypical polymorphic VT known as torsades de pointes (TdP), and, in many but not all cases, a relatively high risk for sudden cardiac death.

The prevalence of this disorder is estimated at 1-2:10,000. Congenital LQTS is subdivided into eight genotypes distinguished by more than 400 mutations in at least seven different ion genes and a structural anchoring protein located on seven chromosomes (Table 25-1).^{16,59-63} All of these genotypes have a similar phenotypic presentation (long QT) but different clinical profiles regarding T wave patterns (Fig. 25-4), arrhythmia triggers (Fig. 25-5), prognosis, and response to therapy.⁶³⁻⁶⁶ The phenotype penetration and expression is variable even in the same mutation.⁶⁷ The most common subgroups are LQT1, LQT2, and LQT3; they account for more than 90% of all genotyped LQTS patients.

a. LQT1:

It is the most common (40% to 50%) and least serious life-threatening genotype.^{63,66} The ECG pattern shows a long QT with a broad-based T wave (see Fig. 25-4). The trigger for cardiac arrhythmia is sympathetic hyperactivity associated with

exercise (especially swimming) or emotions (see Fig. 25-5). Catecholamine increases the function of the slowly activating delayed-rectifier potassium channel (IKs) to shorten the Q-T interval during tachycardia. However, due to “loss-of-function” of the IKs channel in LQT1, the Q-T interval is prolonged and causes TdP, leading to SCD. Two patterns of inheritance have been identified:

- (1) Jervell and Lang-Nielsen syndrome.⁶⁸ It is an autosomal recessive disease associated with deafness. Caused by more than 150 mutations in two genes that encode for the IKs channel (KCNQ1 and KCNE1), which affect the cardiac cell membrane and the production of the endolymph in the inner ear.⁶⁹
- (2) Romano-Ward syndrome.^{70,71} It is an autosomal dominant disease, more common, not associated with deafness, and broader (includes all other LQTS).

b. LQT2:

LQT2 is the second most common (35% to 50%) and second least serious life-threatening genotype.^{63,66} The ECG pattern shows long QT with a bifid, notched, low amplitude T wave (see Fig. 25-4). The triggers for cardiac arrhythmia are acute arousal with auditory stimuli or emotions, or during sleep or rest (see Fig. 25-5). It results from mutations in two genes (*KCNH2* “*HERG*,” and *KCNE2* “*MiRP1*”), causing “loss-of-function” of the rapidly activating delayed-rectifier potassium channel (IKr), and leading to Q-T prolongation, then to TdP and SCD.

c. LQT3:

It accounts for 10% of LQTS and manifests with a late-onset peaked or biphasic T wave pattern on the ECG.^{62,63,65} Triggers for cardiac arrhythmia are rest or sleep. There are more than 50 *SCN5A* mutations that cause LQT3. The *SCN5A*-encoded defect causes “gain-of-function,” leading to production of persistent, noninactivating inward sodium current (INa) during the plateau phase of the action potential and prolongation of the Q-T interval.⁶⁹

d. LQT4:

It is a rare subgroup that manifests with moderate Q-T prolongation, severe sinus bradycardia, and episodes of atrial fibrillation.^{72,73} Usually exercise induces polymorphic ventricular arrhythmia, syncope, or SCD. The responsible gene is *Ankrynb2* encoding the ankyrin B protein, which participates in the anchoring of several ion channels (Na⁺/K⁺ ATPase, Na⁺/Ca⁺ exchanger) and proteins (InsP3 receptor) to the cell membrane.^{72,73}

e. LQT5:

It accounts for 2% to 3% of LQTS (rare), and results from the *KCNE1* (*minK*) gene mutation, causing “loss-of-function” in the IKs channel. In homozygous or compound heterozygous form, it manifests as Jervell and Lange-Nielsen type II syndrome.⁷⁴

f. LQT6:

LQT6 is a very rare subgroup resulting from the *KCNE2* (*MiRP1*) gene mutation, causing “loss-of-function” in the IKr channel.

g. LQT7:

It is another rare subgroup of LQTS, results from the *KCNJ2* (*Kir2.1*) gene mutation causing “loss-of-function” in the IK1 channel. It manifests as an Andersen-Tawil syndrome, which is characterized by potassium-sensitive periodic paralysis, neuromuscular manifestations, facial dysmorphic features, variable degree of Q-T interval prolongation with giant U waves, bidirectional, or polymorphic tachycardia, and, rarely, SCD.^{75,76}

Table 25-1. Ion Channelopathy Disorders' Characteristics

Type	Gene Mutation	Locus	Ion Channel	Frequency	Trigger of TdP	Prognosis (cardiac event rate)*	Syndrome
LQT1	<i>KCNQ1</i>	11p15	I _K s	40%-50%	Exercise or emotion	30%	Jervell and Lange-Nielsen type I
LQT2	1. <i>KCNH2</i> "HERG" 2. <i>KCNE2</i>	7q35	I _K r	35%-50%	Auditory, emotion, or rest/sleep	46%	—
LQT3	<i>SCN5A</i>	3p21	I _{Na}	7%-15%	Rest/sleep	42%	—
LQT4	<i>AnkrynB2</i>	4q25	Several	Rare	Exercise	—	Severe SB, and episodes of AF
LQT5	<i>KCNE1</i> "minK"	21q22	I _K s	2%-3%	—	—	Jervell and Lange-Nielsen type II
LQT6	<i>KCNE2</i> "MiRP1"	21q22	I _K r	Very rare	—	—	—
LQT7	<i>KCNJ2</i> "Kir2.1"	17q23	I _K 1	Rare	—	—	Andersen-Tawil
LQT8	<i>CaCNA1C</i> "Cav1.2"	6q8A	I _{Ca}	Rare	—	—	Timothy
LQT9	<i>SCN4B</i>		I _{Na}	Rare	—	—	—
LQT10	<i>CAV3</i>		I _{Na}	Rare	—	—	—

Characteristics include: gene mutation and its chromosomal location, the affected ion channel, the frequency, the triggers of torsades de pointes, prognosis and name of the syndrome if present. LQT = long QT; SB = sinus bradycardia; AF = atrial fibrillation, ↑ = "gain-of-function"; ↓ = "loss-of-function." (The cardiac event rate is from Priori SG, Schwartz PJ, Napolitano C, et al: Risk stratification in the long-QT syndrome. *N Engl J Med* 2003;348:1866-1874. Copyright 2003 Massachusetts Medical Society. All rights reserved. Reproduced with permission.)

Figure 25-4. Three ECGs illustrating the typical Q-T morphology of the three most common long QT syndromes. Left, ECG of LQT1. Center, ECG of LQT2. Right, ECG of LQT3.

h. LQT8:

LQT8 is a rare subgroup type of LQTS called Timothy syndrome.⁷⁷ It is characterized by multiorgan dysfunction and results from a "gain-of-function" mutation in the *CaCNA1C* gene, which encodes the L-type calcium channel (CaV1.2). The manifestations include congenital heart disease, webbing (syndactyly) of the fingers and toes, immune deficiencies, autism, cognitive abnormalities,

and severe Q-T prolongation with childhood sudden death.

i. Other LQT:

There are other LQTS to be discovered. Two new ones were reported recently, LQT9 ("gain-of-function" *SCN4B* gene mutation of I_{Na}) and LQT10 ("gain-of-function" *CAV3* gene mutation of I_{Na}).

The risk of a second event (syncope or SCA) before age 18 is:⁶⁶

Figure 25-5. Gene-specific triggers for life-threatening arrhythmias in the three most common long QT (LQT) syndromes. *Top*, Exercise, emotion, sleep, or other triggers. *Bottom*, Swimming versus auditory stimulus. (Adapted from Schwartz PJ, Priori SG, Spazzolini C, et al: Genotype-phenotype correlation in the long-QT syndrome: gene-specific triggers for life-threatening arrhythmias. *Circulation* 2001;103:89-95.)

- High (= 50%) in QTc = 500 ms with LQT1 and LQT2, or male sex in LQT3.
- Intermediate (30% to 49%) in QTc = 500 ms with female sex LQT3, or QTc less than 500 ms in LQT3 or female sex LQT2.
- Low (<30%) in QTc less than 500 ms in LQT1 or male sex LQT2.

Exercise should be restricted in all patients to prevent an event. The mechanism of LQTS is related to the amplification of transmural dispersion of repolarization (TDR) because of preferential prolongation of the action potential duration of M cells. The development of early after depolarization-induced triggered activity underlies the substrate and trigger for the development of life-threatening ventricular arrhythmias.⁵⁹

Recent studies have provided validation for reliance on the estimation of TDR index, measuring Tpeak-Tend interval and for the prediction of risk of SCD in patients with congenital or acquired long QT.^{60,61}

2. Acquired LQT:

Acquired Q-T prolongation is more commonly encountered in clinical practice than congenital long QT and may be associated with bradycardia or caused by hypokalemia, hypomagnesemia, hypothermia, or anorexia nervosa or may be a side

effect from the use of class IA or III antiarrhythmic agents, or liquid protein diets. Bradycardia and delayed ventricular repolarization constitute the substrate for the development of polymorphic ventricular tachycardia that frequently degenerates into VF. SCA, in this group of patients, therefore, is usually iatrogenic, and the propensity to manifest Q-T prolongation after exposure to a trigger such as a drug may be related, in some patients, to an underlying genetic predisposition.

Brugada Syndrome

The Brugada syndrome is a rare condition characterized by a spontaneous or class I antiarrhythmic drug-induced, coved-type ST segment with at least a 2 mm J wave elevation (type I ECG pattern) appearing principally in the right precordial leads (V1-V3) (Fig. 25-6), often followed by negative T wave.⁷⁸ Incomplete or complete right bundle branch block morphology may be present. Unfortunately, this ECG pattern is dynamic, where up to 50% of patients with Brugada syndrome may have a transient normalization of the ECG, or a saddleback-type ST elevation (type II ECG pattern).^{16,59,79}

Symptomatic patients have syncope or SCA due to a rapid polymorphic VT or VF. The predictors of an event include spontaneous type I ECG pattern, inducibility of a sustained ventricular arrhythmia during electrophysiologic study, a previous episode of syncope, and male gender (75% of patients with Brugada syndrome are male).⁸⁰

The disease follows an autosomal dominant pattern of inheritance with variable penetrance in 20% to 50% of the patients. More than 70 mutations of the *SCN5A* gene have been identified as leading to a “loss-of-function” of the INa channel.¹⁶ The arrhythmogenic substrate is the amplification of heterogeneities intrinsic to the early phases (Ito) of the action potential of cells residing in different layers of the RV wall of the heart, leading to loss of the action potential dome at some epicardial sites but not others, creating phase 2 re-entry and coupled extrasystole.⁸¹ A marked TDR develops as a consequence of the heterogeneity, creating a vulnerable window—which when captured by a premature extrasystole can trigger a circus movement re-entry in the form of VT/VF and SCD.⁵⁹

Short QT Syndrome (SQTS)

SQTS is an autosomal-dominant inherited syndrome characterized by a QTc less than 320 ms, tall peaked symmetrical T waves in the ECG (Fig. 25-7), and high incidence of VT/VF and atrial fibrillation secondary to increased TDR.^{59,82} Electrophysiology studies show very short atrial and ventricular refractory periods and easily inducible ventricular fibrillation.⁸³ The mutations have been identified in four different genes to date:^{16,84}

1. SQTS1: *KCNH2* “*HERG*” gene causing “gain-of-function” of the IKr channel.
2. SQTS2: *KCNQ1* (KvLQT1) gene causing “gain-of-function” of IKs channel.
3. SQTS3: *KCNJ2* causing “gain-of-function” of IK1 channel. Uncommon to cause SCD.
4. SQTS4: *CACNA1C* and *CACNB2* causing “loss-of-function” of α_1 - and β_2 -subunits of the L-type calcium channel leading to short QT and Brugada ECG morphology.

Catecholaminergic Polymorphic VT (CPVT)

CPVT is a rare inherited syndrome characterized by physical or emotional stress-induced bidirectional VT, polymorphic VT, and a high risk of SCA in the setting of a structurally normal

Figure 25-6. A and B. Types of ECG morphology for Brugada syndrome (**A**) and the proposed mechanism for Brugada syndrome (**B**). A shift in the balance of currents amplifies existing heterogeneities by causing loss of action potential (AP) dome at some epicardial, but not endocardial, sites. A vulnerable window develops as a result of the dispersion of repolarization and refractoriness within the epicardium and across the wall. Epicardial dispersion leads to the development of phase 2 re-entry, which provides the extrasystole that captures the vulnerable window and initiates ventricular fibrillation/ventricular tachycardia (VT/VF) via a circus movement re-entry mechanism. RV, right ventricular. (**A**, From Napolitano C, Priori SG: Brugada syndrome. *Orphanet J Rare Dis* 2006;1:35; **B**, from Antzelevitch C: Ion channels and ventricular arrhythmias: cellular and ionic mechanisms underlying the Brugada syndrome. *Curr Opin Cardiol* 1999;14:274-279.)

heart. Thirty to fifty percent of patients with CPVT will have SCA by age 30. Two mutations have been identified: (1) cardiac ryanodine receptor 2 (hRyR2) results in “gain-of-function” of the ryanodine release channel; (2) calsequestrin 2 (CASQ2) results in “loss-of-function” of the calsequestrin calcium reservoir. Both lead to calcium leak and delayed after depolarization arising from the epicardium, endocardium, or M region. Alternation and migration of the source of ectopic activity is responsible for

the bidirectional VT and slow polymorphic VT, leading to amplification of TDR, giving rise to re-entrant VT/VF and SCA.^{85,86}

Arrhythmogenic Right Ventricular Dysplasia (ARVD)

ARVD is a form of cardiomyopathy with fibrofatty infiltration of the right ventricle, characterized by inverted T waves, ϵ waves, notched S wave, and widening of QRS (>110 ms) in the right precordial leads (V1-V3) (Fig. 25-8).⁸⁷ The signaled-averaged

Figure 25-7. A 12-lead ECG from a patient with short QT syndrome. The Q-Tc = 306 ms (<320 ms) with tall, peaked symmetric T wave. (Bjerregaard P, Gussak I: Short QT syndrome: mechanisms, diagnosis and treatment. *Nat Clin Pract Cardiovasc Dis* 2005;2:86. Reprinted by permission from Macmillan Publishers Ltd. Copyright 2005.)

ECG usually is markedly abnormal. Findings of right ventricular dilation/aneurysm on an echocardiogram (or cardiac MRI) may be helpful in diagnosing ARVD. Suspicion for this diagnosis should increase if there is a family history of the disease since it occurs in 30% to 50% of offspring. Multiple genetic mutations were discovered; most of them code for desmosomal proteins, which anchor intermediate filaments to the cytoplasmic membrane in adjoining cells in the gap junction. Inflammation from myocarditis triggers the expression of these genes, leading to an increase in fibrofatty infiltration. The strands of surviving myocardial fibers from the arrhythmogenic substrate are culpable because they establish re-entrant circuits leading to VT/VF and SCA, and are significant in determining how to best manage these patients. These patients would have a normal life span if their arrhythmias were adequately treated with sotalol, an implantable cardioverter defibrillator (ICD), or ablation.⁸⁸

Wolff-Parkinson-White Syndrome (WPW)

The prevalence of WPW is 0.1% to 0.3%⁸⁹ of the general population, and the incidence of sudden death in asymptomatic individuals is, at worst, 1 per 100 patient years of follow-up.⁹⁰ SCA occurs as a result of atrial fibrillation with a very rapid ventricular response over an accessory pathway with short refractory periods, leading to VF.⁹¹ Most patients who experience SCA as a result of WPW have previously manifested symptomatic arrhythmias. Patients with multiple accessory pathways, a family history of WPW with SCD, and, obviously, those with concomitant heart disease are at a higher risk for SCA.

Cardiac Conduction System Abnormalities

Patients with congenital AV block or nonprogressive intraventricular block have a lower risk for SCA. Abnormalities of the specialized cardiac conduction system are a rare cause of SCA and are usually noted in young, otherwise healthy individuals without a prior history of arrhythmia. Unless an exhaustive and

elaborate autopsy analysis is made, the underlying abnormality may never be discovered in the postmortem examination, leading to the belief that no such abnormality existed. Both acquired AV nodal and His-Purkinje disease, owing to CAD and primary fibrosis, can also, uncommonly, cause SCA.

Congenital Heart Disease

1. Congenital aortic stenosis⁹² can predispose to SCA. The risk for SCA correlates with the severity of the stenosis, and aortic valve replacement does not eliminate the risk but has been shown to reduce it.
2. Eisenmenger syndrome⁹³ can also predispose to SCA.
3. Tetralogy of Fallot:⁹⁴ Potentially fatal arrhythmias have been described as late complications in up to 5% of patients undergoing successful surgical repair of tetralogy of Fallot. The presence of premature ventricular contractions may be a marker of increased risk for SCA.
4. Transposition of the great arteries:⁹⁵ The mechanisms of SCA in patients who have undergone surgical procedures for correction of transposition of the great arteries include bradyarrhythmias, sick sinus syndrome, and atrial flutter (the predominant tachyarrhythmia). The incidence of late SCD is approximately 5%. This risk has been reduced with the use of an alternative technique known as the arterial switch operation.
5. AV canal anomalies: SCA has been seen as a late complication after surgical repair of AV canal anomalies.

Valvular Heart Disease

Disease of the heart valves pose an increased risk for future SCA, usually as a result of left ventricular dilation and hypertrophy. Rheumatic valvular heart disease can, uncommonly, result in SCD due to arrhythmias, ball valve thrombus in the left atrium obstructing the mitral orifice, embolization of the coronary arteries, or acute low-output circulatory failure. SCD is one of

Figure 25-8. ECG morphology of arrhythmogenic right ventricular dysplasia with inverted T waves, ϵ waves, notched S wave, and widening of QRS (>110 ms) in the right precordial leads (V_1 - V_3). (From Nasir K, Bomma C, Tandri H, et al: *Electrocardiographic features of arrhythmogenic right ventricular dysplasia/cardiomyopathy according to disease severity: a need to broaden diagnostic criteria. Circulation* 2004;110:1527-1534.)

the most common modes of death after valve replacement surgery and is attributable to arrhythmias and thromboembolism.

Inflammatory and Infiltrative Diseases

Acute viral myocarditis, with or without left ventricular dysfunction, is an important cause of sudden death in the young. SCA may result from either lethal ventricular arrhythmias or damage to the specialized conduction system during the myocarditis. Collagen vascular diseases (causing myocarditis and vasculitis), progressive systemic sclerosis, granulomatous diseases (such as sarcoidosis), infiltrative diseases (such as amyloidosis and hemochromatosis), intramural tumors, neuromuscular diseases (such as muscular dystrophy, Friedrich ataxia, and myotonic dystrophy), Chagas disease, idiopathic giant cell myocarditis, and cardiac ganglionitis all can cause SCA.¹

Clinical Presentation

It is estimated that only 30% to 40% of SCD victims can be identified as being at risk for SCA before the event. Unfortunately, the majority have only short-lasting symptoms or are completely asymptomatic before experiencing SCD. Some patients report nonspecific symptoms of chest pain, weakness or fatigue, and palpitations weeks to months before the event.⁹⁶ Symptoms occurring a few hours or minutes before the episode are more specific for the underlying heart disease and are usually secondary to arrhythmias, ischemia, or congestive heart failure.

Circulatory deaths are more common with noncardiac terminal events and frequently manifest bradyarrhythmias.

The cardiac arrest itself is characterized by the abrupt loss of consciousness that leads to death without active resuscitation, although, rarely, spontaneous reversions do occur. The maximum survival rates for patients with cardiac arrest outside the hospital are reported to be in the range of 20% to 30%,²⁹ depending upon the availability of bystander and emergency teams. The outcome of resuscitation in the field is strongly influenced by the documented initial rhythm and the time elapsed since the collapse (Fig. 25-9).⁹⁷ Survival is best when the initially documented rhythm is VT. Victims with bradycardia or asystole have a uniformly poor outcome. Only a small subset of patients with bradyarrhythmias, owing to some electrolyte or pharmacologic abnormality, responds well to acute interventions. Young patients with less severe cardiac disease, and without coexisting multisystem disease, have a higher probability of survival. Mortality is higher in patients with associated noncardiac disease, such as renal failure, pneumonia, diabetes, sepsis, and malignancy.

Evaluation Of The Sca Survivor

The initial management of a cardiac arrest survivor, either spontaneously or with advanced cardiac life support (ACLS), is usually performed in an intensive care unit with continuous rhythm monitoring. A significant proportion of these patients

Figure 25-9. Resuscitation success rate versus time. The chance of success reduces 7% to 10% each minute. (From Emergency Medical Technician Department at St. Louis Community College. Available at: <http://users.stlcc.edu/cmittle/emt/aed/sld004.htm>. Accessed February 6, 2008.)

succumb to cardiogenic shock, congestive heart failure, respiratory complications, and sepsis, accounting for an in-hospital mortality of up to 60%.²⁹ Myocardial function in the early phase following resuscitation is usually depressed, and many patients require transient inotropic support for hemodynamic stabilization. Only a small number of patients admitted to the hospital following cardiac arrest are conscious at the time of admission, and, in the first 24 to 48 hours, those that are semiconscious may require heavy sedation or paralysis to facilitate pulmonary toilet and nursing care. The degree of hypoxic brain damage is variable. However, recovery is usually rapid. Coma persisting 3 days beyond the event is usually associated with a poor prognosis.⁹⁸

Following this initial period of stabilization and neurologic improvement, all patients should undergo a complete cardiac evaluation unless it is contraindicated by the presence of terminal illness. The etiology of SCA in these patients can usually be categorized as being associated with either ischemic or nonischemic heart disease, or as occurring in the absence of overt cardiac disease. This approach is helpful in determining the direction to proceed for further evaluation and in determining management strategies. Both noninvasive and invasive laboratory evaluations, including electrophysiologic studies, are performed in these patients and have variable yields and implications depending upon the underlying substrate.

1. History and physical: A detailed history from the patient and witnesses may offer possible clues for triggering mechanisms (such as ischemia and proarrhythmia), and a family history may suggest the underlying heart disease. Knowledge of prodromal symptoms, the nature of activity at the time of the event, and whether there is any history of substance abuse are also important. If antiarrhythmic medications had been prescribed previously, it is useful to draw plasma samples to

determine drug levels. The clinical examination is focused on determining the nature of the underlying heart disease or systemic disease, if any, and the extent of its involvement, particularly with reference to ventricular function. Laboratory evaluation is also aimed at determining the presence of triggering agents (hypokalemia, metabolic disturbances, and toxic substances) and whether the episode of SCA was caused by a reversible circumstance.

- 2. ECG:** An initial resting ECG is useful in determining the presence or absence of underlying structural or functional abnormalities such as acute or prior MI, arrhythmogenic right ventricular dysplasia, long QT syndrome, Brugada syndrome, short QT syndrome, hypertrophic cardiomyopathy, or WPW.
- 3. Holter monitoring:** Ambulatory Holter monitoring and SAECG are commonly used for noninvasive evaluation of cardiac arrest survivors. Although monitoring may or may not document complex ventricular ectopy after cardiac arrest, it has little or no utility in assessing the ability to suppress ventricular ectopy by antiarrhythmic agents or predicting reduction in risk for future SCA. Complex ventricular ectopy therefore appears to be a marker of underlying cardiac disease rather than the cause of increased mortality.
- 4. Signal-averaged electrocardiography (SAECG):** Low-amplitude, high-frequency potentials recorded in the terminal portion of the filtered QRS (SAECG) complex are thought to represent electrical activity from the anatomic arrhythmogenic substrate. Their presence, especially in patients with coronary artery disease, is thought to predict spontaneous future arrhythmic events, mainly when no revascularization was done and particularly when combined with the LV function analysis. SAECG is an excellent negative predictor for SCA in patients with CAD (89% to 99%). It is important to recognize that the prognostic value of the SAECG is less well-defined in patients with nonischemic heart disease, except for in ARVD and hypertrophic cardiomyopathy. The SAECG may be abnormal in 15% to 20% of patients with hypertrophic cardiomyopathy, but its predictive value for SCA remains unproven. Similarly, a recording of asymptomatic nonsustained ventricular tachycardia on Holter monitoring in a patient with HCM does not necessarily predict an adverse prognosis unless the patient experienced prior episodes of syncope or cardiac arrest, or had a history of inducible ventricular tachyarrhythmias.
- 5. Left ventricular (LV) function and echocardiogram:** Evaluation of LV function is critical because LV function is the strongest independent predictor for recurrence and long-term survival following out-of-hospital cardiac arrest.⁹⁹ This may be accomplished using echocardiography or radionuclide ventriculography. The latter may also be employed for imaging the right ventricle to identify ARVD as a cause, but magnetic resonance imaging is probably superior. LV function also predicts successful suppression of inducible ventricular arrhythmias during serial drug testing. In patients with reduced LV function, these arrhythmias are usually not suppressible and are more likely to recur clinically. The two-dimensional (2-D) echocardiography with color Doppler is also used to identify structural abnormalities of wall motion, myocardial contractility, valvular abnormalities, infiltrative myocardial disorders, coronary artery anomalies, and abnormalities of the aortic root.

6. *Exercise stress testing*: Exercise stress testing is used in cardiac arrest survivors primarily to evaluate overt or provokable ischemia. On occasion, the test may be used to provoke the adrenergic form of long QT syndrome or catecholamine-dependent ventricular tachycardias in association with structurally normal hearts. An additional method for evaluating future arrhythmic risk involves measurement of heart rate variability, which is an indirect assessment of the influence of the autonomic nervous system on the cardiovascular system. The loss of the diurnal variation of heart rate variability in patients has been associated with a poor long-term outcome in the post-MI survivor.
7. *T wave alternans*: A noninvasive risk stratifier for SCA is a measurement of beat-to-beat fluctuation in amplitude and/or morphology of the T wave, called T wave alternans. The presence of alternans suggests dispersion of action potential duration and recovery leading to possible risk of re-entry and VT/VF. This test is suitable for all patients who are at risk for SCA, including those with LV dysfunction, post-MI, and heart failure, and has excellent positive and negative predictive value.^{100,101}
8. *Other noninvasive tests*: There are a few other noninvasive assessments to predict risk for SCD, which include measurements of heart rate variability (see above), Q-T dispersion, and baroreceptor sensitivity. There is a lack of strong supportive data for these tests, however, and they are not approved by the U.S. Food and Drug Administration (FDA) at this time for SCA risk stratification.
9. *Cardiac catheterization*: A complete cardiac catheterization, including coronary angiography, left and right heart hemodynamics, and left ventriculography is usually performed initially, even in young patients, to rule out coronary anomalies. In patients suspected of having myocarditis or cardiomyopathy, a right ventricular endomyocardial biopsy may provide additional diagnostic information to guide management, and this may be done during the catheterization procedure.
10. *Electrophysiology study (EPS)*: The practice of assessing antiarrhythmic drug efficacy with an EPS has largely been abandoned. In SCA survivors, there is no indication for an EPS due to strong evidence of ICD benefit in these patients. However, EPS remains the standard tool, especially in high-risk patients who are not candidates for an ICD implantation. The study should be performed in the absence of antiarrhythmic therapy since the results may be influenced by the drug. The likelihood of inducing a sustained ventricular arrhythmia depends upon the underlying heart disease (coronary versus noncoronary), left ventricular function, the presenting clinical arrhythmia (VT or VF), and the aggressiveness of the programmed stimulation protocol. Data suggest that the use of triple versus double extrastimuli yields a higher number of patients who are inducible. Although VF occasionally may be induced, it may be a clinically irrelevant arrhythmia.

EPS is warranted for risk stratification in patients with non-sustained VT, remote MI, and LV dysfunction (ejection fraction of 40%), and in patients with symptoms suggestive of VT/VF (e.g., palpitations, presyncope, or syncope).³ It is a valid diagnostic tool for the investigation of wide-QRS-complex tachycardias of unknown origin, or in conjunction with ablation of ischemic or nonischemic (e.g., right ventricular outflow tract) VT, or

supraventricular tachycardia (e.g., WPW). In addition, it may be helpful in stratifying high-risk patients, who will then need ICD, in Brugada syndrome and HCM. It has not proven useful as a diagnostic tool for other ion channelopathies.

Therapy

Selection of appropriate therapy for SCA survivors should be individualized. Before initiating specific therapy, the patient should undergo electrophysiologic testing and the underlying substrate, ventricular function, and hemodynamic state should be well established.

Pharmacologic Therapy

The selection of pharmacologic therapy as an option for cardiac arrest survivors depends upon the underlying cause.

All post-MI trials and LV dysfunction trials show significant survival benefit associated with the use of a β -blocker agent. In addition, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, and HMG-CoA reductase inhibitors are essential in post-MI patients to reduce risk for acute coronary syndrome and mortality. Nonetheless, antiarrhythmic therapy did not show significant benefit in these patients; instead class IC antiarrhythmic medications were rather harmful and they are contraindicated. Some antiarrhythmic medications such as amiodarone, sotalol, azimilide, or dofetilide may be useful as an adjunct therapy to ICD to reduce the frequency of ventricular arrhythmia and ICD shocks.

In SCA survivors with normal heart structure, pharmacologic therapy may be helpful in reducing the risk of VT/VF and recurrence of SCA. β -blockers, calcium channel blockers, sotalol, or flecainide were used in right ventricular outflow tract tachycardias. Sotalol is the drug of choice in ARVD as a primary therapy or adjunct with ICD therapy to prevent SCD.¹⁰² In low-risk LQTS patients, who are not candidates for ICD implant, β -blockers are the drug of choice to prevent dysarrhythmia. The predictors of failure of β -blockade include Q-T greater than 500 milliseconds, LQT2 or LQT3, and early age episode of SCD (<7 years). Sodium channel blockers (Class IC antiarrhythmic medication) might be helpful in patients with LQT3. On the other hand, sodium channel blockers worsen the Brugada syndrome manifestation, subsequently increasing the risk of arrhythmia and SCA. Quinidine is highly effective in reducing the frequency of VF in Brugada syndrome, especially in ICD shock storm. Quinidine and disopyramide are effective in reducing the frequency of VT/VF in SQTS1 patients. Either disopyramide or β -blockers may be used in patients with HCM. In CPVT, β -blockers, not calcium channel blockers, are used as an adjunct therapy with ICD.

Correcting the secondary causes of SCA may be accomplished with a pharmacologic approach or with oxygen supplementation (e.g., hypoxia). Drug toxicity, leading to dysarrhythmia and SCA, can be managed by stopping the medication or altering its effect. Dysarrhythmia due to electrolyte imbalance (e.g., hypomagnesemia, hypokalemia, hyperkalemia, etc.) can be amended by supplementation or dialysis.

Myocardial Revascularization and Arrhythmia Surgery

Acute myocardial ischemia is considered a contributing factor to SCA based on several clinical observations.⁸ It is therefore likely that prevention or reduction of myocardial ischemia

would consequently decrease the incidence of SCA in those patients with CAD who have either symptomatic or silent myocardial ischemia. In addition, myocardial revascularization has been shown to reduce the incidence of SCA when used as a secondary prevention of cardiac arrest in patients who have been successfully resuscitated from a previous episode related to acute MI.¹⁰³ It is important to note that the induction of VF in the preoperative EPS may be suppressed in over half of these patients by myocardial revascularization.

Revascularization includes using a medical approach (anti-thrombins/antiplatelets), cardiac catheterization and angioplasty, or myocardial bypass graft surgery. Any one of these techniques is associated with reduction of the risk for SCD.³

Revascularization alone is unlikely to eliminate clinical or inducible monomorphic VT, especially in patients with a fixed anatomic substrate (myocardial scar/ventricular aneurysm). Thus ICD will be indicated with a possible need for an electrophysiologic-guided excision or ablation of this tissue, but the technique is fairly complicated and should be performed by a team with experience in this procedure.¹⁰⁴

Catheter Ablation

Catheter ablation is considered a state-of-the-art approach to curative management of VT, and as a primary or adjunct therapy to an ICD. In a minority of patients, the underlying etiology for SCA may be demonstrated to be supraventricular in origin (e.g., WPW). Ablating the source of the supraventricular tachycardia will prevent further VT/VF and risk of SCA. Patients with bundle branch re-entry VT, those with idiopathic VT originating in the right ventricular outflow tract or left ventricle, and patients with fascicular VT may have SCA. The importance of performing a detailed electrophysiologic study in a SCA survivor is highlighted by the fact that all of these arrhythmias can be cured by radiofrequency catheter ablation, thus obviating the need for further therapy and possibly eliminating future risk. In addition, postinfarction refractory VT with multiple ICD shocks can be treated with a meticulous complex electrophysiology study and mapping, and the highly complicated technique of ablating the protected isthmus inside the scar tissue and the exit sites across the scar borders.¹⁰⁵ Most of these sites can be approached endocardially using transvascular catheters; or, if that fails, a percutaneous epicardial approach may be used.¹⁰⁶

Automated External Defibrillator (AED)

Ninety-three percent of SCA victims die before they reach a hospital or other source of emergency help because of the brief window for resuscitation available from the initial onset of VT/VF to the point of death. The chance of successful resuscitation reduces by 7% to 10% each minute. Therefore increased availability of instant defibrillation via AEDs in public areas is essential to improve the out-of-hospital SCA survivor rate.^{107,108} Response time should be less than 4 to 6 minutes for the patient to benefit from the use of AEDs.¹⁰⁹

AEDs were developed in the early 1970s, and trials were conducted during the 1980s. Most of these trials showed AEDs were equivalent if not better than manual defibrillators. The overall sensitivity in detecting VF by AEDs has been reported as 76% to 96%. Specificity (correctly identifying non-VF rhythms) is reported to be nearly 100%.¹¹⁰

Most of the current AEDs are biphasic devices, not due to their superiority over monophasic shock devices, but because

they use less energy, the batteries reach full charge more quickly and have a longer battery life.¹¹¹

Public access defibrillation has been shown to be an important part of a successful chain of survival programs. Placement of AEDs has been most cost-effective in select locations with significant public traffic or density, including casinos, airports, sports stadiums, corporate offices, shopping malls, schools, community centers, high-risk homes, and senior centers. The U.S. Food and Drug Administration (FDA) has approved the use of AEDs in public areas. American Airlines was the first to carry AEDs on aircraft during long overwater flights in 1997, and recent FAA regulations mandate that aircraft carry AEDs and that flight personnel be trained in their use (amendment to part 121 of the Aviation Medical Assistance Act of 1998).

Audible and/or visual prompts guide the user through the process, making them easy to use. Most AEDs require that an operator initiate the delivery of the shock in some way, such as pushing a button. Some AEDs can be purchased over-the-counter; however, most need a physician's prescription. The average price for a single AED unit is between \$1,200 and \$2,300.

In August 2002, the FDA gave approval to the first home-use AED. Since then, most states have passed liability immunity legislation for use of an AED in a nongrossly negligent manner. Today, more than 50,000 AEDs are in use.

Implantable Cardioverter Defibrillator (ICD)

The ICD has emerged as one of the most revolutionary therapies developed to treat patients with life-threatening ventricular arrhythmias. In the past 3 decades, it has evolved from its more primitive form to a sophisticated device capable of tiered therapy and data storage. The basic premise behind the effectiveness of this device is that the majority of SCDs result from malignant ventricular tachyarrhythmias. The ICD system consists of sensing and defibrillation electrodes connected to a generator that houses the battery and integrated circuitry (Fig. 25-10). Ventricular tachyarrhythmias are detected by rate, duration, and morphology criteria, and programmed therapies are automatically delivered based on the detection criteria of the arrhythmia sensed. In addition, all ICD generators now provide backup ventricular bradycardia pacing, providing a safety net for primary or secondary bradyarrhythmic events. The device may be implanted using a thoracotomy approach, but currently the preferred method is the outpatient nonthoracotomy approach. This simplification of implantation and the tremendous benefit of the ICD make it the most effective form of VT/VF treatment.

The therapy choices to treat ventricular tachyarrhythmia include antitachycardia pacing, low-energy synchronized cardioversion, and high-energy cardioversion/defibrillation. A detection algorithm allows differentiation of sinus tachycardia or supraventricular arrhythmias from ventricular tachyarrhythmias to obviate unnecessary delivery of therapy. Noninvasive interrogation of the device using an external wand allows the review of ventricular electrograms stored from detected episodes, affording confirmation of device effectiveness.

Although SCA is the result of a complex interaction of functional disturbances with an underlying structural abnormality, the ICD effectively terminates VT/VF regardless of its mechanism (Fig. 25-11). In this regard, it provides unsurpassed protection against arrhythmic SCD because it does not attempt to modulate structural or functional abnormalities as antiarrhythmic drugs do. The beneficial effect of these drugs, even when

chosen after they have been demonstrated to effectively suppress VT/VF, may be negated by alterations in the functional state of the individual (acute ischemia, hypokalemia, catecholamine surge, etc.).

Perioperative mortality associated with ICD implantation has now been reduced to less than 1%. ICD therapy, compared

Figure 25-10. Schematic representation of a current implantable cardioverter defibrillator and lead system. A right ventricular endocardial rate-sensing/defibrillation lead is shown inserted via the left subclavian vein with its tip in the right ventricular apex. This lead is connected to a pulse generator overlying the left pectoralis major muscle. (From *Implantable/Treatments/Cardioverter Defibrillators (ICDs)*. Available at: www.HRSpatients.org. Accessed January 28, 2008.)

with conventional or traditional antiarrhythmic drug therapy, has been associated with mortality reductions from 23% to 55% depending on the risk group participating in the trial, with the improvement in survival due almost exclusively to a reduction in SCD.³

Secondary prevention of SCD trials solidly support the implantation of an ICD in all patients surviving SCA that was not due to transient causes, regardless of the structural status of their heart.^{3,112-116} ICD is superior to any antiarrhythmic therapy, although, if antiarrhythmic therapy is warranted, amiodarone is the most effective choice to reduce the recurrence of VT/VF. In patients with spontaneous or electrophysiology study-induced sustained VT, ICD implant is strongly recommended for SCD prevention.

Furthermore, recent studies and updated guidelines consider an ICD essential in the primary prevention of SCD in high-risk patients.^{3,115,116} All patients with ischemic or nonischemic LV dysfunction (ejection fraction of 35%) and congestive heart failure who are on optimized medical therapy are considered at high risk for SCD.¹¹⁷ If such a patient has ischemic cardiomyopathy and has undergone revascularization therapy, LV dysfunction may improve, resulting in a decrease in risk for SCD. LV function must be re-evaluated in 90 days; if it remains 35%, the risk for SCD still exists and an ICD is required.¹¹⁸ In medically treated acute myocardial infarction (AMI) patients with LV dysfunction, an ICD implant must be deferred for at least 40 days after AMI since studies show no difference in outcome between patients with or without ICD during this period. If the patient's ejection fraction remains 35% after 40 days, an ICD is warranted.¹¹⁹ An exception to the 90- or 40-day waiting period rule would be if the patient develops nonsustained VT and has inducible sustained VT on an electrophysiology study. In this instance, an ICD would be indicated.¹²⁰ Some patients with LV dysfunction are candidates for cardiac transplantation; the ICD

Figure 25-11. A clinically documented implantable cardioverter defibrillator shock. The rapid ventricular tachycardia is promptly detected and effectively terminated by a single shock with restoration of sinus rhythm (lower panel). (From Tchou PJ, Kadri N, Anderson J, et al: *Automatic implantable cardioverter defibrillators and survival of patients with left ventricular dysfunction and malignant ventricular arrhythmias*. *Ann Intern Med* 1988;109:529.)

may also be used as a “bridge to cardiac transplantation” for SCD prevention in selected individuals.¹²¹

Patients with normal LV function could still be at high risk for SCD, requiring an ICD for primary prevention of SCD. Patients with HCM are an example, where the indications for an ICD include history of prior resuscitation from VT/VF, presence of very thick intraventricular septum (>3 cm), history of failure to raise blood pressure on exercise, nonsustained VT with inducible sustained VT on an electrophysiology study, and a strong family history of SCD.

Patients with normal heart structure can be at high risk for SCA if they have inherited certain ion channelopathy syndromes, although these cases are rare. ICD is necessary in the following high-risk subgroups:

1. **LQTS**: resuscitated from cardiac arrest, syncope at young age (<5 years old), very long QT (>500 ms), Jervell and Lange-Nielsen syndrome, and males with LQT3.
2. **Brugada**: resuscitated from cardiac arrest, Brugada type I ECG morphology, inducible sustained VT on an electrophysiology study.
3. **Idiopathic ventricular fibrillation**.
4. **ARVD**: especially in patients who were resuscitated from cardiac arrest and who had rapid sustained VT, depressed LV function, or inducible sustained VT on an electrophysiology study.
5. **SQTS**.
6. **CPVT**.

There are a few conditions for which ICD implantation is contraindicated; they include the following:^{4,115,116}

1. VT/VF resulting from arrhythmias amenable to surgical or catheter ablation (e.g., WPW, right ventricular outflow tract VT, fascicular VT).
2. VT/VF due to a transient and reversible disorder (e.g., AMI, electrolyte imbalance, drugs, or trauma).
3. Terminal illnesses with projected life expectancy of less than 6 months (e.g., metastatic cancer, drug-refractory advanced heart failure in a patient who is not a candidate for cardiac transplantation).
4. Noninducible VT on an electrophysiology study in cases for which a complex electrophysiology study is indicated.
5. Significant psychiatric illnesses that may be aggravated by device implantation or may preclude systematic follow-up.
6. Incessant VT or VF.

In summary, the results of electrophysiologic study, the degree and type of underlying heart disease, and level of LV function are critical determinants in guiding management.

Wearable Automatic Defibrillator

This vestlike device (Fig. 25-12) has been approved by the FDA for patients with a transient high risk for VF, such as those awaiting cardiac transplantation, as a bridge until the ICD is implanted (during the 40-day waiting period after a recent MI or 90 days after a revascularization), or in patients who are candidates for ICD but who are at high risk for infection during the antibiotic therapy.

Conclusion

SCA is a major public health concern worldwide. CAD is by far the most common underlying pathology, and a substantial proportion of SCAs occur outside the hospital. Noncoronary

Figure 25-12. A LifeVest is a vestlike external defibrillator manufactured by Zoll Lifecor Corporation (Pittsburgh, PA). (Courtesy of Zoll Lifecor Corporation, Pittsburgh, PA. Available at: www.lifecor.com.)

cardiac diseases, although comprising the minority of victims, may occur in otherwise healthy individuals in whom an ante-mortem diagnosis is often difficult. A substantial risk of recurrence persists in these patients and mandates secondary prevention measures. Any significant reduction in the incidence of SCD in the community will require accurate identification of potential victims, training and implementation of bystander cardiopulmonary resuscitation (CPR) (e.g., external cardioverter defibrillators), and effective primary and secondary preventive interventions.

Pacemaker Emergencies NASPE/BPEG Generic (NBG) Pacemaker Code Complications of Cardiac Pacing System Implantation Pacing and Sensing Problems Rapid Paced Ventricular Rates Biventricular Pacing Systems	Cardiac Pacing Under Specific Clinical Circumstances Implantable Cardioverter-Defibrillator Emergencies Inappropriate ICD Shock Electrical Storm Drug Effects on ICD Function ICD-Pacemaker Interactions Ineffective ICD Therapy

SECTION I Pacemaker Emergencies

Since the first cardiac pacemaker was implanted in 1958, the field of cardiac pacing has grown rapidly. The number of pacemakers implanted annually increased from 94,755 in 1990 to 267,278 in 2002. From 1990 to 2002, there were 2.25 million pacemakers and 415,780 implantable cardioverter-defibrillators (ICDs) implanted in the United States.¹ Thus it is likely that most physicians will have an opportunity to manage patients with these devices, and it is therefore important for physicians to be familiar with the various modes of pacing and with certain aspects of normal and abnormal pacemaker and ICD function. In this section, we discuss the evaluation and management strategies of the more commonly encountered clinical problems in patients with permanent and temporary antibradycardia pacing systems.

Indications for permanent cardiac pacemaker implantation have been published by a joint task force of the American College of Cardiology and the American Heart Association.^{2,3} The indications have been classified as follows:

- Class I: Conditions for which there is general agreement that permanent pacemakers should be implanted.
- Class II: Conditions for which permanent pacemakers are frequently used but there is divergence of opinion with respect to the necessity of their insertion.
- Class III: Conditions for which there is general agreement that pacemakers are unnecessary.

Table 26-1 summarizes the indications for permanent cardiac pacing in adults according to the task force guidelines. However, it is recognized that these indications continue to expand, and that clinical situations exist that indicate the need for pacing therapy, yet fall outside the guidelines, in which case documentation of the need is of great importance.

The indications for temporary cardiac pacing are listed in Table 26-2. These indications are relatively broad, both because of the temporary nature of the clinical problem and the relative ease of implantation and removal of the pacing system. Temporary pacing is indicated in patients awaiting a permanent pacemaker who are symptomatic or who require rate support all or most of the time. Additional indications are symptomatic transient bradyarrhythmias, prophylaxis against bradyarrhythmias, or bradycardia-dependent tachyarrhythmias and hemodynamic dysfunction due to slow rate or atrioventricular (AV) dyssynchrony.

NASPE/BPEG Generic (NBG) Pacemaker Code

In 1974, the Inter-Society Commission on Heart Disease Resources introduced a three-letter pacing-mode code for anti-bradycardia pacing systems to convey their functions by simple conversational means.⁴ This mode-code system was expanded to a five-letter one in 1981 to include programmability and anti-tachycardia functions.⁵ This code has been adopted and modified by the North American Society of Pacing and Electrophysiology (NASPE) (now the Heart Rhythm Society) Mode Code Committee and the British Pacing and Electrophysiology Group (BPEG), and is designated the NASPE/BPEG generic (NBG) code. Since its inception, the code has undergone multiple revisions; the last in 2002.⁶ Use of this code by medical and nursing intensive care personnel is recommended, both to facilitate communication and also to accurately describe pacemaker function.

The pacemaker mode code is shown in Table 26-3. The first three letters are always designated. The fourth and fifth letters are omitted if they are "O." With advances in pacing technology, further revision of the code will almost certainly be necessary. A description of the most commonly used pacing modes is shown in Table 26-4.

Table 26–1. Guidelines for Implantation of Cardiac Pacemakers in Adults: Class I and II Indications**Class I**

- A. Atrioventricular block
 - 1. Third-degree and advanced second-degree AV block at any anatomic level, associated with any one of the following:
 - a. Bradycardia with symptoms (including heart failure)
 - b. Documented periods of asystole greater than 3.0 seconds, or escape rate less than 40 beats/min in awake asymptomatic patients
 - c. Arrhythmias and other medical conditions that require drugs that result in symptomatic bradycardia
 - d. Post–AV junction ablation
 - e. Postoperative AV block that is not expected to resolve after cardiac surgery
 - f. Neuromuscular diseases with AV block, with or without symptoms
 - 2. Second degree AV block with symptomatic bradycardia
- B. Chronic bifascicular and trifascicular block
 - 1. Intermittent third-degree AV block
 - 2. Type II second-degree AV block
 - 3. Alternating bundle-branch block
- C. Sinus node dysfunction
 - 1. Sinus node dysfunction with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms. In some patients, bradycardia is iatrogenic and will occur as a consequence of essential long-term drug therapy of a type and dose for which there are no acceptable alternatives
 - 2. Symptomatic chronotropic incompetence
- D. Carotid sinus hypersensitivity
 - 1. Recurrent syncope caused by carotid sinus stimulation; minimal carotid sinus pressure induces ventricular asystole of more than 3 seconds; duration in the absence of any medication that depresses the sinus node or AV conduction
- E. After the acute phase of myocardial infarction
 - 1. Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third degree AV block within or before the His-Purkinje system after AMI
 - 2. Transient advanced (second- or third-degree) infranodal AV block and associated bundle-branch block. If the site of block is uncertain, an electrophysiologic study may be necessary.
 - 3. Persistent and symptomatic second- or third-degree AV block
- F. To prevent tachycardia
 - 1. Sustained pause-dependent VT, with or without prolonged QT, in which the efficacy of pacing is thoroughly documented
- G. Children, adolescents, and patients with congenital heart disease
 - 1. Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output
 - 2. Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia
 - 3. Postoperative advanced second- or third-degree AV block that is not expected to resolve or persists at least 7 days after cardiac surgery
 - 4. Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction
 - 5. Congenital third-degree AV block in the infant with a ventricular rate less than 50 to 55 bpm or with congenital heart disease and a ventricular rate less than 70 bpm
 - 6. Sustained pause-dependent VT, with or without prolonged QT, in which the efficacy of pacing is thoroughly documented
- H. Hypertrophic cardiomyopathy
 - 1. Class I indications for sinus node dysfunction or AV block as described previously
- I. Dilated cardiomyopathy
 - 1. Class I indications for sinus node dysfunction or AV block as described previously
- J. After cardiac transplantation
 - 1. Symptomatic bradyarrhythmias/chronotropic incompetence not expected to resolve and other Class I indications for permanent pacing

Class IIa and b

- A. Atrioventricular block
 - 1. Asymptomatic complete AV block with ventricular rates of greater than 40 beats/min
 - 2. Asymptomatic Type II second-degree AV block with a narrow QRS
 - 3. Asymptomatic Type I second-degree AV block at intra-His or infra-His levels
 - 4. First- or second-degree AV block with symptoms similar to pacemaker syndrome
 - 5. Marked first-degree AV block (more than 0.30 second) in patients with LV dysfunction and symptoms of congestive heart failure in whom a shorter AV interval results in hemodynamic improvement
 - 6. Neuromuscular diseases such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle), and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms

Table 26–1. Guidelines for Implantation of Cardiac Pacemakers in Adults: Class I and II Indications—cont'd**Class IIa and b—cont'd**

- B. Chronic bifascicular and trifascicular block
 1. Syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically ventricular tachycardia (VT)
 2. Incidental finding at electrophysiologic study of markedly prolonged HV interval (greater than or equal to 100 milliseconds) in asymptomatic patients
 3. Incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic
 4. Neuromuscular diseases such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle) and peroneal muscular atrophy with any degree of fascicular block, with or without symptoms
- C. Sinus node dysfunction
 1. Sinus node dysfunction, occurring spontaneously or as a result of necessary drug therapy, with rate less than 40 beats/min when a clear association between symptoms and documented bradycardia has not been shown
 2. Syncope of unexplained origin when major abnormalities of sinus node function are discovered or provoked in electrophysiologic studies
 3. In minimally symptomatic patients, chronic heart rate less than 40 bpm while awake
- D. Carotid sinus hypersensitivity
 1. Recurrent syncope without clear, provocative events and with a hypersensitive cardioinhibitory response
 2. Significantly symptomatic and recurrent neurocardiogenic syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing
- E. After the acute phase of myocardial infarction
 1. Persistent second- or third-degree AV block at the AV node level
- F. To automatically detect and pace to terminate tachycardias
 1. Symptomatic recurrent supraventricular tachycardia that is reproducibly terminated by pacing in the unlikely event that catheter ablation and/or drugs fail to control the arrhythmia or product intolerable side effects
 2. Recurrent supraventricular tachycardia or atrial flutter that is reproducibly terminated by pacing as an alternative to drug therapy or ablation
- G. To prevent tachycardia
 1. High-risk patients with congenital long Q-T syndrome
- AV re-entrant or AV node re-entrant supraventricular tachycardia not responsive to medical or ablative therapy
 2. Prevention of symptomatic, drug-refractory, recurrent atrial fibrillation in patients with coexisting sinus node dysfunction
- H. Children, adolescents, and patients with congenital heart disease
 1. Bradycardia-tachycardia syndrome with the need for long-term antiarrhythmic treatment other than digitalis
 2. Congenital third-degree AV block beyond the first year of life with an average heart rate less than 50 bpm, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or associated with symptoms due to chronotropic incompetence
 3. Long Q-T syndrome with 2:1 AV or third-degree AV block
 4. Asymptomatic sinus bradycardia in the child with complex congenital heart disease with resting heart rate less than 40 bpm or pauses in ventricular rate of more than 3 seconds
 5. Patients with congenital heart disease and impaired hemodynamics due to sinus bradycardia or loss of AV synchrony
 6. Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block
 7. Congenital third-degree AV block in the asymptomatic infant, child, adolescent, or young adult with an acceptable heart rate, narrow QRS complex, and normal ventricular function
 8. Neuromuscular diseases with any degree of AV block (including first-degree AV block), with or without symptoms, because there may be unpredictable progression of AV conduction disease
- I. Hypertrophic cardiomyopathy
 1. Medically refractory, symptomatic hypertrophic cardiomyopathy with significant resting or provoked LV outflow obstruction
- J. Dilated cardiomyopathy
 1. Biventricular pacing in medically refractory, symptomatic NYHA Class II or IV patients with idiopathic dilated or ischemic cardiomyopathy, prolonged QRS interval (greater than or equal to 120 milliseconds), LV end-diastolic diameter greater than or equal to 55 mm, and ejection fraction less than or equal to 35%
- K. After cardiac transplantation
 1. Symptomatic bradyarrhythmias/chronotropic incompetence that, although transient, may persist for months and require intervention

Abbreviations: AV, atrioventricular; MI, myocardial infarction

Adapted from Gregoratos G, Abrams J, Epstein AE, et al: ACC/AHA/NASPE 2002 guideline for implantation of cardiac pacemakers and antiarrhythmia devices: summary article: report of the American College of Cardiology/American Heart Association task force on practice guidelines (ACC/AHA/NASPE committee to update the 1998 pacemaker guidelines). *Circulation* 2002;106:2145-2161.

Complications of Cardiac Pacing System Implantation

The complications of cardiac pacing can be classified as those related to the presence of the pacing system as a foreign body (mechanical complications) and those related to apparent or real pacing system malfunction. Acute complications related to the temporary or permanent pacing system implantation procedure itself, such as hemothorax, pneumothorax, subclavian artery puncture, and myocardial perforation, are outside the scope of this chapter.

Table 26–2. Indications for Temporary Cardiac Pacing

Class I

1. Asystole
2. Symptomatic bradycardia (includes sinus bradycardia with hypotension and Type I second-degree AV block with hypotension not responsive to atropine)
3. Bilateral BBB (alternating BBB or RBBB with alternating LAFB/LPFB) (any age)
4. New or indeterminate age bifascicular block (RBBB with LAFB or LPFB, or LBBB)
5. Mobitz Type II second-degree AV block

Class IIa

1. RBBB and LAFB or LPFB (new or indeterminate)
2. RBBB with first-degree AV block
3. LBBB, new or indeterminate
4. Incessant VT, for atrial or ventricular overdrive pacing
5. Recurrent sinus pauses (greater than 3 seconds) not responsive to atropine

Class IIb

1. Bifascicular block of indeterminate age
2. New or age-indeterminate isolated RBBB

Abbreviations: AV, atrioventricular; BBB, bundle branch block; R, right; L, left; LAFB, left anterior fascicle block; LPFB, left posterior fascicle block; VT, ventricular tachycardia.

Adapted from Ryan TJ, Anderson JL, Antman EM, et al: J Am Coll Cardiol 1996;28:1367-1368

Infection

Infection is an uncommon complication of pacemaker implantation, with the incidence ranging from 0.8% to 5.7%, reported in a review of 21 studies of pacemaker and ICD implantations.⁷ Routine use of antistaphylococcal antibiotic prophylaxis at the time of implantation or generator change has been shown to have consistent benefit in a meta-analysis of seven randomized controlled trials, representing 2023 patients, in decreasing the rates of short-term pocket infection, skin erosion, or septicemia.⁸ We recommend routine prophylaxis with antistaphylococcal antibiotics.

Pacemaker pocket infection can occur as early as hours to days after the implantation procedure or as late as several years. *Staphylococcus aureus* and *S. epidermidis* are the most common organisms involved; episodes arising within 2 weeks of implantation are more likely to be due to *S. aureus*, whereas *S. epidermidis* is the principal organism causing late infections.^{10,11} Despite the established trend of performing permanent pacemaker implantation in the cardiac catheterization laboratory rather than in the operating room, the incidence of pocket infection has remained the same.¹² Clinical manifestations of pocket infection are usually obvious and include fever, chills, purulent drainage, and signs of inflammation at the pocket site. Initial therapy is usually with intravenous antibiotics that provide antistaphylococcal coverage. Management frequently requires removal of the entire pacemaker system.¹³⁻¹⁵

Endocarditis can occur after pacemaker implantation and has a mortality rate as high as 27%.¹⁵ The most frequent pathogens are *S. aureus* and *S. epidermidis*.^{10,11} The diagnosis of device-related endocarditis is suggested by modified Duke criteria; it has been suggested that in the case of devices, pulmonary emboli and generator pocket abnormalities should be used as additional major criteria.^{15,16}

Fever and chills are the most common symptoms. Other signs of endocarditis, such as new murmurs of tricuspid or pulmonary insufficiency or signs of pulmonary hypertension due to septic emboli, should be carefully sought. Vegetations can be best demonstrated by transesophageal echocardiography (TEE), although they are sometimes visualized by transthoracic echocardiography (TTE). TEE has been repeatedly shown to be superior to TTE in the diagnosis of device-related endocarditis, with vegetations on the tricuspid valve or pacing lead visualized

Table 26–3. The NASPE/BPEG Generic (NPG) Pacemaker Code

Position	I	II	III	IV	V
Category	Chamber(S) Paced	Chamber(S) Sensed	Response to Sensing	Rate Modulation	Multisite Pacing
	O = None	O = None	O = None	O = None	O = None
	A = Atrium	A = Atrium	T = Triggered	R = Rate modulation	A = Atrium
	V = Ventricle	V = Ventricle	I = Inhibited		V = Ventricle

Table 26–4. Commonly Used Pacing Modes

Position of Letter				Description
I	II	III	IV Rate	
<i>Chamber Paced</i>	<i>Chamber Sensed</i>	<i>Mode of Response</i>	<i>Adaptation</i>	
A	O	O		Asynchronous (fixed rate) atrial pacing
A	A	T		Triggered atrial pacing. Output pulse is delivered (and sensed by the atrial electrode) at the time of sensing, or at the programmed escape interval (rarely used)
A	A	I		Demand atrial pacing; output inhibited by sensed atrial activity
A	A	I	R	Demand atrial pacing; output inhibited by sensed atrial activity; paced rates increase and decrease in response to sensor input
V	O	O		Asynchronous (fixed rate) ventricular pacing
V	V	T		Triggered ventricular pacing. Output is delivered (and sensed by the ventricular electrode) at the time of sensing or at the programmed escape interval (rarely used)
V	V	I		Demand ventricular pacing; output inhibited by sensed ventricular activity
V	V	I	R	Demand ventricular pacing; output inhibited by sensed ventricular activity; paced rates decrease and increase in response to sensor input.
V	D	D		Paces ventricle; senses in both atrium and ventricle and paces ventricle after the programmed atrioventricular interval.
D	D	I		Demand atrial and ventricular pacing; tracking of atrial rhythm does not occur
D	D	I	R	Demand atrial and ventricular pacing; paced rates increase and decrease in response to sensor input; tracking of atrial rhythm does not occur
D	D	D		Paces and senses in both atrium and ventricle; paced activity up to programmed upper rate limit
D	D	D	R	Paces and senses in both atrium and ventricle; paces up to the programmed upper rate limit; paced rates increase and decrease in response to sensor input

by TEE in 90% to 96% of patients, compared with 22% to 43% by TTE.^{15–20} Complete eradication of the infection usually involves removal of the entire pacing system.^{13,15,21}

Thrombosis and Thromboembolism

Venous thrombosis due to the presence of the pacing lead(s) in the subclavian vein and superior vena cava occurs quite commonly, as assessed by venographic techniques.²² One prospective trial found that six months after pacemaker or defibrillator implantation, 14% of patients developed a new obstructive venous lesion, none of whom were symptomatic.²³ Most thromboses are subclinical, and fortunately, major thrombosis causing symptoms and signs of significant venous obstruction (such as the superior vena cava obstruction syndrome) is rare.²⁴ The propagation of thrombus and dislodgement with embolism can cause or contribute to acute or chronic right ventricular inflow or outflow obstruction and can cause acute or recurrent pulmonary embolism.²⁵ Patients with an implanted permanent pacing system having unexplained right-sided heart failure, tachycardia, chest pain, dyspnea, and nonspecific systemic symptoms such as weakness and malaise should be promptly evaluated for these complications, and appropriate studies such as echocardiography and venography should be performed to document their presence. Major and symptomatic venous

thrombosis can cause arm and facial edema, pain, absence or diminution of ipsilateral venous pulsations, prominent subcutaneous venous pattern due to collateral circulation, and even exophthalmos. Treatment usually requires intravenous heparinization followed by oral anticoagulation; other treatment modalities include local thrombolysis and balloon angioplasty.^{26,27}

Intracardiac (generally right atrial) thrombosis around the intracardiac portion of the electrode catheter is more dangerous and more difficult to manage. The size of a right atrial thrombus can range from one to several centimeters in diameter.²⁸ The hemodynamic significance of the intracardiac clot depends on its size and location; atrial arrhythmias can occur if the sinoatrial area is involved. Functional tricuspid stenosis or insufficiency can be manifestations of thrombus, similar to those of an atrial myxoma. Intracardiac thrombosis should be considered when refractory right ventricular failure is present; the diagnosis can be confirmed by transthoracic or preferably transesophageal echocardiography.^{29–31}

The true incidence of pulmonary embolism due to transvenous pacing leads is higher when assessed by ventilation perfusion scans than is clinically apparent,³² the latter reported to range from 0.6% to 3.5%.^{33,34} This discrepancy indicates that most emboli are not of sufficient size to be clinically significant, at least acutely, although chronic pulmonary hypertension in

Figure 26-1. Intermittent failure to capture in the ventricle. All P waves are paced in this patient with a DDD pacing system. Alternate ventricular pacing pulses do not capture, leading to spontaneous conduction to the ventricle from the paced P waves. The problem was corrected by output programming. The changing atrioventricular intervals may be hemodynamically detrimental in critically ill patients.

patients with pacemakers should prompt consideration of this diagnosis. The treatment is anticoagulation with intravenous heparin and subsequent oral warfarin. The use of streptokinase, urokinase, or alteplase should be considered when an active clot is considered to be recurring. When pulmonary emboli are recurrent, thoracotomy with cardiopulmonary bypass may be necessary to remove the clot and pacing lead.³⁵

Systemic embolization can occur in patients with permanent pacemakers in two ways. A paradoxical embolus can result from a venous thrombosis in the presence of an established or transient intracardiac right-to-left shunt (i.e., patent foramen ovale); a careful search both for venous thrombosis and a patent foramen ovale by echocardiography with bubble contrast study may be warranted.³⁶⁻³⁸ In addition, patients implanted with a VVI(R) pacing system (see Table 26-4) have a higher incidence of paroxysmal and chronic atrial fibrillation,³⁹⁻⁴² which predisposes to embolic events.⁴³⁻⁴⁶ A meta-analysis evaluating over 35,000 years of patient follow-up showed that patients with a VVI pacemaker had a 22% rate of atrial fibrillation compared with a 17% rate with atrial and dual-chamber-based systems; a possible increase in the rate of stroke was also suggested.⁴² It has not been established if anticoagulation can reduce the incidence of thromboembolic events or prolong life in these patients.

Pacing and Sensing Problems

Pacing and sensing problems in patients with permanent pacemakers can originate in the pulse generator, the pacing leads, or the interface between myocardial tissue and the lead electrodes. Pacing problems can be classified as failure to capture and failure of pacing output. Sensing problems are due to oversensing (sensing of unwanted signals) or undersensing (failure to sense) of the intracardiac signal.

Pacing Problems

Failure to capture and failure to output are serious complications that can be life-threatening. The severity of their consequences depends on the duration of the problem (intermittent versus persistent) and whether the patient is pacemaker-dependent (asystolic or symptomatic without adequate rate support). Symptoms that should alert one to the possibility of pacing failure include symptoms of cerebral hypoperfusion (dizziness, presyncope, syncope) and those due to pulmonary venous hypertension, such as breathlessness. These symptoms occur because the patient's native escape cardiac rhythms are too slow to maintain adequate cardiac output and systemic perfusion.

A complete pacing sequence involves delivery of the pacing stimulus and subsequent depolarization of cardiac tissue. Temporal opportunity to capture must be present; that is, the

atrial or ventricular tissue must be in a nonrefractory state. The minimal amount of electrical energy required to cause a depolarization is called the stimulation or capture threshold. The energy delivered by the pulse generator is the product of pulse duration (in milliseconds) and the voltage amplitude (in volts). The stimulation threshold should ideally be less than or equal to 1.0 V (at pulse width of 0.4 to 0.5 ms) at the time of initial implantation. At implant, this stimulation threshold is highly dependent on the electrode-tissue interface, which is determined in large part by lead position. The stimulation threshold increases to variable degrees during a maturation process and reaches a stable value 6 to 8 weeks after implant. Thus, at the time of implantation, the voltage output is programmed to a higher level than the measured threshold, with individualized optimal reprogramming undertaken 2 to 3 months later. Currently used leads have reduced both acute and chronic stimulation thresholds by up to 50%.^{47,48}

Failure to Capture

The electrocardiographic diagnosis of failure to capture is made by demonstrating the occurrence of the stimulus output, which, when delivered outside the refractory period of atrial or ventricular tissue, is not followed by a P wave or QRS complex (Figs. 26-1, 26-2, 26-3, and 26-4). The causes of failure to capture fall into one of three major categories: (1) increase in stimulation threshold from various causes; (2) defective pacing leads; and (3) pulse generator battery depletion. It is important to note that stimulus delivery during tissue refractoriness is not true failure to capture, and is designated "functional noncapture."

Failure to capture is usually due to an increase in atrial or ventricular stimulation threshold. An increase in myocardial stimulation threshold can occur under several circumstances (Table 26-5). Increase in stimulation threshold is the most common cause of failure to capture that occurs in the first 8 weeks after pacemaker implantation and is due to the maturation process at the interface of the electrodes and myocardial tissue. This problem can be managed by noninvasively reprogramming the energy output of the pulse generator to a higher value (by increasing the pulse duration or the voltage amplitude or both). The stimulation threshold decreases to a stable level after 2 months, at which time the energy output can be reprogrammed to a lower value to prolong the battery life. The use of corticosteroid-eluting pacing leads has decreased the local tissue reaction and the thickness of the fibrous capsule surrounding the tip electrode,⁵⁴ reducing both acute and chronic stimulation thresholds.^{47,48} Although now quite rare, continued increases in capture threshold over months can occur, reaching voltage outputs that could potentially exceed the capacity of the pulse generator.

Figure 26-2. Continuously recorded lead II in a patient with a VVI pacing system with lead wire fracture. Failure to sense and intermittent failure to capture are present. The pacing artifact amplitudes vary, with the smaller artifacts not followed by paced QRS complexes. The long intervals between pacing artifacts are a multiple of the basic pacing rate of about 68 beats/min. The problem was corrected by lead replacement. The *closed circles* indicate pacing stimuli, many of which are barely visible.

Figure 26-3. “Functional noncapture” in the atrium in a patient with a DDD pacing system, owing to lack of temporal opportunity. The QRS complexes are paced. Following each QRS complex are retrogradely conducted P waves that are not sensed because they fall in the postventricular atrial refractory period; they do not inhibit the subsequent atrial output. The atrial stimulus does not capture atrial tissue, however, because the atria have just been depolarized retrogradely. Failure to capture cannot be correctly diagnosed unless it is established that temporal opportunity to capture is present.

Figure 26-4. The intermittent failure to capture in the atrium results in a retrogradely conducted atrial depolarization from the paced QRS complexes. If the retrograde P wave is sensed, ventricular pacing is triggered, potentially resulting in a pacemaker-mediated tachycardia. In this case, the retrograde P wave falls within the programmed postventricular atrial refractory period and was not sensed. Atrial noncapture with resulting ventriculoatrial conduction can be hemodynamically detrimental, especially in critically ill patients. The problem was solved by atrial output reprogramming.

Various metabolic disturbances are known to increase the myocardial stimulation threshold. Although hypoglycemia does not cause important changes in stimulation threshold, severe hyperglycemia (serum glucose level above 600 mg/dL) has been reported to cause a more than 50% increase.⁵⁵ Hyperkalemia can also increase the stimulation threshold significantly, generally when the serum potassium level exceeds 7 mEq/L (Fig. 26-5).⁵⁶⁻⁵⁹ Although determination of the serum potassium level can take time, there is usually electrocardiographic evidence of hyperkalemia that should suggest this diagnosis: this evidence includes a prolonged P wave duration, loss of visible P waves, markedly prolonged QRS complex duration (spontaneous or paced), and merging of the QRS complex with the ST-T wave (“sine wave” morphology, see Fig. 26-5). Management includes

Table 26-5. Causes of Pacemaker Noncapture

1. Elevation of stimulation threshold
• Metabolic disturbances (hyperkalemia, hyperglycemia, alkalemia or acidosis, hypoxemia or hypercapnia, hypothyroidism) • Drugs (quinidine, procainamide, lidocaine, mexiletine, encainide, flecainide) • Acute myocardial infarction • Exit block due to lead fibrosis
2. Pacing lead defects (fractures, insulation break)
3. Lead maturation, dislodgement, or perforation
4. Inappropriately low programmed output
5. Battery end of life

Figure 26-5. Lead MCL₁ rhythm strip recorded in a hyperkalemic patient ($K^+ = 7.9$ mEq/dL) during cardiopulmonary resuscitation after an asystolic arrest. A VVI pacing system is present. Type II pacemaker exit block is present, in which every third pacing stimulus is not followed by a QRS complex. The patient had no pulse with this rhythm. Resuscitation was unsuccessful despite correction of the hyperkalemia. This type of failure to capture is more common with hyperkalemia than with acidosis secondary to cardiac arrest. That these QRS complexes represent paced ventricular depolarizations is diagnosed from their presence only after a pacing stimulus and the irregular periodicity of the rhythm.

correction of the hyperkalemia and/or temporarily increasing the energy output of the pulse generator by noninvasive programming or both. This latter maneuver is not always successful, however, and simply increasing pulse generator voltage output will not reverse electromechanical dissociation. Both metabolic acidosis and alkalosis can increase the stimulation threshold by as much as 70% to 80%.⁵⁹ Hypoxemia and hypercarbia can also cause elevation of the capture threshold, which can be reversed by supplemental oxygen and hyperventilation⁵⁵; although uncommon today, this may be especially relevant during induction of general anesthesia in patients with cardiac pacemakers. Many of these metabolic disturbances occur during cardiopulmonary resuscitation. In patients with cardiac pacing systems who are pacemaker-dependent, correction of these metabolic disturbances is crucial to a successful resuscitation. Despite the foregoing, failure to capture using today's pacing systems is not common because of both a high safety margin provided by the programmed energy output and improved lead design.

Drugs that affect the excitability of the myocardium can increase the stimulation threshold, especially when high doses are required to achieve a therapeutic effect. All classes of antiarrhythmic agents are used in intensive care units, and many of them have been shown to affect the myocardial stimulation threshold. Sodium channel blockers, including quinidine and procainamide (Vaughn Williams Class IA antiarrhythmic agents), lidocaine and mexiletine (Class IB), and encainide and flecainide (Class IC), have all been reported to increase cardiac stimulation thresholds.⁶⁰⁻⁶⁶ Digitalis, β -adrenergic antagonists (class II antiarrhythmic agents), and angiotensin-converting enzyme inhibitors have no important effect on the pacing threshold.^{61,64-66a} The effect of amiodarone (a Class III antiarrhythmic agent), whether given intravenously or orally, on the pacing threshold is not well defined, although evidence suggests no significant effect.⁶⁷ Verapamil, a calcium channel antagonist (Class IV antiarrhythmic agents), has been reported to increase capture threshold,⁶¹ but this is unusual. Atropine, isoproterenol, corticosteroids, and epinephrine have been shown to decrease the myocardial capture threshold.^{66a} Successful management of failure to capture because of the effects of antiarrhythmic agents includes rapid detection and correction of any accompanying metabolic disturbance or electrolyte imbalance. Hyperkalemia

potentiates the effect of some Class IA antiarrhythmic agents, particularly quinidine.⁶⁸ Sodium lactate and sodium bicarbonate have been reported to reverse the effects of the sodium channel antagonists quinidine and procainamide.^{69,70} Removal of quinidine or procainamide by hemodialysis or hemoperfusion is not effective because of their extensive tissue distribution. Noninvasive programming of the pulse generator to a higher energy output may temporarily allow consistent capture until the offending drugs are excreted. As indicated earlier, current pacing systems are only rarely associated with these clinical problems.

Acute myocardial infarction can result in an increase in stimulation threshold and failure to capture. This is usually, but not always, accompanied by sensing problems (usually undersensing). The mechanisms responsible for the elevation of pacing threshold include local hyperkalemia from tissue necrosis, shock, and high levels of certain antiarrhythmic agents. The failure to capture can be intermittent or complete and can present as type I (Wenckebach) or type II exit block (see Fig. 26-5).^{71,72} The management of failure to capture in the setting of acute myocardial infarction, in addition to correcting any coexisting metabolic or electrolyte disturbances, is to increase energy output by noninvasive programming of the generator. With current early and aggressive treatment strategies in acute myocardial infarction, failure to capture in this clinical setting is uncommon.

Failure to capture can also result from insufficient energy reaching myocardial tissue because of too high a resistance along the lead wire or to leakage or short-circuiting of current before its reaching the electrode-tissue interface. This can be due to lead fracture or lead insulation failure, respectively. Because permanent pacing leads bend with each systole, the cumulative stress on the lead over years can be substantial. Stresses on leads introduced into the subclavian vein are also imposed when they are compressed by soft tissues during movement of the clavicle. In one large, albeit older, study of 2226 patients, the incidence of lead fracture was reported to be 3.9% (1.2% per patient year).⁷³ Common sites of lead fracture are between the connector and the venous entry, with only 7% occurring within the vascular system itself.⁷³ Although complete lead fracture is manifested on the electrocardiogram by the absence of pacing stimulus artifacts (no energy reaching body tissues), a partial fracture, in which the circuit is sometimes "made" or "broken," is more common, normal

Figure 26-6. Inappropriate pauses (closed circles) in paced rhythm and failure to sense (arrowhead) are shown in this tracing recorded from a patient with a VVI pacing system. The interstimulus interval is about 840 ms (base rate about 71 beats/min), and is measured as the shortest pacing artifact-to-pacing artifact interval. The pauses in stimulus output delivery are not explained by any event registered on the rhythm strip. The absence of pacing stimuli could indicate either “far field” oversensing with normal inhibition or conductor wire fracture. Because of the accompanying failure to sense a native R wave that would be well outside the refractory period of the pacemaker, lead fracture is more likely and was documented in this patient.

Figure 26-7. Oversensing resulting in a pause in paced rhythm (top) in this VVI pacing system is corrected by applying the magnet over the pulse generator, stimulating the sensing function, and achieving stable ventricular pacing (bottom). The arrowhead indicates the expected time of delivery of the pacing stimulus. In the case of complete lead fracture, because current is not reaching body tissues owing to the fracture, pacing artifacts would not be seen on the surface ECG. In this instance, the differential diagnosis of no visible output includes battery end of life. Interrogation of the pulse generator is required for definitive diagnosis. In the case of lead fracture, lead resistance would be extremely high, but battery voltage would be normal.

sensing and pacing during the “making” of the circuit will be seen, along with intermittent abnormal sensing and pacing function (Fig. 26-6, and see Fig. 26-2). Potential differences between the two ends of a broken electrode can cause electrical signals (“false” signals) that can be sensed, resulting in pauses in pacing stimulus intervals in single chamber devices and either pauses or earlier-than-expected ventricular stimulation in dual chamber systems, the cause of which is not readily apparent. Applying the magnet over the pulse generator, which disables the sensing function, can secure the diagnosis of oversensing due to lead fracture if the visible interstimulus intervals are a multiple of the basic pacing rate (Fig. 26-7). Highly penetrated chest radiographs in both posteroanterior and lateral views should be performed and evidence of a lead fracture should be carefully sought. Interrogation of the pacing system will reveal high lead impedance along the fractured lead, reflecting discontinuity within the lead. Lead wire fracture with failure to capture can be an emergency if the patient is pacemaker dependent.

Lead insulation failure can cause current to leak into body tissues and insufficient current to be delivered at the myocardium to cause depolarization, with resultant failure to capture. An insulation break can be caused by needle nick damage at the time of pacemaker pocket closure or, much less commonly

today, by degradation due to design-related failure.^{74,75} Inappropriate sensing of unwanted signals generated by the current leak (oversensing) may coexist. On the electrocardiogram, a bipolar lead with an insulation break may manifest a larger than usual pacing stimulus artifact; the pacing artifact polarity may also change. Comparison should be made with a baseline 12-lead analog electrocardiogram for magnitude and polarity of the pacing artifacts. The definitive diagnosis of lead insulation failure can be made by interrogation of the pacing system, which demonstrates lead resistance below the normal range for the particular lead in question.

Lead displacement, including myocardial penetration and perforation, is a common cause of failure to capture early after implantation. Undersensing usually coexists. When suspected, highly penetrated radiographs of the chest in both posteroanterior and lateral views should be obtained and compared with those taken immediately after pacing system implantation. A 12-lead electrocardiogram should also be obtained so that the morphology of the paced QRS complexes can be compared. Once lead dislodgement is confirmed, repositioning is usually required, although occasionally output and sensing threshold programming can restore normal pacing system function. The use of active and passive fixation leads in the atrium and

Figure 26-8. T wave oversensing (arrowheads) in a 45-year-old woman with a VVI pacing system. The base rate is 65 beats/min (interstimulus interval about 920 ms), shown by the first three consecutive paced QRS complexes. The T waves of the third and seventh paced QRS complexes are sensed, inhibiting the ventricular output so that a pacing stimulus is not delivered at the expected time. A spontaneous QRS complex follows the first oversensed T wave. The refractory period set up by the oversensed T wave causes functional undersensing of some spontaneous QRS complexes (closed circles). The problem was resolved by sensitivity programming.

Figure 26-9. Failure to sense in a 59-year-old hypertensive patient with renal insufficiency, who had a VVI pacing system implanted for episodic atrioventricular block. Failure to sense is diagnosed from the inappropriate appearance of pacing artifacts despite a normal QRS rhythm. Capture function is intact (3rd, 10th, and 16th QRS complexes); the second captured complex is a fusion complex in which ventricular depolarization is caused in part by the sinus P wave preceding the QRS complex and the pacing stimulus. The refractory period of ventricular tissue is about 400 ms; output stimuli occurring before this interval has elapsed do not produce ventricular depolarizations (functional noncapture).

Figure 26-10. Intermittent failure to sense in the atrium leading to dissociation between sinus P waves and the ventricular paced QRS rhythm (all QRS complexes are paced). The failure to sense results in the delivery of the atrial stimulus output, which does not capture, owing to atrial refractoriness (functional noncapture). The sinus P waves can be seen to be deforming the T waves of the paced QRS complexes. The 2nd, 8th, and 13th paced QRS complexes result from normal triggered response to the intermittently sensed P waves.

ventricle has largely obviated the problem of lead dislodgement in permanent pacing systems, although the problem still exists in the temporary pacing setting.

Failure of Output

Failure of output is manifested on the surface electrocardiogram as an absence of pacing artifacts. Absence of pacing stimuli due to failure of output should not be confused with absence of visible pacing stimuli due to lead fracture, loose connections between the pulse generator and the leads, oversensing, and low programmed voltage generating low amplitude artifacts (see Figs. 26-6 and 26-7); in these circumstances, pacing pulses are emitted by the pulse generator in the normally expected manner.

True output failure indicates battery depletion or component failure. To confirm the diagnosis of failure of output, a magnet can be placed over the pulse generator to demonstrate absence of pacing artifacts on the electrocardiogram. The differential

diagnosis of lead fracture can sometimes be detected on an overpenetrated chest radiograph; the lead impedance measured during pacemaker interrogation (the diagnostic maneuver of choice) will be high or infinite. In contrast, true output failure due to battery end-of-life will yield the expected battery voltage depletion on pacemaker interrogation.

Sensing Problems

Problems related to sensing the intracardiac electrical signal can be conveniently divided into those caused by oversensing of unwanted signals or undersensing of the intrinsic intracardiac signal (Figs. 26-8, 26-9, 26-10, and 26-11; Tables 26-6 and 26-7). In asynchronous or magnet mode of pacing (AOO, VOO, DOO), the sensing function is disabled and fixed-rate pacing at the manufacturer-specific magnet rate and other intervals, such as the AV interval, result. Appropriate sensing in the atrium and ventricle is an indispensable part of pacemaker function. Several

Figure 26-11. Failure to sense resulting in ventricular tachycardia. The patient was admitted to the hospital with an acute anterior wall myocardial infarction and developed high-degree atrioventricular block. Temporary cardiac pacing was instituted. Despite setting the highest sensitivity value to allow for sensing of signals of small magnitude, undersensing resulted in delivery of a pacing stimulus on the T wave of ventricular extrasystoles (arrow and arrowhead). In the *top strip*, no tachycardia resulted, but sustained ventricular tachycardia requiring cardioversion is seen in the *bottom strip*. The patient did not survive.

Table 26-6. Causes of Oversensing

1. Intracardiac events

- P wave sensing by ventricular lead
- R wave sensing by atrial lead
- T wave sensing by ventricular lead
- “False” signals generated by the two ends of a fractured lead or by current leaks due to insulation failure

2. Skeletal myopotentials

3. Medical sources of environmental (electromagnetic) interference

- Diathermy (obsolete)
- Ionizing radiation
- Magnetic resonance imaging
- Cardioversion, defibrillation
- Transcutaneous pacing
- Electrotherapy (transcutaneous nerve stimulation, implanted neuromuscular stimulators, electroconvulsive shock therapy)
- Lithotripsy

4. Ambient sources of environmental (electromagnetic) interference

- Radiofrequency emissions (short wave, mobile radio transmitters, garage door openers)
- High tension lines
- Arc welding
- Rotating radio detectors
- Induction furnaces
- Electronic article surveillance devices
- Tasers
- Portable music players

factors influence sensing functions, including the lead configuration (bipolar versus unipolar), the amplitude and the slew (rate of change of voltage [dV/dt]) of the intracardiac signals, and the sensitivity setting (sensing threshold) of the pacemaker generator. The pacemaker “senses” the voltage difference between the two electrodes (anode and cathode) of the pacing system. In unipolar systems, one electrode (the cathode) is the tip of the pacing wire and the other electrode (the anode) is the pacemaker generator itself. The large antenna thus created enlarges the intracardiac signal (and extracardiac signals), allowing for

Table 26-7. Causes of Undersensing

1. Low amplitude or slew of intracardiac signals

- Acute myocardial infarction
- Congestive heart failure
- Ventricular origin
- Hyperkalemia
- Some antiarrhythmic agents (especially Class IA agents)

2. Pacing system

- Lead fracture
- Lead insulation break
- Lead maturation or dislodgement
- Inappropriately programmed sensitivity
- Magnet application
- Battery depletion

easier sensing. In bipolar pacing systems, the electrodes are in proximity to each other on the lead; the sensed signal is between the closely spaced electrodes. Although studies indicate little difference in the sensed signal between unipolar and bipolar lead configurations, on occasion, in the acute setting unipolarization of a temporary pacing system can be useful.⁷⁶ Unipolarization can also be used in permanent pacing systems in some cases of lead insulation break to re-establish normal pacing and sensing function, at least temporarily.

The intracardiac ventricular signal is generally between 6 and 15 mV and the atrial signal is generally 1 to 4 mV. A signal with a lower slew such as one originating in ventricular tissue is more likely not to be sensed than one with a high slew rate. After each pacing output pulse and after every sensed spontaneous cardiac signal, atrial and ventricular refractory periods are initiated during which the pacemaker will not respond to incoming signals (Table 26-8). The refractory period in the ventricular channel is usually programmed between 250 and 400 milliseconds to prevent sensing of the late part of the QRS complex and T wave. T wave oversensing can occur if the refractory period is programmed too short or if the sensitivity is too low (see Fig. 26-8).

Oversensing

Oversensing is present when the polar generator sensing circuit identifies an electrical event sensed in the ventricular channel as an R wave or an electrical event sensed in the atrial channel as a P wave (see Figs. 26-7 and 26-8). These electrical events

Table 26–8. Parameters of Cardiac Pacing System Relevant to the Critical Care Unit

Rates:
• Low (base) rate: the rate that the patient's spontaneous rate must fall below to initiate pacing • Upper rate limit: the highest rate at which the pacemaker will output; either in response to the atrial rate ("atrial driven") or to sensor input ("sensor driven") • Magnet: the rate during application of the magnet. This rate will differ depending on the manufacturer and the model of the pacemaker • Elective replacement indicator (ERI): the (usually magnet) rate that indicates the elective replacement time for a particular pulse generator • End of life indicator (EOL): the (usually magnet) rate that indicates that the pulse generator should be replaced urgently
AV interval: The interval between the atrial and ventricular stimulus delivery, or between the time of sensing the atrial depolarization and the delivery of the ventricular stimulus (this can be a dynamic value, changing with rate and other factors)
Refractory period: The interval during which the pulse generator will not respond to electrical signals, independently programmable for atrial and ventricular channels
Pacemaker energy output: The factors in the output are voltage, current, and pulse duration contemporary pacemaker generators allow programming of the voltage and pulse duration; to control energy output; independently programmable for atrial and ventricular channels
Sensitivity: The amplitude of the electrical signal that the pulse generator is programmed to sense, independently programmable for atrial and ventricular channels
Mode of function: See Table 31-4. The mode programming operation in the critical care setting is to program from dual-chamber to single-chamber (almost always ventricular) mode of operation to prevent rapid paced ventricular rates due to tracking of atrial tachyarrhythmias.

may be generated in the pacing system itself, in the heart, in the body musculature, or in the environment (see Table 26-6). The consequence of oversensing is a pause in paced rhythm (AAI or VVI modes) or, if the oversensed atrial event causes triggered pacing in the ventricle, an earlier than expected paced ventricular event (DDD modes may have either response, depending on where the impulse was oversensed). Appropriate pacing function can be demonstrated by placing the magnet over the pulse generator, temporarily disabling sensing function (AOO, VOO, DOO modes). This maneuver serves to exclude failure of output as a cause of absent pacing artifacts and can also clarify a diagnosis of lead fracture.

The sensing circuits of the pacemaker generator are able to differentiate P, R, and T waves by their amplitudes, slew rates, and durations. It is not uncommon for the atrial sensing circuit to detect a remote ("far field") R wave because of its large amplitude, a phenomenon termed *far-field oversensing*. Oversensing can cause inhibition of output, resulting in a pause in delivery of the atrial output stimulus. "Crosstalk" can occur in the ventricular channel upon sensing an atrial pacing stimulus of high

output, especially if the ventricular sensitivity is programmed to a low value. Inhibition of ventricular output due to crosstalk can result in long pauses in rhythm. Management of far-field oversensing and crosstalk consists of (1) decreasing the sensitivity of the atrial or ventricular channel by noninvasive programming; (2) programming a sufficiently long postventricular atrial refractory period (PVARP), a period of time after paced or spontaneous ventricular depolarization during which the atrial channel does not respond to sensed input; and (3) in the case of ventricular crosstalk, decreasing the atrial output. Rarely, crosstalk can occur when the atrial lead is positioned, or has dislodged, near the tricuspid valve or into the ventricle.⁷² It is extremely unusual to sense sinus P waves in the ventricular channel if the ventricular pacing lead is positioned in the right ventricular apex. An ectopic P wave originating close to the AV node, on the other hand, has been reported to be sensed in the ventricular sensing circuit.⁷⁸

T wave oversensing is rare in today's permanent pacing systems but is still observed in temporary pacing. It is often the paced T wave with its larger intracardiac amplitude that is oversensed, although oversensing of ventricular fusion complex T waves has been reported.⁷⁹ T wave oversensing in a VVI paced system is usually not hazardous because the pause in paced rhythm due to inhibition by the oversensed signal is only slightly larger than the programmed escape interval. The requirements for T wave oversensing are a short programmed refractory period and a high programmed sensitivity, and management is by noninvasive programming to more appropriate settings; the pulse generator can be programmed to a decreased sensitivity or to a longer refractory period so that the T wave falls within it, thus avoiding inhibition of output. Oversensing of concealed ventricular extrasystoles (depolarization confined to the His-Purkinje system and invisible on a surface electrocardiogram) was first reported in 1972⁸⁰⁻⁸¹; its prevalence is unclear but is considered to be low.

Skeletal myopotentials, particularly pectoralis major myopotentials, can achieve an amplitude as high as 3 mV. Myopotential oversensing is not uncommon in unipolar pacing systems, and the incidence of inappropriately long pauses can be as high as 30%.⁸² The high incidence is due to the amplitude of the signal being augmented by the distance between the cathode (intracardiac electrode) and anode (pulse generator). In contrast, bipolar pacing systems are relatively immune to skeletal muscle interference even when programmed sensitivity is increased, which is one of the reasons that the majority of current systems implanted use bipolar leads. Diaphragmatic myopotential oversensing by bipolar electrodes⁸³ has been reported, however, and has been accompanied by a high programmed sensitivity and provoked by cough, hiccoughs, or a Valsalva maneuver.⁸³ Patients having symptoms of light-headedness, syncope, presyncope, or dyspnea during certain arm or torso movements should have these same movements repeated with electrocardiographic monitoring to identify pauses due to skeletal myopotential oversensing. It is not unusual that only particular types of movement cause oversensing whereas others do not. In a unipolar system, if myopotential oversensing cannot be corrected by noninvasive programming to a lower sensitivity, or if undersensing results from the programming change, change to a bipolar lead may be required. If absolutely necessary, mode change to an asynchronous one (AOO, VOO, DOO) by placing the magnet over the pulse generator or by noninvasive programming will eliminate

the oversensing; however, the possibility of competitive atrial and ventricular rhythms is real.

External electromagnetic interference (EMI) from the environment, particularly from electrical appliances emitting energy at frequencies of 50 to 60 Hz, can also cause oversensing with resulting inhibition of output or triggered pacing. The sources of interference include radiofrequency transmitting devices,^{84,85} arc welding,⁸⁶ automobile ignition systems,⁸⁶ radar,⁸⁷ and portable music players.⁸⁸ Several other exogenous sources of EMI encountered in a medical setting can affect pacing system function (see Table 26-6) and are discussed later in this chapter in response to interference, some pulse generators revert from their programmed mode to an “interference mode,” which is usually a fixed-rate (asynchronous) mode of function at a specific “interference rate.” Some bipolar pacing systems revert to unipolar pacing, a design feature that should be appreciated so that an erroneous diagnosis of pacemaker malfunction is avoided. Reversion to an interference mode is designed to prevent the occurrence of asystole in the presence of EMI. EMI oversensing is more common in unipolar pacing systems. Newer pacemaker generators have special shielding and filters that have eliminated or significantly reduced the incidence of EMI oversensing.

Undersensing

When native R waves and P waves are not detected by the sensing circuits of the pacemaker system, inappropriate delivery of pacing stimuli ensues (see Figs. 26-9, 26-10, and 26-11). The consequences of undersensing depend on the response of the pacing system to sensed events. In single-chamber demand pacing systems (AAI, VVI), undersensing causes asynchronous fixed-rate pacing. In VVI systems, R wave undersensing could cause a stimulus output to be delivered in the T wave, the vulnerable period, potentially causing a transient or sustained ventricular arrhythmia (see Fig. 26-11). Similarly, an atrial stimulus delivered in the vulnerable period of atrial tissue can cause atrial arrhythmias such as atrial fibrillation. The common causes of undersensing are listed in Table 26-7 and generally reflect poor quality of the intracardiac signals or an inappropriately low programmed sensitivity.

Native intracardiac signals can become smaller in magnitude and longer in duration with a slower rate of change of voltage during conditions such as congestive heart failure and acute myocardial infarction.⁸⁹ Hyperkalemia or drug toxicity, especially from Class IA antiarrhythmic agents, can decrease the slope and amplitude of phase 0 of the cardiac action potential, thereby generating a suboptimal intracardiac signal. Undersensing during these conditions is often transient and can be managed by watchful waiting, providing there is no accompanying failure of capture and the patient is not pacemaker-dependent. Because of the altered and nonuniform membrane excitability under these conditions, however, the risk of pacemaker-induced arrhythmias is high.^{59,90-96} In addition to treating the underlying clinical problems, the pulse generator can be programmed to a higher sensitivity or programmed to unipolar configuration (in specific devices) to enhance the magnitude of the native depolarization.

Undersensing of ectopic ventricular complexes can be due to suboptimal signal quality (true undersensing) or to their occurrence within the ventricular channel's refractory period, which follows all ventricular sensed events and stimulus outputs. The

former condition can be managed by noninvasively programming the pacemaker to a higher sensitivity. The latter condition can be managed by decreasing the refractory period of the ventricular channel at the potential expense of oversensing T waves. Yet another approach is to suppress the ventricular extrasystoles with antiarrhythmic medications; the decision should depend on the clinical condition of the patient and the risk-benefit ratio of the various approaches.

Local fracture or dislodgement should always be considered when undersensing occurs. These conditions are serious and are often accompanied by a failure to capture. Chest radiographs should be obtained to evaluate lead position and integrity, although lead fracture is often not visible on standard radiographs. Interrogation of the pulse generator reveals high lead impedance with lead fracture, and lead replacement will be required.

The preceding discussion has been predominantly focused on issues with permanent pacemakers, although many of the same principles apply to temporary transvenous pacing. A guide to troubleshooting temporary pacemaker problems is given in Table 26-9.

Rapid Paced Ventricular Rates

Tracking the sensed sinus rate is an important function of a dual-chamber pacing system that senses in the atrium (DDD, VDD, see Table 26-4). During tracking, a sensed atrial event triggers a ventricular output at the end of the programmed AV interval (similar to a PR interval) unless a spontaneous ventricular event is sensed (Figs. 26-12 and 26-13). One potential problem during normal tracking function is oversensing in the atrial channel, which inhibits atrial output but triggers ventricular pacing at an inappropriate time. The consequence is an undesirable paced ventricular arrhythmia or even pacemaker-mediated tachycardia (PMT). Decreasing the atrial sensitivity risks atrial undersensing; programming to a nonsensing mode such as DDI or VVI may be necessary in the acute clinical situation. Removal of the patient from the source of environmental interference will eliminate the problem of electromagnetic interference oversensing. If a unipolar atrial lead has been used and noninvasive programming cannot solve the problem, change to a bipolar lead may be required as it will be less prone to oversensing.

If atrial tachyarrhythmias occur in patients with DDD pacing systems, tracking up to the programmed upper rate limit can occur (see Table 26-8). This upper rate is programmed based on the patient's activity, age, and presence of coronary artery or other cardiac disease. When the atrial rate exceeds the programmed upper rate limit (sinus tachycardia, atrial tachycardia, atrial flutter), ventricular pacing can resemble an “electronic AV block,” either as a second-degree fixed-ratio block or Wenckebach response (Fig. 26-14). With these rapid paced ventricular responses to rapid atrial rates, cardiac output can suddenly decrease, particularly with fixed ratio block. If the atrial rhythm is fibrillation, the paced ventricular rhythm is usually irregular (see Fig. 26-14). It must be remembered that sensor-based pacing systems have a programmable upper rate that may be independently programmed and different from the atrial-driven upper tracking rate.

Pacemaker-mediated tachycardia (PMT) is a well-known complication of DDD pacing.⁸⁹⁻⁹⁴ The PMT usually begins with a premature ventricular complex with retrograde ventriculoatrial

Table 26–9. Troubleshooting in Temporary Cardiac Pacing

Problem	Possible Causes	Corrective Measures
Failure to capture (pacing output pulses visible)	Output programmed inappropriately low High stimulation threshold due to ischemia, antiarrhythmic drugs, electrolyte imbalance, metabolic disorders Lead malposition	Increase output Increase output, treat ischemia, alter medications, correct electrolyte and metabolic abnormalities Chest radiograph, paced electrocardiogram; reposition lead
No visible output (pacing output pulses not seen)	Loose connections Oversensing (inhibition of pacer output by inappropriately sensed signals) Crosstalk inhibition (sensing of atrial output by the ventricular channel leading to inhibition of ventricular output)	Check all connections Decrease sensitivity Reduce atrial output; decrease ventricular sensitivity
Failure to sense (inappropriate delivery of pacing stimulus outputs)	Sensitivity programmed inappropriately low Lead malposition Poor intracardiac signal	Increase sensitivity Reposition lead Treat correctable causes of poor signal (such as acidosis, hyperkalemia, congestive heart failure)

Figure 26-12. Normal tracking function of sinus tachycardia in a patient with a DDD pacing system. In the beginning of the lead II rhythm strip, there is group beating owing to the third sinus P wave of the group occurring in the postventricular atrial refractory period and not triggering an output in the ventricle. At the end of the strip, 1:1 tracking of the sinus rate is present. The diagnosis of the cause of a rapid paced ventricular rate in non–rate-adaptive pacing systems can be established by programming to VVI mode of function (in which tracking of atrial activity does not occur) at slow rate; this clarifies the atrial rhythm and rate.

Figure 26-13. VDD mode of function. This pacing system senses atrial and ventricular electrical activity, but paces only the ventricle. Atrial sensing is followed by triggered ventricular pacing at the programmed atrioventricular interval, unless a spontaneous QRS complex has occurred, in which case the device is inhibited. The pacing stimulus terminating a pause is delivered in the ventricle (*closed circles*) because atrial pacing does not occur, a finding that allows the diagnosis of VDD function. In this example, the upper rate limit has been programmed to 100 beats/min. Because the upper rate cannot be violated, the sensed P waves (*arrowheads*) initiate a longer than programmed atrioventricular interval so that the timing of the ventricular pacing stimulus does not exceed this upper rate limit. The automatic extension of the atrioventricular interval is a form of “electronic AV block” that can also resemble type I and type II atrioventricular block.

conduction; the retrograde P wave is sensed in the atrial channel, triggering a ventricular output that once again causes retrograde ventriculoatrial conduction, thus creating an “endless loop” (Fig. 26-15). The initiating mechanism of PMT is almost always AV dissociation, created by a ventricular extrasystole,

loss of atrial capture, or oversensing in the atrial channel. The easiest way to terminate PMT is by application of a magnet over the pulse generator. The elimination of atrial sensing will abolish the triggered ventricular output. Other more definitive ways to prevent sensing of retrograde P waves include programming

Figure 26-14. A 12-lead ECG in a 68-year-old patient with a DDD pacing system placed for complete atrioventricular block recorded during the complaint of palpitations. The pacemaker had been programmed to a base rate of 60 beats/min and an upper rate of 150 beats/min. The atrial rhythm is not discerned. The paced ventricular rhythm (all QRS complexes are paced) is irregular. The pacing system is not a rate-adaptive one. The irregularity of the paced ventricular rate suggests the presence of an atrial tachyarrhythmia with normal tracking of sensed atrial depolarizations. The V_2 rhythm strip (*bottom*), recorded after programming to VVI mode of function, shows atrial fibrillation. The rapid paced ventricular rate could represent normal tracking function in response to atrial flutter, fibrillation, or tachycardia; the irregularity of the rate suggests that flutter or fibrillation is most likely. Atrial flutter and fibrillatory waves can often have an amplitude of greater than 2 mV, allowing them to be sensed.

Figure 26-15. Continuous telemetry strip (leads V_1 and II) in a 54-year-old patient with a DDD pacing system placed for sick sinus syndrome. The pacemaker had been programmed to a base rate of 50 beats/min and an atrioventricular interval programmed to 280 ms. The top rhythm shows atrial pacing with narrow QRS complexes preceded by pacing stimulus suggestive of pseudofusion. A premature ventricular complex (denoted by the stars) is followed by retrograde P wave that is sensed, and it initiates a pacemaker-mediated tachycardia (sensing in the atrium followed by pacing in the ventricle). The tachycardia was terminated by placing a magnet over the pacemaker (that caused lack of sensing of the P waves). A final programming change was made to increase the postventricular atrial refractory period (PVARP) to prevent this tachycardia in the future.

a longer postventricular atrial refractory period (PVARP) and programming the specific pulse generator response to detection of premature ventricular depolarizations. Similarly, PMT can be terminated by programming “on” specific algorithms designed for this purpose.

Biventricular Pacing Systems

The implantation of biventricular pacing systems has become more common with evolving indications for their use in patients with systolic dysfunction. The basis for this newer therapy is the

observation that existing left bundle branch block or intraventricular conduction delay can worsen heart failure by creating ventricular dyssynchrony. Randomized controlled trials have demonstrated benefit in these patients, including a decrease in mortality, reduction in heart failure hospitalizations, and improvement in New York Heart Association (NYHA) heart failure class.^{95a-l} Current recommendations for implantation of these devices include NYHA Class III to IV heart failure, symptomatic heart failure despite appropriate medical therapy, left ventricular ejection fraction less than 35%, and QRS duration greater than 120 msec.^{95a-l}

Implantation of the left ventricular lead via the coronary sinus carries with it unique procedure-related complications. These include coronary vein trauma or dissection with the possibility of cardiac tamponade, and diaphragmatic or phrenic nerve pacing. The management of these immediate complications is beyond the scope of this chapter.

Biventricular pacemakers carry their own set of capture, sensing, and lead-related problems that are unique to the presence of the left ventricular lead, in addition to the problems delineated above for all pacing devices. Malfunction of the left ventricular lead may itself lead to ventricular dyssynchrony and a clinical presentation of worsening heart failure, or lack of improvement in symptoms and functional class.

Because of the location of the left ventricular lead in the coronary sinus, pacing impulses must penetrate the venous wall and any surrounding fat to reach the myocardium. For this reason, higher capture thresholds are often seen, and any migration of the lead within the coronary sinus may cause elevated thresholds and consequent loss of capture. Although loss of pacing through the left ventricular lead may, in comparison to prior tracings, lead to a widened QRS or different QRS morphology, these findings are not reliable and intracardiac electrograms seen on pacemaker interrogation may be necessary to confirm the diagnosis. If the right and left ventricular leads are programmed to stimulate in an “offset” fashion (one ventricle stimulated slightly in advance of the other to optimize interventricular synchrony), there will be two stimulus artifacts visible on the electrocardiogram if the biventricular leads are

functioning appropriately; these should not be confused with artifacts or false signals (Fig. 26-16, A and B).

Cardiac Pacing under Specific Clinical Circumstances

Myocardial Infarction

Myocardial infarction occurring in the patient with a pacemaker presents a variety of challenges, including those discussed earlier. The initial challenge is presented by the abnormal depolarization and repolarization patterns caused by pacing, obscuring the classic electrocardiographic diagnostic clues to the presence of myocardial infarction. An effort to discern spontaneous QRS complexes, including temporary programming to a low pacing rate or a long AV interval to facilitate spontaneous QRS activity, may reveal the diagnostic findings. In the presence of right ventricular pacing, the most useful findings are (1) primary ST segment and T wave changes (displacement of the ST segment and T wave vectors toward the major QRS vector), especially in comparison to prior paced electrocardiograms; (2) abnormal q or Q waves in leads V₃ or V₆; and (3) late notching of the S wave in the precordial leads (Cabrera sign).⁹⁵ These criteria and others are similar to those used in patients with left bundle branch block and are described in detail elsewhere⁹⁶⁻⁹⁸; despite good specificity for the diagnosis of myocardial infarction, the sensitivity is less than 20%⁹⁵⁻⁹⁸. Use of QRST isointegral maps has been reported to be helpful in detecting myocardial infarction in patients with paced rhythms.⁹⁹

Another potential complication in the diagnosis of acute myocardial infarction in a paced patient is the effect of a recently implanted pacemaker on serum creatine kinase isoenzyme and troponin patterns. Although minor transient increases in creatine kinase and troponin do occur, small prospective studies suggest that cardiac pacemaker implantation causes no significant confounding of the enzymatic diagnosis of myocardial infarction.^{100-100b} A pericardial friction rub, a not uncommon finding after pacemaker lead implantation that has been well documented in case reports, may mimic the mechanical

Figure 26-16. A, A 12-lead ECG in a 72-year-old patient with a biventricular pacemaker implanted for advanced heart failure. There is simultaneous delivery of pacing stimuli in the right and left ventricles as denoted by the star in lead I. **B,** A 12-lead ECG in the same patient with sequential delivery of pacing stimuli in the left and right ventricles (denoted by star in lead I) that leads to narrower QRS complexes and more effective biventricular pacemaker therapy (improved heart failure symptoms). In this patient, the left ventricle was paced earlier than the right ventricle.

complications of a myocardial infarction.^{101a-101d} In one case report, the finding of a loud systolic sound and apical thrill suggestive of mitral regurgitation or ventricular septal defect in a patient with a myocardial infarction was, in fact, due to a temporary pacing wire.¹⁰¹

Several aspects of the pathophysiology of myocardial infarction can cause failure to capture, including hyperkalemia (both systemic or local, from myocardial necrosis), metabolic acidosis, hypoxemia, and hypercarbia in patients with cardiogenic shock or pulmonary edema, and antiarrhythmic agents, most frequently those in Vaughn Williams Class I. All of these conditions can increase the myocardial stimulation threshold, and treatment of failure to capture in these settings is directed at correcting the underlying abnormality; if failure to capture persists, the pacemaker energy output should be increased.

Undersensing in the setting of myocardial infarction most often reflects a decrease in the integrity of the intracardiac signal.^{83,102} The deterioration of the signal can be caused by local myocardial ischemia, acidosis, electrolyte abnormalities, edema, and necrosis. The local effects are exacerbated by regional abnormalities in signal propagation owing to necrosis and changes in ventricular geometry and by systemic hyperkalemia and Class I antiarrhythmic agents. These alterations in the intracardiac signal are usually transient, requiring only careful observation. However, if life-threatening pacemaker-induced arrhythmias occur as a result of undersensing causing a stimulus to be delivered at a critical time (see Fig. 26-11), the sensitivity can be increased. If the appropriate programming equipment or personnel are not immediately available, complete inhibition of the pacemaker output can be achieved with continuous chest wall stimulation, although this technique is rarely necessary in current practice.^{88,103} It is important to note that in the presence of myocardial infarction, the exact nature of the intracardiac signal abnormality is not evident on the surface electrocardiogram and thus neither undersensing or oversensing can be predicted from the surface ECG.¹⁰⁴ Pulse generator interrogation with intracardiac electrography, acquired through the generator via the programmer, is required in many cases to confirm these diagnoses.

Cardiopulmonary Resuscitation

The paced patient requiring cardiopulmonary resuscitation often has or develops specific clinical problems that can contribute to pacing system malfunction, including myocardial ischemia, acidosis, hyperkalemia, and many other metabolic abnormalities. The standard resuscitation protocols should be followed in patients with permanent pacemakers; although attention must also be directed to establishing normal pacemaker function after the resuscitation procedure is completed. Not only can the myocardial stimulation threshold be markedly increased during cardiopulmonary resuscitation, necessitating either reprogramming of the pacemaker or additional pacing through transcutaneous or temporary transvenous routes, but also significant problems with sensing can occur during chest compressions. Although one might anticipate that chest compressions could cause lead dislodgement with complications ranging from failure to capture to myocardial perforation, these rarely occur. In one report there was no evidence of damage to permanent leads in four patients who had prolonged chest compressions.¹⁰⁵ In another report the function of VVI pacing systems in four patients with witnessed well-documented out-of-hospital cardiac arrest was analyzed; sensing malfunction,

presumably due to the severely damaged state of the myocardium, was demonstrated in all patients, with more pronounced pacemaker dysfunction in those patients receiving defibrillation.¹⁰⁶ In no case did the pacemaker malfunction have an adverse effect on outcome. Most sensing and pacing problems are transient, but thorough evaluation of the pacing system, including interrogation and programming functions, should be made after the resuscitation procedure.

Direct Current Cardioversion and Defibrillation

Transthoracic direct current (DC) shock is used as both an emergent and nonemergent treatment for atrial and ventricular tachyarrhythmias. Modern pacemakers are equipped with protection mechanisms against damage from DC shock. The most common of these mechanisms is the Zener diode,¹⁰⁷ which directs a surge in current toward the electrode, protecting the pacemaker circuitry but delivering this energy to the endocardium. In addition, the cardioverter-defibrillator can cause capacitive coupling with the endocardial lead, causing direct discharge at the electrode-endocardium interface.¹⁰⁸ This large focal discharge is thought to be responsible for the ensuing transient or permanent failure to sense and capture that is observed after DC shock in the absence of apparent damage to the pulse generator itself.^{108a} Failure to capture by an implanted pacing system can also occur after discharge of an automatic implanted cardioverter-defibrillator.^{109,110} Other electrostatic discharges caused merely by placement of the defibrillator paddles can also generate noise that is interpreted as signals by the pacemaker.¹¹¹ The protective mechanisms of the pacemaker are not always sufficient to safeguard the electronic components, and there are multiple reports, albeit from the older literature, of damaged circuitry,^{112,113} changes in programmed mode of function^{111,114,115} and even model number,¹¹⁶ complete pacemaker failure,¹¹⁷ and microdislodgement of the lead.¹¹⁸ In a recent study of 36 patients with unipolar pacing systems,¹¹⁹ DC shock resulted in failure to capture in 50% of the patients, lasting from 5 seconds to 30 minutes. Predictors of pacemaker dysfunction included higher peak and cumulative shock energies and lower pacemaker pulse amplitude. In patients in whom the pacing threshold was measured before and after the DC shock, there was a sixfold increase in pacing threshold 3 minutes after cardioversion, returning to baseline at 24 hours; failure to sense was noted in 7 of the 17 patients (41%) in whom this could be assessed. Although not studied, it is believed that bipolar electrodes are less susceptible to some of those complications owing to the decreased distance between cathode and anode.

The general precautions for DC cardioversion and defibrillation in patients with pacemakers attempt to minimize the current delivered to the pacemaker system. These precautions include placing the defibrillator paddles at least 10 cm away from the pulse generator, ensuring that the paddles are placed perpendicular to the dipole of the pacing system (usually an anteroposterior position of the defibrillator paddles is optimal) and using the minimal effective energy setting. More specific precautions will depend on the individual patient. For example, in a patient whose pacemaker has been programmed to VOO mode, the "synchronized" defibrillator may track the asynchronous outputs of the generator and discharge in the myocardial relative refractory period, inducing ventricular fibrillation.¹²⁰ Regardless of the precautions taken before cardioversion or defibrillation, a thorough evaluation of the pacing system should

be performed as soon as practically possible, including sensing and capture functions, measurements of base and magnet rates, integrity of programming commands, and telemetry function.

Electrotherapy

Electrical stimulating techniques such as transcutaneous electrical nerve stimulation are often indicated to treat pain related to muscular or neurologic problems. Studies have indicated a low incidence of adverse effects of transcutaneous electrical nerve stimulation on older pacemaker models that were more susceptible to electromagnetic interference than contemporary devices.¹²¹

Electroconvulsive therapy represents another application of electric current to reset excitable tissue, in this case, that of the brain. However, because of the localized application of the electrical stimulus to the head, there is a low probability for the occurrence of problems, although monitoring and standard resuscitation equipment, and a trained programmer, should be available.¹²²⁻¹²⁵

Electrocautery and Anesthesia

Electrocautery is the most common exogenous source of electromagnetic interference that can interact with pacemakers. Electrocautery uses radiofrequency current to transect tissue and achieve hemostasis. Coagulation and cutting circuits of electrocautery devices differ in their effects on permanent pacemakers. Bipolar coagulation cautery, in which the current flow is localized between the two poles of the instrument, is not expected to cause problems if kept more than 6 inches from the pulse generator. However, in unipolar electrocautery devices, the electrical current flow is not restricted to the tissue interposed between two electrodes and spreads throughout the body. This conductive electromagnetic interference, and the myopotentials resulting from the procedure itself, can result in pulse generator inhibition, electrical burns at the myocardial-electrode interface, atrial or ventricular tachycardia and fibrillation,¹²⁶ pulse generator component failure,^{115,127,128} loss of or change in output, reprogramming of rate or mode of function,^{115,129,130} runaway pacing,^{131-132a} and other malfunctions.^{133,134} Occasionally, electrocautery signals, perceived as “noise” by the pulse generator, can result in reversion mode pacing at a specific rate. Despite these reports, electrocautery is, in general, very safe in patients with pacemakers, although special precautions are helpful.^{135,136}

As with DC shock, these precautions attempt to limit the electromagnetic interference delivered to the pacemaker. The vector of the dipole for the electrocautery device with respect to that of the pacemaker is important.¹³⁷ These should not intersect with each other if at all possible. Bipolar electrocautery can minimize this interference, if only unipolar electrocautery is available, then the indifferent electrode should be placed as far from the pacemaker leads as possible. In addition, the use of low energy and short electrocautery bursts spaced far apart can minimize the hemodynamic effects of pacemaker inhibition. A magnet should not be applied prophylactically in all patients because there is no uniform pulse generator response to this maneuver and magnet rates and AV intervals are often different from programmed values. Magnet application may result in initiation of a programming procedure and inappropriate random reprogramming by the electrocautery device. In addition, an ICD will behave differently in response to a magnet than will a pacemaker without defibrillation functionality. Electrocautery can cause electromagnetic noise on the ICD sensing lead that is detected as ventricular fibrillation (VF) and can lead to inappropriate shock. Magnet placement over

the ICD (taped in place) will suspend detection of ventricular tachycardia (VT) or VF without interrupting back-up bradycardia pacing. Removal of the magnet will cause the ICD to resume detection and therapy (within 10 seconds) if VT or VF occur intraoperatively unless permanent magnet inactivation is programmed in the ICD. An alternative approach is to program the detection and therapy “off” during surgery and turn it “on” postoperatively; external defibrillators are used for intraoperative VT/VF. As in any procedure in pacemaker-dependent patients, the availability of programming equipment and trained personnel is essential. We have advocated using a pacemaker specialist to evaluate and clear the paced patient for procedures involving electrocautery.¹⁸⁰

General anesthesia can present a range of problems for the paced patients, although it rarely does so due to contemporary anesthesia techniques. Many metabolic and electrolyte abnormalities can affect pacemaker function, including hypoxemia, hypercarbia, and hyperkalemia, but except in emergent cases, these conditions rarely develop during anesthesia. However, vigilance and an understanding of the specific pacemaker's programmed parameters is crucial in the event of an emergency. For example, anesthetic induction with depolarizing agents that cause significant muscle fasciculations can cause complete inhibition of pacemakers because of oversensing, resulting in cardiac arrest in pacemaker-dependent patients.¹³⁸ This complication can be prevented by temporary reprogramming of the pacemaker to an asynchronous mode.

Other Minor Surgical Procedures (Lithotripsy, Endoscopic Electrocautery)

Advances in technology have produced a variety of new special procedures and techniques that can interact with implanted pacemakers. Extracorporeal shock wave lithotripsy is associated with electromagnetic and mechanical forces that may influence pacing system function.¹³⁹⁻¹⁴² Published studies of in vitro testing have indicated that about 4% of 15 pacemaker generators of various manufacturers tested failed when exposed to lithotripsy. Pulse generators employing a piezoelectric crystal sensor seem to be the most susceptible to failure,¹⁴⁰ and rate-adaptive generators that use this type of sensor should have the sensor mode programmed “off” during lithotripsy; this will prevent an unwanted increase in paced heart rate and shatter injury to the piezoelectric element. Patients in whom rate-adaptive pacing devices are implanted in the abdomen should probably not undergo lithotripsy because of the possibility of injury to the sensor. Despite these concerns, lithotripsy has been used successfully for the treatment of nephrolithiasis in patients with pacemakers,^{143-143b} including some with abdominal pulse generator sites,¹⁴⁴ although complications have been reported.¹⁴⁵ In a survey of 131 patients treated in 98 sites,¹⁴⁶ there were four pacemaker-related complications, none of which were fatal or required replacement of the pacemaker. All pacemakers should be thoroughly checked for proper function immediately after treatment.

Endoscopic electrocautery is also a frequently performed procedure that is generally safe in patients with pacemakers, although complications have been rarely reported.¹⁴⁷ Intra-aortic balloon counterpulsation can be triggered from the pacemaker output stimuli on the electrocardiogram, and care must be taken to ensure that proper timing is achieved. Consultation with a cardiologist or the pacemaker manufacturer is advisable before these procedures, and the availability of a trained programmer and continuous cardiac monitoring is essential.

Radiation Therapy

Epidemiologic data suggest that as the population ages, more patients with both cancer and pacemakers will be presenting for medical care. In some patients, the cancer itself may cause damage to the conducting tissue, necessitating pacemaker placement,¹⁶¹ whereas in other patients, the radiating therapy can cause complete heart block^{162,163} or sinus node dysfunction.¹⁶⁴ The high-energy ionizing radiation used in radiation therapy can cause significant damage to the semiconductors of pacemakers, even at very small doses.¹⁶⁵ This damage can be divided into three types: (1) temporary change in “interference mode” pacing lasting for the duration of the irradiation only; (2) change to interference mode pacing that necessitates reprogramming the pulse generator to restore original parameters; and (3) severe damage, in which the pacemaker ceases to generate output pulses. Pulse generator recovery may occur long after the end of the radiation treatment and is mostly incomplete, and the pacemaker cannot be used reliably thereafter.¹⁶⁶ Thus, in pulse generators exposed to radiation, transient loss of function should be regarded as a precursor of permanent damage. Currently available pulse generators that use the complementary metal-oxide semiconductor (CMOS) circuitry may actually be more sensitive to the effects of ionizing radiation than older generators.^{167-170b} Although some studies have shown no adverse effects on pacemakers,^{171,172} it is imperative that guidelines be followed for ensuring the lowest possible radiation dose to the pacemaker¹⁷³ and that careful follow-up be performed during and after completion of the radiation therapy. Therapeutic radiation should be accomplished with the pulse generator shielded, and if the patient is pacemaker-dependent and the pulse generator is situated near or in the radiation field, consideration should be given to relocating the generator to another site. The low-energy x-rays used for diagnostic radiology have not been reported to have any adverse effect in pacemakers.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is generally considered to be contraindicated in pacemaker patients, although controversy exists.¹⁷⁴⁻¹⁷⁸ MRI affects pacemaker function by the development of strong static and time-varying magnetic fields and pulsed radiofrequency fields. The changing magnetic fields can result in actual physical movement of the pulse generator's internal components, or generate transient currents and heating of the components or leads. During MRI, most pacemakers revert to an asynchronous mode of function. Although asynchronous pacing per se may not cause problems in the stable patient, radiofrequency pulsing can result in induced voltage across the pacemaker electrodes that may stimulate myocardial tissue, leading to rates equal to the MRI pulsing rates (cycle lengths of 200 to 1000 milliseconds).¹⁷⁷ Radiofrequency pulses can also cause inhibition of the pulse generator, with resulting bradycardia and asystole. Resetting of DDD pulse generators in the back-up mode can occur as the circuit is activated by a high radiofrequency pulse rate.¹⁷⁵

There will be times when the imaging modality may be essential, in which case consultation with the pacemaker manufacturer and cardiologist is recommended. Device manufacturers have made changes in devices to make them more compatible with MRI (less use of ferromagnetic material in battery construction). Recent studies have evaluated the utility and safety of performing MRI with modern scanners (1.5 Tesla) in animals and humans with modern devices (manufactured after 2000).¹⁷⁹⁻¹⁸³ Table 26-10 gives a list of modern devices

that were tested in a protocol with 1.5 Tesla MRI scanner. They excluded patients with fresh implants (<6 weeks), non-transvenous epicardial leads, leads without fixation (separate SVC coil, abandoned leads) and pacemaker dependent ICD patients.¹⁷⁹ Magnet response, rate response, noise response, ventricular sense response, premature ventricular contraction response, conducted atrial fibrillation response, and tachyarrhythmia functions should be disabled. Pacemaker-dependent patients should be programmed to VOO mode and non-pacemaker-dependent patients can be programmed to the VVI or DDI mode.¹⁷⁹ A case report describes a patient with a pacemaker having a head MRI after the pacemaker was programmed to an OOO mode.¹⁸⁴ While near or in the scanner, the patient should have continuous ECG telemetry and pulse oximetry monitoring and noninvasive blood pressure measurements should be obtained every 3 minutes.

Metabolic Abnormalities

Metabolic and electrolyte disorders are frequent causes of pacemaker dysfunction in an emergent setting and must always be considered when evaluating a patient with apparent pacemaker malfunction. Electrolyte and metabolic abnormalities, especially hyperkalemia, alkalosis, acidosis, and hyperglycemia, increase the pacing threshold, causing failure to capture.⁵⁷ Hyperkalemia increases the myocardial stimulation threshold by decreasing the transmembrane resting potential, decreasing the rate of depolarization, and shortening the action potential duration. These effects are independent of other abnormalities, including hypoxemia, hypercarbia, acidosis, alkalosis, and sodium or calcium concentration,⁵¹ reinforcing the importance of immediate correction of the hyperkalemia. There are numerous reports of many different types of pacing abnormalities,¹⁴⁸ ranging from pacemaker exit block of Wenckebach type¹⁴⁹ to higher grades of heart block¹⁵⁰ with eventual complete pacemaker exit block.¹⁵¹ In theory, reprogramming the pacemaker to higher energy output should be able to overcome this block, although practically the maximal output of the pacemaker is not infrequently insufficient. In addition to immediately restoring normal potassium levels, temporary cardiac pacing may prove beneficial.¹⁵²

Table 26-10. MRI Testing in Newer Implantable Devices

Pacemakers

- St. Jude Pacemaker AFP (262), Trilogy (2360), Entity (5326), Affinity (5130, 5330), Integrity (5142, 5342, 4346), Identity (5172, 5370, 5380, 5386)
- Guidant-Vigor (12320), Discovery (1272), Insignia (1194, 1290)
- Medtronic-EnPulse (AT-500, E2SRO1, E2DRO1), Kappa (701, 901), Prodigy (7860), Insync BiV (8040, 8042)

Implantable Cardioverter-Defibrillators

- St. Jude-Photon (V-194, V-230, V-232), Atlas (V-240), Epic (V-197, V-235, V-239)
